Abstract: Tunable ferroelectric capacitors, which exhibit a decrease in the dielectric permittivity under an electric field, are widely used in electronics for RF tunable applications. Current devices use barium strontium titanate (BST) as the tunable dielectric, but new applications call for tunable materials with specific performance improvements. It is then of crucial importance to dispose of a large panel of electrically characterized materials to identify the most suited compound for a given set of device specifications. Here, we report on the dielectric tuning properties of Ba_{1-x}Ca_xTi_{1-y}Zr_yO₃ (BCTZ) thin films libraries (0 ≤ x ≤ 30% and 0 ≤ y ≤ 28.5%) synthesized by combinatorial pulsed laser deposition (CPLD). An original CPLD approach allowing reliable and statistical ternary phase diagrams exploration is reported. The effects of Ca and Zr content on tunability, breakdown voltage and dielectric losses are explicated and shown to be beneficial up to a certain amount. Compounds close to (Ba_{0.84}Ca_{0.16})(Ti_{0.8}Zr_{0.2})O₃ exhibit the highest figures of merit, while a zone with compositions around (Ba_{0.91}Ca_{0.09})(Ti_{0.81}Zr_{0.19})O₃ show the best compromise between tuning ratio and figure of merit. These results highlight the potential of BCTZ thin films for electrically tunable applications.

1. Introduction

Ferroelectric (FE)-perovskite-films-based heterostructures are found in many micro-electronic components dedicated to RF and microwave (MW) applications thanks to the large electric field dependence of the relative dielectric permittivity $\epsilon_r(E)$ near the Curie temperature T_C [1]. FE Capacitors are thus voltage tunable to be used for tuning filters, resonators, phase shifters [2]. In addition, dielectric losses below 1% are required. The solid solution Ba_{1-x}Sr_xTiO₃ (BST) is the most used FE material in nowadays RF and MW tunable capacitors because of its excellent tunability/losses compromise and adjustable T_C (via Sr content x) [1,2]. However, emerging technologies call for improved tunable capacitor properties. In particular, for Near Field Communications (NFC) technology, the operating voltage is reduced to a 0–3 V range compared to 0–24 V for actual tunable capacitor products in mobile phone application [3], resulting in a lowered electric field and tunability. Thus, for a given application with a defined operating window (maximum applicable voltage, temperature range, minimum filters quality factor and Figure of Merit from circuit design), one has to seek for the FE material with the best compromise between various properties (tunability, dielectric losses, temperature coefficient TC). Improving BST's tunability and leakage current by chemical doping, e.g., by compensating donor-type defects with acceptor-type dopants or by bringing the ferroelectric-paraelectric transition

temperature closer to room temperature, has been largely attempted [4–6], but only a few dopants were found actually to work [7–10].

Another possibility is to look for other BaTiO₃-based systems to keep device integration close to the one already in use for BST tunable capacitors. Recently, the (Ba,Ca)(Ti,Zr)O₃ system has been attracting attention due to its high tunability, low dielectric losses and large piezoelectric coefficient [11–20]. In particular, Liu and Ren studied the system (1–x)Ba(Ti_{0.8}Zr_{0.2})O₃–x(Ba_{0.7}Ca_{0.3})TiO₃ which shows, for x = 0.5, a piezoelectric coefficient (d₃₃) of about 620 pm/V in ceramics [11], while it is reduced to about 70 and 80 pm/V for 350 nm and 600 nm thick films, respectively, with a tunability of 80% at about 330 kV/cm [12,16]. The large piezoelectric coefficient has been ascribed to the presence of a morphotropic phase boundary (MPB) between ferroelectric phases with rhombohedral and tetragonal symmetries, similarly to the PbTiO₃-PbZrO₃ (PZT) system and the presence of a triple point. It was later shown that a phase with orthorhombic symmetry was present between the rhombohedral and tetragonal symmetries, leading to a quadruple point, also called the phase convergence region (PCR) [18,19]. Our goal is to investigate the tunability properties of compositions in the BaTiO₃-BaZrO₃-CaTiO₃ ternary phase diagram (BCTZ) in thin film libraries using combinatorial pulsed laser deposition (CPLD). It is appealing to try synthesizing an entire ternary phase diagram on a single substrate using three targets with CPLD [21]. This approach, however, requires complex masking schemes and a uniform deposition rate across the substrate in order to control local compositions and thicknesses [22]. This is very challenging, as the strongly forward peaked plume makes PLD an intrinsically non-uniform deposition technique. Another severe drawback of this approach is its non-statistical character, as one composition is only represented in a single location. An intrinsic drawback of PLD is the generation of sub-micrometric droplets. Although their density can be strongly reduced by working at a laser fluence close to the ablation threshold, some of them reach nevertheless the surface and may give rise to electrical shorts in parallel plate capacitors' structures with electrode areas of thousands of micron square. It is thus necessary to rely on a statistical population per composition to spot possible outliers not reflecting the material's properties.

We developed an original CPLD approach with a less complex masking scheme and a statistical character allowing us to produce continuous slices across the BCTZ ternary phase diagram using three targets [23,24]. Eight BCTZ polycrystalline thin film libraries were synthesized where 280 different compounds with Ca and Zr contents spreading in the ranges $0 \leq \text{Ca} \leq 11\%$ and $0 \leq \text{Zr} \leq 30\%$ were statistically characterized. The produced tunability map reveals the presence of two zones with high tunability in the ternary phase diagram. Insights on the impact of higher Ca concentration (up to 30%) on the tunability were obtained from three additional composition spread libraries deposited using two additional targets (binary samples). Taking dielectric losses (tanδ) into account via the figure of merit (FOM) allowed the identification of a zone with compositions around (Ba_{0.84}Ca_{0.16})(Ti_{0.8}Zr_{0.2})O₃ showing the highest figures of merit (≈ 9000), while compositions close to (Ba_{0.91}Ca_{0.09})(Ti_{0.81}Zr_{0.19})O₃ showed the best compromise between tuning ratios and figures of merit.

2. Materials and Methods

CPLD BCTZ composition spread thin films, with thicknesses of about 130 nm, were synthesized on polycrystalline IrO₂ electrodes (140 nm) sputter deposited onto Si (100) substrates (10 × 10 mm²). CPLD is based on the localization of a successive deposition from 2 or 3 targets on the substrate with a shadow mask. The local composition then depends on the precise relative amount of material coming from each target. The mixing of the cations issued from different targets was conducted at the perovskite single layer (psl) level with a CPLD deposition cycle corresponding to the growth of a single perovskite layer thick film (thickness ≈ 4 Å, see Figure 1a). Repetition of this cycle then led to forming of the film with a homogeneous composition in the thickness direction. Tight lateral control of the local composition requires a uniform deposition rate and cationic composition over

the whole substrate surface for each target separately. This is quite challenging with the strong radial distribution of PLD and the composition dependence on laser fluence and spot size [25]. A demonstration of single target PLD thin film uniformity, although essential for CPLD samples' credibility, is unfortunately seldom made in published work. To obtain film uniformity, the optical image projection of a homogenized laser beam is raster scanned across the target, staying in focus at all times. The ablation plume is thus sweeping across the substrate surface. Laser fluence is in-situ monitored prior to each deposition. Multiple demonstrations of PLD films' thickness and composition uniformity have already been published [24].

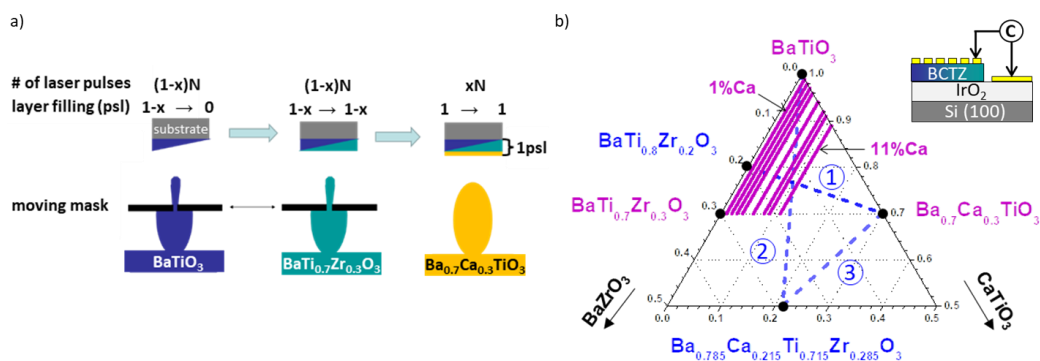

Figure 1. (a) Schematic of the perovskite single layer (psl) CPLD cycle deposition using 3 targets. A unique deposition rate of N laser pulses/psl is assumed and $0 < x < 1$. (b) Targets' composition (black dots) and synthesized libraries (purple lines from 3 targets, blue dashed lines from 2 targets) represented within the BaTiO_3 - BaZrO_3 - CaTiO_3 ternary phase diagram. Inset represents a schematic of the sample's microstructure.

We explored a part of the BCTZ phase diagram using an original 3 targets CPLD scheme. The control of the linear variation of the composition was obtained as in classical CPLD [8] using BaTiO_3 (BTO) and $\text{BaTi}_{0.7}\text{Zr}_{0.3}\text{O}_3$ (BZT) targets (see Figure 1a). The trick is to use sub-psl deposition from these two targets and to complete the perovskite single layer using the 3rd target $\text{Ba}_{0.7}\text{Ca}_{0.3}\text{TiO}_3$ (BCT). Let us assume, for the sake of discussion, that the deposition rates are identical for the 3 targets with N laser pulses required for one psl. We fix, for a given sample, an x value with $0 \leq x \leq 1$. Then, the combinatorial deposition cycle comprises $(1-x)N$ pulses on the 1st target synchronized with the mask displacements in one direction, followed by $(1-x)N$ pulses on the 2nd target with opposite mask displacements, and finally xN pulses on the 3rd target without a mask (Figure 1a). The Ca content of such a sample is then constant (fixed by x) while the Ti/Zr ratio is continuously varying (controlled by mask positions). Its composition gradient is represented in the ternary phase diagram by a line parallel to the BaTiO_3 - BaZrO_3 border with an offset toward the CaTiO_3 summit. The gradient compositions are given by $\text{Ba}_{(1-x)+0.7x}\text{Ca}_{0.3x}\text{Zr}_{0.7(1-x)(1-y)}\text{Ti}_{(1-x)y+x}\text{O}_3$ with $0 \leq y \leq 1$. We deposited 8 BCTZ libraries with fixed Ca contents (1%, 2%, 3%, 4%, 6%, 8%, 9% and 11% at. composition) which are represented by the purple lines in Figure 1b. Properties of the sample with 3% Ca have been reported elsewhere [23]. In addition, two extra targets ($\text{Ba}(\text{Ti}_{0.8}\text{Zr}_{0.2})\text{O}_3$ and $(\text{Ba}_{0.785}\text{Ca}_{0.215})(\text{Ti}_{0.715}\text{Zr}_{0.285})\text{O}_3$) were used to synthesized 3 additional libraries (binary samples), represented by the blue dashed lines in Figure 1b and dubbed route 1 to 3. Route 1 is equivalent to the solid solution studied by Liu and Ren [11]. The KrF excimer laser fluence was set at $2 \text{ J}\cdot\text{cm}^{-2}$, the temperature at $700 \text{ }^\circ\text{C}$ and the deposition dynamic oxygen pressure at 0.3 mbar . These deposition conditions led to epitaxial growth of well-crystallised and smooth BCTZ film libraries on (001) SrTiO_3 single crystal substrates (See supplementary Figures S1–S3). Part of the substrate was covered during growth to allow access to the IrO_2 bottom electrode (see details in supplementary Figure S4). After deposition, a static oxygen pressure of 500 mbar was introduced in the chamber. The samples were then cooled down to $400 \text{ }^\circ\text{C}$ at $3 \text{ }^\circ\text{C}\cdot\text{min}^{-1}$ and then kept for 1 h at this temperature before

cooling down to room temperature. DC magnetron sputtering was then used to deposit Au top electrodes ($100 \times 300 \mu\text{m}^2$) through a shadow mask. A matrix of 600 capacitors (50 columns along the composition gradient with 12 repetitions per composition) was thus defined on each library. A schematic of the sample structure is represented in the top-right of Figure 1b. The composition gradient extends along 7 mm, edged by two 1.5 mm wide stripes with constant composition to accommodate for the mask/substrate relative alignment resolution and allowing precise gradient localization during electrical characterization. Thus, 35 different compositions between gradient end members were actually electrically measured. The composition gradient along the sample libraries was characterized either by Wavelength Dispersive Spectroscopy (WDS JEOL JXA-8230 EPMA) or by Rutherford Backscattering Spectroscopy (RBS). The capacitance measurements were realised using an Agilent 4294a impedance analyzer and a motorized cascade probe station. A fast initial C(V) scan through the libraries was performed at 100kHz under an AC voltage of 50mV and sweeping the DC voltage from -5 V to $+5 \text{ V}$ and then from $+5 \text{ V}$ to -5 V . The automatization of these measurements allowed for the total 6600 capacitors (11 libraries) to be characterized within 24 h. After treating the initial fast scan data, selected lines of compositions were then destructively measured from -7 V to 30 V to determine high field tunability and breakdown voltage versus the composition variation.

3. Results

3.1. Composition Gradient Characterization

To establish the control of both local composition and BCTZ thickness across the libraries, WDS profiles of Ba, Ca, Zr, Ti, Ir, Si elements were measured along the gradient (250 steps every 40 microns) and perpendicular to the gradient (250 steps every 20 microns) on the 6% Ca library. E-beam excited elements emit specific photons that travel through various layers before arriving to the detector. Within these layers, the photon absorption rates depend on its energy and on the composition and thickness of the said layers. Perpendicular to the gradient, the constant nominal BCTZ composition and thickness should lead to constant absorptions rates, i.e., a constant WDS signal from Si and Ir. Indeed, we found very small relative intensity variations (σ_I/\bar{I}) for Si (1.73%) and for Ir (1.4%) (see supplementary Figure S5), implying a good homogeneity of both the composition and thickness of the BCTZ layer. BCTZ homogeneous composition was further confirmed from the relative signal variation for Ba, Ca, Ti and Zr ($\sigma_I/\bar{I} = 2.33\%, 3.7\%, 1.94\%, 1.75\%$, respectively, see supplementary Figure S5). Note that the higher variation for Ca was correlated to its small signal amplitude relative to its small weight proportion within the probed volume. Along the gradient direction, the absorption rates within the BCTZ layer vary with the composition. However, the Zr and Ti signals showed, as expected, an anti-correlated almost linear continuous variation, while the Ba and Ca signals showed little variation (see supplementary Figure S6). To quantify the BCTZ composition, we self-consistently simulated the photon absorption within each layers using a commercial software (STRATAGEM) after acquiring the WDS signals in one location at several acceleration voltages. Assuming an oxygen stoichiometric formula $\text{Ba}_x\text{Ca}_y\text{Ti}_z\text{Zr}_t\text{O}_3$ and no conditions on x , y , z and t , the extracted composition was $\text{Ba}_{0.91}\text{Ca}_{0.08}\text{Ti}_{0.87}\text{Zr}_{0.14}\text{O}_3$, close to the nominal $\text{Ba}_{0.94}\text{Ca}_{0.06}\text{Ti}_{0.845}\text{Zr}_{0.155}\text{O}_3$. Note that the total self-consistently extracted atomic composition for the A and B site ($\text{A}_{0.99}\text{B}_{1.01}\text{O}_3$) are very close to unity. The composition gradient was also checked by RBS on the 3% Ca library [23].

3.2. Fast Initial C(V) Screening

Figure 2 shows a map of the tunability of the 280 compounds tested on the eight ternary libraries as a function of the nominal Zr and Ca content. For comparison purposes, the tunability of the capacitors was extracted from the C(V) curves within the same voltage range taking into account the offsets associated with composition dependent hysteretic behavior

(see top-left Figure 2). The maximum capacitance (C_{max}) and its associated voltage ($V_{C_{max}}$) were extracted, and the tunability was calculated between $V_{C_{max}}$ and $V_{C_{max}} + 5V$ as:

$$\text{tunability}(\%) = \frac{C_{max} - C(V_{C_{max}} + 5V)}{C_{max}} * 100, \quad (1)$$

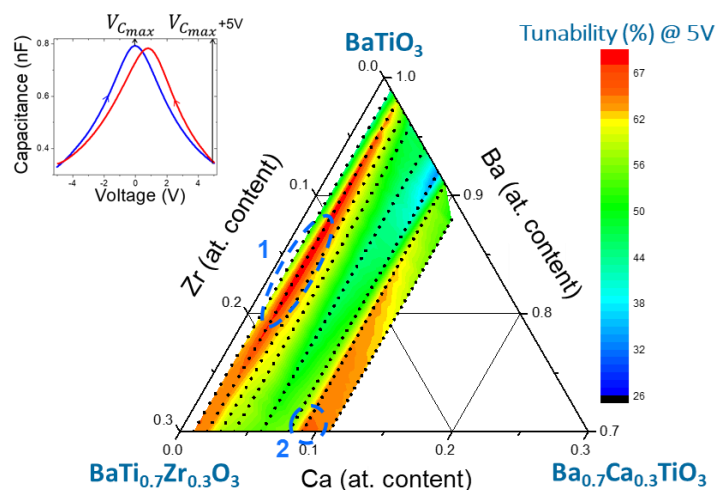

Figure 2. Fast initial screening tunability map (5 V amplitude). The black dots are the actual data points. Top-left is a typical hysteretic $C(V)$ curve.

A statistical analysis among the 12 representative capacitors per composition then gave the represented tunability value in Figure 2.

From this figure, two zones dubbed zone 1 and 2 with local tunability maxima are revealed: zone 1 peaking at 69% for low Ca content (2–3%) and a Zr content of about 12% and zone 2 peaking at 66% for about 10% of Ca and 21% of Zr (see blue dashed ellipses in Figure 2). We established that for the 3% Ca library, the maximum tunability was obtained for the composition that has its paraelectric to ferroelectric transition temperature (T_c) at room temperature [23]. It is then safe to assume, at least for the smaller amount of Ca (<5%), that the maximum tunability is due to the temperature dependence of the capacitance. Considering the zone 2, a decrease in T_c towards room temperature with increased Zr content could explain the higher tunabilities too. However, the much higher Zr content than in zone 1 should induce a more drastic drop in T_c ; as Ca doping in BST is known to have little effect on T_c , it is not anticipated that higher Ca content in zone 2 would counteract the Zr effect. Instead, it could be an indication that we are approaching a morphotropic phase boundary.

Even though the zone at lower Ca content seems to display higher tunabilities than the zone around 10% Ca, the global device performances do not depend solely on the tunability but also on dielectric losses and on accessible voltage range. To characterize overall properties further, we selected the 2%, 4%, 6% and 9% Ca content libraries and destructively measured the $C(V)$ curves from -7 V to 30 V along the composition gradient for a single line of capacitors to study their tunabilities and losses up to the breakdown voltage. The reason for selecting capacitors on the same lines is to ensure a fair comparison of the dielectric losses vs. composition. Indeed, dielectric losses do not depend solely on the dielectric material but also on the device connections in general, and on the bottom electrode access resistance in particular. In our sample geometry, only capacitors on a same row (line) are at the same distance from the bottom electrode contact pad, i.e., have the same access resistance. The tuning ratio ($TM = C_{max}/C(V)$), dielectric losses $\tan \delta$ and the figure of merit ($FOM = \text{tunability}(\%)/\tan \delta$) of the devices were then compared. Figure 3 shows the tuning ratio (a)(b)(c)(d), the FOM (e)(f)(g)(h) and $\tan \delta$ (i)(j)(k)(l) for different Ca content (2%, 4%, 6% and 9%) as a function of applied voltage and increasing the Zr amount for the ternary systems.

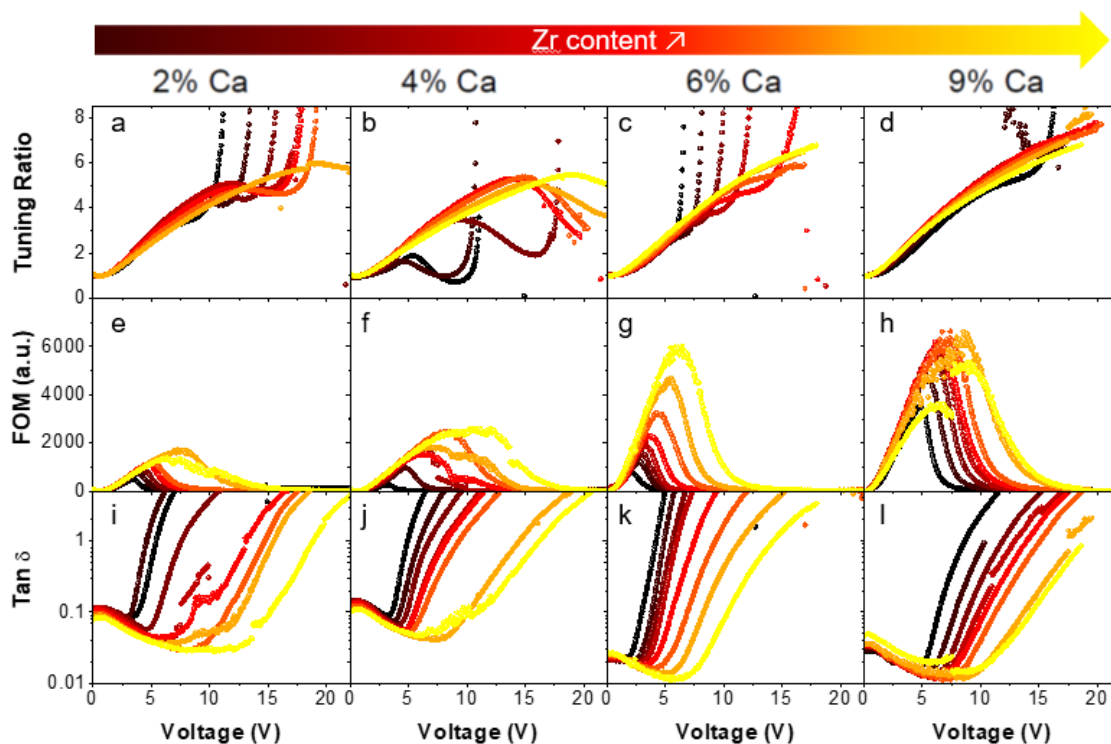

Figure 3. Tuning ratio (a–d), FOM (e–h) and $\text{Tan } \delta$ (i–l) vs. applied dc voltage and Zr content for different amounts of Ca. From left to right: 2%, 4%, 6%, 9% Ca. The amount of Zr increases from black (dark) to yellow (bright) in each graph.

Based on Figure 3a–d, a tuning ratio of 5/1, corresponding to a tunability of 80%, could be reached in most of the compositions which is already promising for applications. Tuning ratios up to 7/1 were even attained for some compositions. It can also be seen that the breakdown voltage (V_{bd}), corresponding to the sharp increase in the tuning ratio as $C(V_{bd})$ goes to zero, increased with increasing Zr content for all the Ca content, as reported previously for 3% Ca²³. From Figure 3e–h, the maximum reachable value for the FOM increased with Ca content, from about 2000 for 2% Ca, up to about 6000 for some compositions from the 6% and 9% libraries. However, the FOM decreased continuously down to 0 after a certain voltage, while the tuning ratio kept increasing so that a compromise between FOM and tuning ratio needs to be met for the best performance. This decrease in the FOM is directly related to the non-monotonic behavior of $\text{Tan } \delta$, as shown in Figure 2i–l. The dielectric losses first decrease with the bias field, as expected for ferroelectrics, before shooting up very rapidly at an upturn voltage V_{up} ranging from 3 to 10 V depending on the composition. The peak in FOM occurs for the same upturn bias. Comparing curves from top and bottom panels, it can be seen that the breakdown voltage V_{bd} is several volts higher than V_{up} . The addition of Ca to BTO (i.e., Zr content = 0, black curves) has a moderate and non-monotonic effect on the $\text{Tan } \delta$ upturn voltage (V_{up} = 3.1 V for 2%, 3.25 V for 4%, 1.8 V for 6% and 4.5 V for 9%). Oppositely, the addition of Zr at a constant Ca content strongly and systematically increases V_{up} in the $\text{Tan } \delta$. As a consequence, a continuous offsetting of the increasing branch of the losses is observed, up to 7.5 V for the Zr maximum content of 28% (Figure 3i). This is correlated with the improvement in breakdown voltage upon the Zr addition, as seen in the top panel of Figure 3. Another feature is the decrease in the dielectric loss at 0 V with the increase in Ca content (about one order of magnitude from 2% Ca to 9% Ca), whatever the Zr content.

Thus, both the addition of Ca and Zr are beneficial to the overall performance of the devices, although in different ways: Ca improves the 0 V dielectric losses, while Zr improves both the losses' upturn voltage and the dielectric breakdown voltage.

To select the optimum composition for a given application, multiple device specifications have to be taken into account: the minimum required tuning ratio and FOM,

and the maximum driving voltage available. These parameters are inter-related and have to be considered as a set. In Figure 4a–c, we represented maps of the maximum FOM (FOM_{max}), tuning ratio (TR) obtained at FOM_{max} and applied voltage (V_{dc}) at FOM_{max} for the four lines of capacitors from the 2%, 4%, 6% and 9% Ca libraries as a function of Ca and Zr contents. We summarized these data in Figure 4d where the interconnection of the operational parameters FOM_{max} , TR at FOM_{max} and V_{dc} at FOM_{max} is explicitly shown. Figure 4d allows us to assess quickly if some compounds fulfill all specifications of a given application. One can see from these maps that the highest V_{dc} value (11 V) obtained for 4% of Ca and about 26% of Zr leads to the highest TR but not necessarily to the highest FOM_{max} . The best set of (TR, FOM_{max}) is obtained for higher Ca content (9%) and high Zr content (about 19%).

Figure 4. Maps of FOM_{max} (a), V_{dc} at FOM_{max} (b) and TR at FOM_{max} (c) for the 2%, 4%, 6%, 9% Ca libraries vs. Ca and Zr amount. (d) Map of FOM_{max} vs. TR at FOM_{max} and V_{dc} at FOM_{max} for the same capacitors. Black dots are the actual data points.

To access rapidly to the part of the phase diagram containing, at the same time, a high content of Ca and Zr and to reproduce the solid solution from [11], we used two extra targets, respectively, $Ba_{0.785}Ca_{0.215}Ti_{0.715}Zr_{0.285}O_3$ (BCTZ) and $BaTi_{0.8}Zr_{0.2}O_3$ (BZT), to produce three binary samples dubbed route 1, 2 and 3 (see dotted blue lines Figure 1). The same analysis was then conducted on the binary sample. Figure 5a–f shows the FOM and tuning ratio for the three lines.

Figure 5. Tuning ratio (a–c), FOM (d–f) and Tan δ (g–i) vs. applied dc voltage for varying Ca and Zr content along route 2 (BTO-BCTZ), route 1 (BCT-BZT) and route 3 (BCTZ-BCT).

The highest reachable FOM values among all the samples were displayed by the BTO-BCTZ system (route 2 Figure 5d). However, as both the amount of Zr and Ca were increasing up to 0.285 and 0.215, respectively, it can be seen that the voltage required to reach a tuning ratio, e.g., a tuning ratio of 5, increased (Figure 5a). Thus, while adding Zr and Ca is beneficial for the FOM, increasing their amount above a certain limit led to the decrease in the tuning ratio at a given voltage. From Figure 5b,e, along route 1 from BCT to BZT, i.e., decreasing Ca and increasing Zr amounts, the tuning ratio at a given voltage increased, while the FOM improved before deteriorating at a low amount of Ca, consistent with our previous observations for the ternary systems. In Figure 5c,f (route 3 from BCT to BCTZ), where the amount of Ca decreased from 0.3 to 0.215, while the Zr amount was increasing from 0 to 0.285, it can be seen that the FOM and especially the tuning ratio are overall the worst of those three samples. This may be related to the solid solution limit of Ca found in the BTO structure, which is at about 22% Ca for ceramics prepared by conventional solid-state reaction [26] up to about 34% Ca for ceramics prepared by the zone-melt method [27].

There is no point to map the evolution of FOM_{max} , V_{dc} and TR at FOM_{max} vs. the composition for the binary samples, the lines being too far away in the ternary phase diagram. It is, however, possible to display those parameters vs. the Ca content in a continuous way, taking advantage of the common end members' composition that are the BCTZ and BCT targets for routes 2–3 and 3–1, respectively (Figure 6a–i). As pointed out earlier, in these set of capacitors measured destructively, one composition has only one representative, so no statistical analysis could be applied per composition. Instead, we have taken advantage of the continuous spread of composition by smoothing the data in Figure 6a–i using three adjacent points averaging. Error bars in the FOM data are estimated to about 300 from the noise present in the loss signal close to its minimum. A sort of plateau can be seen in the tuning ratio at FOM_{max} ($TR \approx 3.6$) for the BTO-BCTZ system (Figure 6a) for $8\% \leq Ca \text{ content (at.)} \leq 12\%$, but interestingly both FOM_{max} and V_{dc} increase by 50% over this range. A similar trend was reported on BCTZ thin film obtained by co-sputtering along the line $Ba_{1-x}Ca_xTi_{1-x}Zr_xO_3$, with a maximum of tunability recorded for $x = 0.12$. [28]. Although the TR starts to decrease for $Ca > 12\%$, the FOM_{max} still increases and reaches

about 8900, i.e., the highest value of this study, for $16.5\% \leq \text{Ca} \leq 19\%$. In route 3, adding some Ca while removing some Zr from BTCZ towards BCT helps neither the TR nor the FOM_{max} (Figure 6b,e respectively), and route 3 is clearly not the way to go for tunable capacitors. Finally, along the BCT-BZT route analogous to [11], no local enhancement of TR, FOM_{max} or V_{dc} was observed around a Ca content (at.) of 15% corresponding to the MPB [11–18] (Figure 6c,f,i). Instead, a steady increase in TR, FOM_{max} and V_{dc} is observed as Ca content decreases below 15%, with a peak at Ca (at.) = 3.33% corresponding to $\text{FOM}_{\text{max}} \approx 6740$, $\text{TR} \approx 4$ and $V_{\text{dc}} \approx 5.7$ V at FOM_{max} , i.e., close to the best values reported in the ternary libraries.

Figure 6. (a–c) TR at FOM_{max} , (d–f) FOM_{max} and (g–i) V_{dc} at FOM_{max} along route 2 (BTO-BCTZ), route 3 (BCTZ-BCT) and route 1 (BCT-BST) (from left to right). (j) Map of FOM_{max} vs. TR at FOM_{max} and V_{dc} at FOM_{max} for all the capacitors (binary and ternary systems) characterized at high voltage. Black dots are the actual data points.

Again, we summarized these data in Figure 6j where FOM_{max} vs. TR and V_{dc} at FOM_{max} is mapped for the binary libraries together with the ternary libraries.

4. Discussion

The original CPLD approach described here in exploring ternary phase diagrams in a reliable and statistical way by taking multiple slices across the diagram is a major upgrade of the combinatorial exploration in thin film developed so far. There are multiple improvements of this approach with respect to published work on combinatorial exploration of ternary phase diagrams using a single sample. First, the simple masking scheme used here to localize the deposition on the substrate allows a tight control of the local composition and thickness. In previous published work using shadow masks, the masking scheme was quite complex [21,22], implying a very difficult control of both the composition and the thickness over the library. Hence, the reported local composition in ref [21] was off nominal, with no mention of the thickness uniformity, while in most studies, a comparison between actual and nominal local compositions is not even addressed [29]. Other groups produced ternary phase diagrams by PLD without shadow masks, relying on rotated and off-centred substrates to produce lateral thickness variations in different directions for each target. Prediction of thickness variation and local composition were then made using simple models and simulations, which correlate at least semi-quantitatively with the measured compositions and thicknesses for binary oxides [30]. A demonstration has not been made for multi-cationic targets, and by nature this deposition scheme cannot produce uniform thickness libraries. Another improvement over previous work is the statistical population per composition given here by the slicing approach, which gives confidence and credibility in the determined properties. Outliers are easily spotted and dismissed with a statistical analysis. Furthermore, in previous work on tunable material with a complete ternary phase diagram on a single sample, there was no room for an access to bottom electrodes. Tunability and losses were evaluated by a scanned microwave microscope [29]

at GHz frequencies with no electrodes; thus, it did not encompass any electrode/dielectric interface effect.

Regarding the exploration of the BCTZ phase diagram presented here, we characterized 35 different compounds on each of the 11 synthesized libraries, i.e., a total of 385 different compositions. A fast initial low voltage $C(V)$ screening allowed us to identify two regions with high tunabilities. Higher voltage characterizations, up to the breakdown voltage, were made to investigate the relative roles of Ca and Zr further with respect to tunability, losses, voltage at loss upturn (V_{up}) and breakdown voltages (V_{bd}). It has been shown that Ca and Zr substitutions are beneficial up to a certain point with different benefits. Ca substitution for Ba reduces the losses at zero biasing voltage, while Zr substitution for Ti improves both the losses' upturn voltage and the dielectric breakdown voltage. As a higher dc field and tuning ratio are accessible when increasing V_{up} , Zr substitution is also beneficial for the FOM. In general, for a given composition, the best performances with minimal losses were obtained at V_{up} where the FOM reached its maximum. The representation in a single map of the maximum FOM vs. V_{dc} and TR at FOM_{max} (Figure 6j) for the 385 tested compounds allows us to identify quickly whether compositions exist that fulfill all specifications associated with a given applications. Indeed, no composition maximizes all the operational parameters, and the overall maximum FOM found here (about 9000 for $Ba_{0.84}Ca_{0.16}Ti_{0.8}Zr_{0.2}TiO_3$) did not correspond with the maximum overall tuning ratio (4.4 for $Ba_{0.91}Ca_{0.09}Ti_{0.81}Zr_{0.19}TiO_3$ with $FOM_{max} = 6600$ and $V_{dc} = 8.5$ V). For comparison purposes, let us consider state-of-the-art tunable BST-doped material found in commercial STMicroelectronics RF tunable capacitors for antenna impedance matching in 4G mobile phones. In the capacitor specifications [31] are reported a tuning ratio of 5/1 from 1 V to 24 V (i.e., $V_{dc} = 24$ V, tunability = 80%) and a quality factor $Q = 55$ (at 2 V and 700 MHz, $Q = 1/\tan\delta$) giving a FOM of 4400. Comparing with $Ba_{0.91}Ca_{0.09}Ti_{0.81}Zr_{0.19}TiO_3$, we have a slightly smaller tuning ratio (4.4 vs. 5), a higher FOM (6600 vs. 4400) and a much lower driving voltage (8.5 V vs. 24 V). This compound might be better suited than doped BST for near field communications (NFC) applications where the driving field does not exceed 3 V. Finally, the large range of properties described here illustrates the flexibility of the BCTZ system depending on the needs.

5. Conclusions

We deposited polycrystalline BCTZ thin films libraries on $IrO_2/Si(100)$ substrates using a refined combinatorial pulsed laser deposition (CPLD) scheme. We showed that CPLD is a powerful technique to study continuous lines reliably through the $BaTiO_3$ - $CaTiO_3$ - $BaZrO_3$ phase diagram (or any other phase diagram) in thin film form, which is crucial for their integration into devices, and allows a comparison with their bulk counterpart. By investigating the tunabilities and the figures of merit of the devices at room temperature, we were able to determine regions of the phase diagram with either the highest tunability or the highest FOM. Thus, we were able to determine a composition depending on the needs: low operation voltage (if high tunability is not required), high tuning ratio (up to 4.4) and high FOM (up to 9000). Finally, these results showed that BCTZ is a good candidate for tunable application and can potentially be used as a starting block for further improvements in their functionality.
