L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Spatially Constrained Online Dictionary Learning for Source Separation

Argheesh Bhanot*, Céline Meillier, Fabrice Heitz and Laura Harsan

***Abstract*—Whether in medical imaging, astronomy or remote sensing, the data are increasingly complex. In addition to the spatial dimension, the data may contain temporal or spectral information that characterises the different sources present in the image. The compromise between spatial resolution and temporal/spectral resolution is often at the expense of spatial resolution, resulting in a potentially large mixing of sources in the same pixel/voxel. Source separation methods must incorporate spatial information to estimate the contribution and signature of each source in the image. We consider the particular case where the position of the sources is approximately known thanks to external information that may come from another imaging modality or from *a priori* knowledge. We propose a spatially constrained dictionary learning source separation algorithm that uses *e.g.* high resolution segmentation map or regions of interest defined by an expert to regularise the source contribution estimation. The originality of the proposed model is the replacement of the sparsity constraint classically expressed in the form of an ℓ_1 penalty on the localisation of sources by an indicator function exploiting the external source localisation information. The model is easily adaptable to different applications by adding or modifying the constraints on the sources properties in the optimisation problem. The performance of this algorithm has been validated on synthetic and quasi-real data, before being applied to real data previously analysed by other methods of the literature in order to compare the results. To illustrate the potential of the approach, different applications have been considered, from scintigraphic data to astronomy or fMRI data.**

***Index Terms*—Source separation, dictionary learning, fMRI, scintigraphy, hyperspectral data.**

I. Introduction

The issue of source separation, or unmixing, is well known to the signal and image processing community. It concerns a very large number of applications and can occur under different conditions of source mixing. A large part of the literature is devoted to blind source separation (BSS) [1]–[3]. BSS methods allow to solve *cocktail party* problems for which P signals (or images) composed of a mixture of R sources are observed, without any *a priori* on the properties of the sources. If the number of sources involved in the mixtures is not known *a priori*, then they must also be estimated [4], [5]. Early BSS methods mainly comprised Independent Component Analysis (ICA) and sparse decomposition analysis. Many variants of the ICA approach have been proposed in the literature to solve BSS problems. All of them are based on the general principle of spatial independence of the sources, which makes it possible to estimate their temporal (or spectral) signatures.

For instance, in brain functional networks detection in functional Magnetic Resonance Imaging (fMRI) data, ICA is widely used to separate spatial sources by assuming the independence of the temporal signals associated

with each spatial source, *i.e.* functional network. Spatial ICA has proven effective in [6], [7] for fMRI data, but the main drawback of ICA approaches is the unknown number of sources which is set arbitrarily and may lead to a large number of nuisance sources, that must be screened manually or by a semi-automatic method [8].

In contrast to the BSS problem, many unmixing problems involve a dictionary of predefined sources. For example, in hyperspectral imaging for remote sensing, libraries of light spectra corresponding to the different materials that may be observed in the scene are available, so only the proportion of the different materials in each pixel is estimated. Between these two extreme cases, there are a large number of unmixing problems where some information on the form or location of the sources or the type of mixture is known. *Sum-to-one* and *positivity* constraints on the coefficients of the mixing matrix are classic in signal and image processing. In remote sensing applications, hyperspectral data linear unmixing is for instance carried out by methods based on non-negative matrix factorization [9], [10]. In recent years, sparse decomposition methods have been widely used to solve source separation problems. The sparsity constraint is another way to reduce the set of solutions and can be combined with the two latter constraints. The sparsity may concern the mixing itself, *i.e.* for a given observed signal, only a few number of sources is involved, or the decomposition of the sources on a dictionary (wavelet, discrete cosine transform, or custom atoms) [11]. Dictionary learning methods take into account the spatial sparsity of the sources in the form of ℓ_1 constraints on the mixing matrix in the minimisation problem. Recently for fMRI application, where sources are functional networks, sparse analysis based on dictionary learning methods have proven to be promising [12]–[15]. In hyperspectral imaging unmixing, with a library of spectra provided, Constrained-Sparse Unmixing by variable Splitting and Augmented Lagrangian (C-SUnSAL) [16] is a classical algorithm for solving the optimisation problem with the *sum-to-one*, *positivity* condition and an ℓ_1 constraint on the spatial maps matrix.

In this paper, we are interested in the problem of source separation in spatially structured data: 2D or 3D images that contain temporal information (fMRI, scintigraphy) or light spectrum information (hyperspectral imaging). We consider two categories of this kind of unmixing problems. In the first one, for a given pixel/voxel, different sources contribute to the mix in the sense that the spatial resolution is not fine enough to allow spatial separation of the sources. This is the case, for example, with unmixing problems in remote sensing [10] or fMRI applications [15], [17]. In this case, the mixing matrix is a matrix of proportions, where for a given pixel, the sum of the contributions of each source is equal to 1. In the second category of unmixing problems, the mixing is additive, the signals of the different sources are superimposed, and their sum forms the observed mixing signal. Decomposition of scintigraphic image sequences into tissue images and their time-activity curves, or unmixing of light sources in hyperspectral data in astronomy are examples of this second category of problems. In this case, the *sum-to-one* constraint is not relevant, the coefficients of the mixing matrix are the intensity of the contribution of each source in the mixture. Since the observed signals are observed in the form of images, the constraints that can be defined in the optimisation problem should be related to the location of the sources and not to their shape. In this context, this article presents an unmixing method for cases where the approximate position of the sources is available from another imaging modality or from *a priori* knowledge. We consider the case where no information on the temporal or spectral signature of the different sources,

or on their dependence is available. Unlike multimodal image fusion problems, such as pansharpening [18], our goal is not to produce a spatially and spectrally or temporally well-resolved image. We rather aim at exploiting segmentation information from a high spatial resolution image in order to improve the unmixing of spectral or temporal sources at a lower resolution image level. In the case of multimodal observations, information regarding the possible spatial location of sources is usually derived from a high spatial resolution image that does not provide the second dimension, namely temporal or spectral information. In some applications, such a segmentation map is not available, but approximate spatial location information can be provided by an expert who can define regions of interest (ROIs) (see for example the unmixing method for the highly realistic simulated renography dataset in [19], [20]).

The contributions of this paper are the following:

- A generic dictionary learning method that introduces *a specific* sparsity constraint on the spatial localisation of sources from external knowledge. Additional constraints on the mixing matrix (*positivity* and *sum-to-one* constraints) can be added or removed depending on the application. In the same way, constraints on the temporal/spectral signatures can be added. We propose an algorithm that adapts to any type of constraint in addition to the specific spatial location constraint.
- An illustration of the potential of the approach, on a variety of different applications, from scintigraphic data to astronomy or fMRI data, with experimental results on par with state-of-the-art algorithms in these fields. The considered data are of very different natures, as well as the *a priori* information available on the location of the sources. We thus show that our algorithm is adaptable to different types of data and different types of *a priori* knowledge on the location of sources.

A previous work, published in [17], presented a particular version of this generic algorithm dedicated to fMRI data unmixing where information on localisation is provided by registering an anatomical atlas on the data.

This paper is organised as follow: section II presents the generic observation model and the dictionary learning approach for unmixing spatially structured data based on the spatial location constraint. To the best of our knowledge, a model with the same spatial constraint does not exist, and section III presents models that are related or could be adapted to the problem presented. The performance and adaptability of the algorithm to different applications are illustrated on synthetic data in section IV and on real data in section V. Comparisons of our approach with application-specific state-of-the-art methods (Robust Unmixing of Dynamic Sequences Using Regions of Interest [19] and expert manual evaluation [21]), and a dictionary learning algorithm with C-SUnSAL as the solution to the optimisation problem for spatial maps, are proposed on three different applications: unmixing in scintigraphic image sequences, fMRI and hyperspectral astronomic datacubes.

II. Model and method

The classical linear model used in source separation may be written as:

$$\mathbf{Y} \simeq \mathbf{U}\mathbf{A}, \tag{1}$$

where $\mathbf{Y} \in \mathbb{R}^{N \times P}$ is the observed data. In spatio-spectral separation, N can be interpreted as the spectral length and in spatio-temporal separation N is the length of the temporal signals. P is the number of voxels or pixels, depending upon the dataset. Matrix $\mathbf{U} \in \mathbb{R}^{N \times R}$ contains the temporal/spectral signatures where R is the number of sources. Matrix $\mathbf{A} \in \mathbb{R}^{R \times P}$, usually called

mixing or abundance matrix, codes the fraction of the R components contributions at each voxel or pixel.

A. Constrained optimisation formulation

Given the observation model (1), the following minimisation problem:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\ \|_F^2 \tag{2}$$

does not have a unique solution because of the joint estimation of $\mathbf{A}$ and $\mathbf{U}$, and the ill-posedness of the problem. In order to restrain the number of solutions, we introduce a specific constraint on the form of matrix $\mathbf{A}$ defined according to some extra information from high resolution (HR) segmentation of sources or source locations knowledge: we know which ROIs may contribute to a given voxel, i.e. present a non-zero proportion at this voxel. When the total number of sources R is high, this *a priori* knowledge allows to constrain the possible solutions of the minimisation problem. Some standard constraints on matrix $\mathbf{A}$, such as *positivity* of the mixing coefficient, can be added in an additional constraint term $g(\mathbf{A})$. In the same way, some constraint on matrix $\mathbf{U}$ can be modelled by a generic constraint $h(\mathbf{U})$. In the most general setting, the unmixing problem is recast as:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2 + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}) + g(\mathbf{A}) + h(\mathbf{U}), \tag{3}$$

where the first term is the data fidelity term and the second term $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ is the indicator function on the set $M(\tilde{\mathbf{A}})$ of matrices having a structure similar to a given binary "structure matrix" $\tilde{\mathbf{A}}$, *i.e.* $\mathbf{A} \in M(\tilde{\mathbf{A}})$ if and only if $\mathbf{A} \in \mathbb{R}^{R\times P}$ and coefficient $\mathbf{A}_{i,j} = 0$ if $\tilde{\mathbf{A}}_{i,j} = 0$. $\tilde{\mathbf{A}}$ is a binary matrix, where element $(\tilde{\mathbf{A}})_{r,i} = 1$ if, according to a priori knowledge about spatial localisation of the sources, the r^{th} region of interest could exist in the i^{th} voxel, and 0 otherwise. This results in $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}) = \infty$ if at least one element of $\mathbf{A}$ is non-zero while it is zero in $\tilde{\mathbf{A}}$, and 0 otherwise.

Estimating jointly $\mathbf{U}$ and $\mathbf{A}$ in eq. (3) is a typical problem of dictionary learning (DL). But, unlike conventional DL algorithms, there is no sparsity regularisation term in the form of an ℓ_1 penalty: it is the sources localisation information coded in the structural term $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ which enforces the sparse decomposition of each voxel. A classical way to solve the joint estimation problem is to optimise alternatively the cost function eq. (3) along $\mathbf{U}$ and $\mathbf{A}$ as presented in algorithm 7.

```
Initialisation of binary matrix Ã
Initialisation of U^(0), l = 0
while STOPPING CRITERIA ≠ TRUE do
    Minimisation of problem ( 3) with respect to A
    Minimisation of problem ( 3) with respect to U
end
return U^(l+1), A^(l+1)
```

Algorithm 1: Alternated optimisation scheme of the dictionary learning algorithm to solve generic problem (3).

An example of a typical problem we propose to solve is:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2 + \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2 + \mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) + \mathcal{I}_S(\mathbf{A}) + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}), \tag{4}$$

where the first term is the data fidelity term, the second term is a Tikhonov regularisation controlled by parameter μ_σ set to 10^{-4} to prevent bad conditioning. The third term is a *positivity* constraint where $\mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) = \infty$ if at least one of the elements of $\mathbf{A}$ is negative, and 0 otherwise. The fourth term in eq. (4) codes an optional *sum-to-one* constraint on each column of matrix $\mathbf{A}$, $\mathcal{I}_S(\mathbf{A}) = \infty$ if at least one column of $\mathbf{A}$ does not sum to one, and 0 otherwise. In this case, $g(\mathbf{A}) = \mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) + \mathcal{I}_S(\mathbf{A})$ and $h(\mathbf{U}) = \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2$.

B. Estimation of the temporal / spectral signatures matrix $\mathbf{U}$

Considering that $\mathbf{A}$ is fixed, problem (3) becomes:

$$\min_{\mathbf{U}} \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\ \|_F^2 + h(\mathbf{U}). \tag{5}$$

In a generic case, $h(\mathbf{U})$ may be the sum of convex constraints but not necessarily differentiable. Let $h(\mathbf{U})$ be decomposed into the addition of a convex and differentiable term $h_d(\mathbf{U})$ and a convex but non differentiable term $h_{nd}(\mathbf{U})$. Problem (5) can be rewritten as:

$$\min_{\mathbf{U}} f_U(\mathbf{U}) + h_{nd}(\mathbf{U}), \tag{6}$$

where $f_U(\mathbf{U}) = \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\ \|_F^2 + h_d(\mathbf{U})$ is convex. In many differentiable applications, a Tikhonov regularisation term $\frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2$ is introduced in $h_d(\mathbf{U})$ to improve the conditioning of problem (3), μ_σ is set to 10^{-4} to prevent collinearity between columns of $\mathbf{U}$. The resulting optimisation problem requires proximal gradient methods to estimate $\mathbf{U}$ such as the alternating-direction method of multipliers (ADMM) [22], projections onto convex sets (POCS) or proximal gradient descent algorithms, e.g. Fast Iterative Soft Thresholding Algorithm (FISTA) [23], depending on the form of the constraints in $h_d(\mathbf{U})$ and $h_{nd}(\mathbf{U})$. If $h_{nd}(\mathbf{U}) \neq 0$ then solution of problem (6) with proximal gradient descent is:

In the case of FISTA algorithm, proximal operator and gradient are not evaluated at point $U^{(k)}$, but at an intermediate point $w^{(k)} = \mathbf{U}^{(k)} + \left(\frac{t^{(k-1)}-1}{t^{(k)}}\right)(\mathbf{U}^{(k)} - \mathbf{U}^{(k-1)})$ where expression of $t^{(k)}$ is given in [23] for increasing theoretically the convergence.

C. Estimation of the abundance / mixing matrix $\mathbf{A}$

Consider that $\mathbf{U}$ is fixed, then problem eq. (3) becomes:

$$\min_{\mathbf{A}} \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\|_F^2 + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}) + g(\mathbf{A}). \tag{7}$$

```
Initialisation of U^(0), k = 0
while STOPPING CRITERIA ≠ TRUE do
    for k ← 1 to proxsteps do
        U^(k+1) = prox_{h_nd}(U^(k) − λ∇f_U(U^(k)))
        k = k + 1;
    end
end
return U^(k+1)
```

Algorithm 2: Proximal gradient algorithm for estimation of $\mathbf{U}$, where $prox_{h_{nd}}$ is the proximal operator of h_{nd}, ∇f_U corresponds to the gradient of function f_U and λ is equal to the inverse of the Lipschitz constant of ∇f_U.

Note that if this function is separable according to the pixels/voxels $i \in \{1,\ldots, \mathrm{P}\}$, it leads to:

$$\min_{\mathbf{a}_i} \frac{1}{2}\|\mathbf{y}_i - \mathbf{U}\mathbf{a}_i\|_F^2 + \mathcal{I}_{M(\tilde{\mathbf{a}}_i)}(\mathbf{a}_i) + g(\mathbf{a}_i), \tag{8}$$

where $\mathbf{a}_i$ is a column vector from the matrix $\mathbf{A}$. In that case, the minimisation according $\mathbf{A}$ can be parallelised w.r.t. the pixels to decrease the computation time. The set of all the vectors with a structure similar to $\mathbf{a}_i$ is given by $\tilde{\mathbf{a}}_i$, where $\tilde{\mathbf{a}}_i$ is a column of $\tilde{\mathbf{A}}$. In a generic case, $g(\mathbf{A})$ may be the sum of convex constraints but not necessarily differentiable. Let the constraints $g(\mathbf{A}) + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ be decomposed into the addition of a convex and differentiable term $g_d(\mathbf{A})$ and a convex but non differentiable term $g_{nd}(\mathbf{A})$ that gathers non differentiable terms in $g(\mathbf{A})$ and $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ which is also non differentiable. Problem (7) can be rewritten as:

$$\min_{\mathbf{A}} f_A(\mathbf{A}) + g_{nd}(\mathbf{A}), \tag{9}$$

where $f_A(\mathbf{A}) = \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\ \|_F^2 + g_d(\mathbf{A})$.

Minimisation of the objective function given by eq. (9) belongs to the class of problems to which the proximal gradient methods can be applied. As for the estimation of $\mathbf{U}$, different proximal gradient algorithm

can be used. ADMM might be preferred when minimisation problem (9) is not separable w.r.t. the voxels, for example with total variation constraint on the spatial abundance of each source. For the proposed applications in this paper, only voxel-separable constraints on $\mathbf{A}$ are used, then the FISTA algorithm is implemented for estimating $\mathbf{a}_i$ for $i \in \{1,\ldots, \mathrm{P}\}$.

Convergence towards a global minimum of DL algorithms cannot be proven. In practice, a good initialisation of $\mathbf{A}$ and the presence of pure pixels (as in remote sensing applications) in each region guarantee a good joint estimation of $\mathbf{U}$ and $\mathbf{A}$. Previous work [17] has demonstrated the importance of well-defining the spatial constraint on abundance $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ to ensure an acceptable estimate of abundances and spectral or temporal signatures.

III. Related works

To our knowledge, the optimisation problem eq. (4) is not solved in the state of the art with the spatial constraint $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$. The closest form to it consists in replacing the indicator on the support of matrix $\mathbf{A}$ by a sparsity constraint of type ℓ_1. Without the *sum-to-one* and *positivity* constraints, we would then have a classical problem of online dictionary learning where coefficients of the mixing matrix $\mathbf{A}$ and dictionary update are optimised alternatively until convergence to an acceptable solution. In presence of *sum-to-one* and *positivity* constraints, estimation of matrix $\mathbf{A}$ must be adapted. The constrained sparse unmixing by variable splitting and augmented Lagrangian method (C-SUnSAL) [16] is a possible candidate algorithm, widely used in the community of hyperspectral imaging, that contains the constraints of *sum-to-one* and *positivity* and an ℓ_1 constraint on the abundance map matrix. The optimisation problem then takes the following form, which is close to the problem we propose to solve:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2+\frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2+\mathcal{I}_{\mathbb{R}^+}(\mathbf{A})+\mathcal{I}_S(\mathbf{A})+\|\mathbf{A}\|_1, \tag{10}$$

where $\mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) = \infty$ if at least one of the elements of $\mathbf{A}$ is negative, and 0 otherwise. The fourth term in eq. (4) codes an optional *sum-to-one* constraint on each column of matrix $\mathbf{A}$, $\mathcal{I}_S(\mathbf{A}) = \infty$ if at least one column of $\mathbf{A}$ does not sum to one, and 0 otherwise. Problem (10) can be rewritten as:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\|_F^2 + h(\mathbf{U}) + g(\mathbf{A}) + \|\mathbf{A}\|_1, \tag{11}$$

and it can be used to compare to results of our optimisation problem (4) where only the sparsity constraint on $\mathbf{A}$ changes. In the alternate optimisation scheme, the FISTA estimation of mixing matrix $\mathbf{A}$ is replaced by C-SUnSAL, while the estimation of $\mathbf{U}$ remains the same. Here a simple ridge regression is necessary since $h(\mathbf{U}) = \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2$ is convex. For convenience purpose, let us call this algorithm DL-C-SUnSAL (Dictionary Learning-C-SUnSAL). As mentioned in the original paper [16], *sum-to-one* or *positivity* constraints can be dropped if necessary in the same way than our algorithm, which makes it an ideal candidate to compare performances. In the following, we provide comparisons with this modified version of the optimisation problem solved by DL-C-SUnSAL (the code distributed by the authors of C-SUnSAL, with default parameters was used).

In the specific application of scintigraphic imagery, the robust unmixing of dynamic sequences using regions of interest (RUDUR) [19] is another unmixing method based on an objective function minimisation that promotes non-null abundances inside regions of interest (ROIs) while relaxing the model outside ROIs. The considered optimisation problem includes the same data fidelity term, the Tikhonov regularisation on temporal signature, but no *sum-to-one* constraint. The integration of ROIs knowledge is formulated as a soft constraint

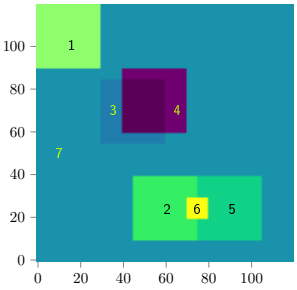
based on the distance to the ROIs that replace our regularisation $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$. This method has been compared in [19] to different ROI-based algorithms commonly used in scintigraphy such as FAMIS [20], FAROI [5], F_{PLS} [24], and another method based on variational Bayesian approach [25]. Various results in [19] show that RUDUR performs better at estimating spatial maps and temporal signals than the other ROI-based algorithms. In scintigraphic imagery, our method will therefore only be compared to RUDUR by setting $g(\mathbf{A}) = \mathcal{I}_{\mathbb{R}^+}(\mathbf{A})$ and $h(\mathbf{U}) = \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2 + \mathcal{I}_{\mathbb{R}^+}(\mathbf{U})$.

IV. Evaluation on synthetic datasets

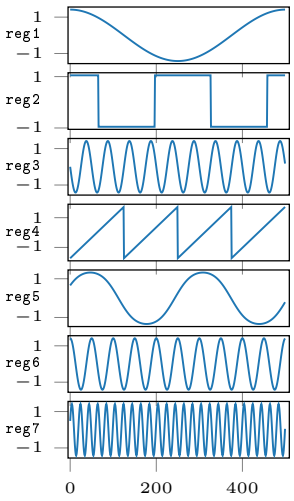
In this section, we evaluate the unmixing performance of our algorithm on two different synthetic datasets. Dataset I was created to show unmixing of signals/spectra taking into account different situations that could occur in real applications such as fMRI or astronomical data unmixing. The performance of the proposed algorithm is compared to the adaptation of DL-C-SUnSAL for dataset I. Dataset II is an example of realistic synthetic data in scintigraphy used in [19], for which the authors propose an unmixing method based on prior knowledge of the location of the regions of interest (RUDUR). The performance of our algorithm is compared to RUDUR and DL-C-SUnSAL for dataset II.

A. Dataset I

1) Data description: Unmixing algorithms are often sensitive to the assumption of pure pixels (i.e. each source or region has an abundance of 1 in at least one pixel of the image). To challenge this hypothesis, synthetic temporal data were simulated. Seven temporal signatures are mixed in a 120×120 pixels image. Ground truth signals and locations for the different regions are presented in Fig. 1. In Fig. 1a, we see a region 6 superimposed on two regions (2 and 5). Two other regions (3 and 4), partially covering each other, are included. Region 7 and region 1 are comprised of pixels not belonging to any other region. Data was generated for different SNRs ranging from -20dB to 20dB with a zero-mean Gaussian white noise.



(a) Localisation map for the 7 different sources. Region 6 is a difficult region, which overlaps region 2 and region 5. Region 7 and 1 do not intersect any other region. Regions 3 and 4 are partially overlapping.



(b) Nature of signals

Fig. 1: Localisation map and temporal signatures used to build synthetic data.

2) Algorithm details: We consider here the unmixing problem (4). In that case we note:

$$
\begin{aligned}
f_{\mathbf{U}}(\mathbf{U}) &= \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2 + \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2,\\
h_{nd}(\mathbf{U}) &= 0,\\
f_{\mathbf{A}}(\mathbf{A}) &= \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2,\\
g_{nd}(\mathbf{A}) &= \mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) + \mathcal{I}_S(\mathbf{A}) + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}).
\end{aligned}
$$

Since $h_{nd}(\mathbf{U}) = 0$, the minimisation problem w.r.t. $\mathbf{U}$ admits a simple solution: the ridge estimation. Minimisation of the objective function given in eq. (9) is more complex since the proximal operator of $g_{nd}(\mathbf{A}) = \mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) + \mathcal{I}_S(\mathbf{A}) + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}) = \mathcal{I}_{M(\tilde{\mathbf{A}})\cap S\cap\mathbb{R}^+}(\mathbf{A})$ must

be computed. This function is separable according to the pixels and computation can be parallelised. For a given pixel i, the set $M(\tilde{\mathbf{a}}_i) \cap S \cap \mathbb{R}^+$ is convex since the intersection of any collection of convex sets is convex, and $\mathcal{I}_{M(\tilde{\mathbf{a}}_i)\cap S\cap\mathbb{R}^+}(\mathbf{a}_i)$ is convex but non differentiable. Computing the proximal operator of $\mathcal{I}_{M(\tilde{\mathbf{a}}_i)\cap S\cap\mathbb{R}^+}(\mathbf{a}_i)$ will require the iterative algorithm projection onto convex sets (POCS) as explained in the following. Details of the proposed dictionary learning algorithm are given in Algorithm 3. For solving the minimisation problem w.r.t. $\mathbf{A}$, FISTA was preferred for its rapid convergence: its implementation for the i^{th} pixel is given in lines 7 to 13 in Algorithm 3

In Algorithm 3, $\nabla f_A(\boldsymbol{\omega}_i)$ is the gradient of $f_A(\boldsymbol{\omega}_i)$, given by $\mathbf{U}^T(\mathbf{U}\boldsymbol{\omega}_i - \mathbf{y}_i)$. The step size λ is set equal to the inverse of the Lipschitz constant of $\nabla f_A(\boldsymbol{\omega}_i)$ i.e. $1/L$, where $L = \|\mathbf{U}^T\mathbf{U}\|_F$. The auxiliary variable $t^{(k+1)}$ helps in the fast convergence of FISTA, $\boldsymbol{\omega}_i$ calculates intermediate values based on a special linear combination of the last two points $\mathbf{b}_i^k$ and $\mathbf{b}_i^{(k-1)}$, and $prox$ refers to the proximal operator [23]. In our case, the proximal operator is just the projection of $\boldsymbol{\omega}_i^{(k)} - \lambda\nabla f_A(\boldsymbol{\omega}_i^{(k)})$ in the positive orthant, with the vector normalised to *sum-to-one*. This projection also forces the elements of abundance matrix $(\mathbf{A})_{r,i}$ to be non-zero only at positions where the region of interest r projects on pixel/voxel i ($\mathcal{I}_{M(\tilde{\mathbf{a}})}$ constraint). The proximal operator of the function g_{nd} is:

$$prox_{g_{nd}}(\mathbf{y}) = \underset{\mathbf{x}\in M(\tilde{\mathbf{a}})\cap S^+}{\operatorname{argmin}} \|\mathbf{x}-\mathbf{y}\|_2 = \mathcal{P}_{M(\tilde{\mathbf{a}})\cap S^+}(\mathbf{y}), \tag{12}$$

where $\mathcal{P}$ is the projection operator on set $M(\tilde{\mathbf{a}}) \cap S^+$. The orthogonal projection of a vector $\mathbf{y} \in \mathbb{R}^R$ on $M(\tilde{\mathbf{a}}) \cap S^+$ is obtained using the implementation of the projection onto convex sets (POCS) method [26]. POCS algorithm alternates projection onto the simplex $S^+ = \mathbb{R}^+ \cap S$ and projection onto the set $M(\tilde{\mathbf{a}})$ of vectors having the same structure as $\tilde{\mathbf{a}}_i$. Only a few iterations are required for convergence of the POCS algorithm.

Algorithm 3: Alternate optimisation algorithm to estimate $\mathbf{A}$ and $\mathbf{U}$ that combines three nested iterative algorithms. At each iteration l, the $\mathbf{A}$ and $\mathbf{U}$ matrices are updated. The estimation of $\mathbf{A}$ is pixel-parallelised, i.e. for a given pixel i, the index k refers to the iterations of the FISTA algorithm. In each iteration k, the calculation of the $prox_{g_{nd}}$ requires an iterative POCS algorithm detailed in II-C.

The ground truth is given by the localisation map in Fig. 1a. To initialise $\mathbf{A}^{(0)}$, each region was dilated with a 7 pixels square structuring element, and then the proportion for each region over each pixel was

calculated, respecting the *sum-to-one* condition. The dilatation was done to introduce the uncertainty in the localisation of regions; as the localisation is seldom precise when dealing with real data. The algorithm used for unmixing is given in Algorithm 3. 400 steps were adopted for FISTA, in combination with 50 steps of alternate optimisation. The weighting parameter in the Tikhonov regularisation was set to 10^{-4} as no more smoothing was required. A standard normalisation was applied to the data before processing: $\mathbf{y}_i = \frac{\mathbf{y}_i - \mu_i}{\sigma_i}$, where μ_i is the mean of the temporal signal $\mathbf{y}_i$ of the i^{th} pixel and σ_i is the standard deviation of the timecourse of the i^{th} pixel.

3) Results and discussion: We observe that the timecourses and the abundances for the seven regions are well estimated even if the abundances are not perfectly initialised. The mean squared errors (MSE) for the estimation of the timecourses are displayed in table I, The MSE in estimating the abundances are given in table III. From table I and table III we see that for most of the regions the errors decrease as SNR increases. The spectral angle distances (SAD)(formula in Appendix B) given in table II follow a similar trend, proving the effectiveness of the unmixing method. In all the tables, it can be observed that the proposed method due to the unmixing performed solely in the interior of regions has a better performance than DL-C-SUnSAL. DL-C-SUnSAL requires time/spectral signals initialisation; this information is provided by ridge estimation using our initialisation of abundance maps that exploits *a priori* knowledge on the spatial localisation of sources. The estimated timecourses for each region were normalised by standard deviation before calculating the SAD and MSE. We also generated synthetic data, where region 6 was completely included in region 5. In this case, due to noise, it was impossible to correctly estimate the timecourse of the region included in the other (and therefore its abundance).

TABLE I: Region wise mean squared errors for $\mathbf{U}$ for different SNRs. Best estimations for different cases have been highlighted in bold.

Fig. 2 illustrates the convergence of the algorithm for different SNRs. Fig. 2 plots $\frac{\|\mathbf{Y}-\mathbf{UA}\|_F}{\|\eta\|_F}$, as a function of the number of steps in the alternate minimisation and η denotes the white Gaussian noise present in the dataset at different SNRs. In the very first steps of the alternate optimisation, we see that the curves decrease sharply and ultimately settle around a particular value when convergence is achieved. In Fig. 2 the -20dB and -10dB curves converge to values less than 1 since some noise remains in the estimated timecourses. The 0^{th} iteration shows the ratio $\frac{\|\mathbf{Y}-\mathbf{UA}\|_F}{\|\eta\|_F}$ calculated with the initial enlarged $\mathbf{A}$ and $\mathbf{U}$, estimated with ridge regression.

B. Dataset II

In an effort to objectively evaluate the performances of our approach, we propose to test and compare our method on a more realistic synthetic data set of scintigraphy images created for the evaluation of the perfor-

mances of the state-of-the-art RUDUR method [19]. The unmixing model has been adapted as explained at the end of section III. We have reused their dataset and the RUDUR code with the default parameters, as it is distributed by the authors [19].

1) Data description: This second dataset provides a first test case in which the method is confronted with a real application, on physical model-based simulations of scintigraphic images, with ground truth. It enables a comparison with a recent reference method in the field [19]. Region of interest-based unmixing methods are common in scintigraphy [5], [20], [27]. All standard methods are source separation methods. They estimate the time activity curves (TACs) and emissions of a tracer (a radioactive element) in the different body organs. A dataset of scintigraphic data has been made available at [28]. This dataset is based on a Monte Carlo simulation of scintillation camera imaging [29]. The datacube comprises images of size 21×26, with N = 60. The dataset, containing R = 3 regions, is shown in Fig. 3. In Fig. 3 the first row (a) shows the ground truths for the spatial maps. In the second row (b) the ROI initialisation

is presented. This initialisation is not the same as in [19] as our method needs strictly greater initial ROIs than the regions which need to be unmixed.

2) Algorithm details: RUDUR algorithm has a soft constraint on the source locations which allows the regions to unmix data even if the ROIs selected lie in the interior of the actual locations of the regions. In our model, we use a hard constraint on the locations of the regions, through the regularisation term $\mathcal{I}_{M(\tilde{\mathbf{A}})}$, so initial ROIs should be strictly enclosing the regions for which we want to estimate the timecourses. To achieve this, the binary masks of ROIs used in [19] have been dilated with a 5 pixels square structuring element.

We should note that this application corresponds to an additive case of unmixing, so the *sum-to-one* constraint was dropped off in our algorithm as well as for DL-C-SUnSAL. Further, as scintigraphy timecourses should be strictly positive (representing the emission of the tracer), eq. (3) was changed to:

$$\min_{\mathbf{A},\mathbf{U}} \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2+\frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2+\mathcal{I}_{\mathbb{R}^+}(\mathbf{A})+\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})+\mathcal{I}_{\mathbb{R}^+}(\mathbf{U}).$$

In this problem we note:

$$\begin{aligned} f_{\mathbf{U}}(\mathbf{U}) &= \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2+\frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2, \\ h_{nd}(\mathbf{U}) &= \mathcal{I}_{\mathbb{R}^+}(\mathbf{U}), \\ f_{\mathbf{A}}(\mathbf{A}) &= \frac{1}{2}\|\mathbf{Y}-\mathbf{U}\mathbf{A}\|_F^2, \\ g_{nd}(\mathbf{A}) &= \mathcal{I}_{\mathbb{R}^+}(\mathbf{A})+\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}). \end{aligned}$$

Due to the addition of $\mathcal{I}_{\mathbb{R}^+}(\mathbf{U})$, the constraint of positivity on the TACs, the ridge estimation step given in step 4 of Algorithm 3 to solve for $\mathbf{U}$ had to be replaced by FISTA steps to estimate $\mathbf{U}$ in each alternate step. The corresponding proximal operator must be evaluated for $h_{nd}(\mathbf{U}) = \mathcal{I}_{\mathbb{R}^+}(\mathbf{U})$ that is a simple orthogonal projection on the positive orthant. The initialisation of the algorithm was done with the help of ridge estimation using the initial dilated ROIs.

As the *sum-to-one* condition is dropped, the proximal operator of the function g_{nd} changes to:

$$prox_{g_{nd}}(\mathbf{y}) = \underset{\mathbf{x}\in M(\tilde{\mathbf{a}})\cap R^+}{\operatorname{argmin}} \|\mathbf{x}-\mathbf{y}\|_2 = \mathcal{P}_{\mathbb{R}^+\cap M(\tilde{\mathbf{a}})}(\mathbf{y}), \tag{13}$$

where $\mathcal{P}$ is now the projection operator on the set $\mathbb{R}^+ \cap M(\tilde{\mathbf{a}})$ which do not need anymore POCS algorithm to be evaluated.

3) Results and discussion: We ran our algorithm with 500 steps of alternate optimisation. At each iteration l, convergence is monitored by the optimisation gain κ_l defined as:

$$\kappa_l = \frac{\|\mathbf{Y}-\mathbf{U}^{(l)}\mathbf{A}^{(l)}\|_F - \|\mathbf{Y}-\mathbf{U}^{(l-1)}\mathbf{A}^{(l-1)}\|_F}{\|\mathbf{Y}-\mathbf{U}^{(l-1)}\mathbf{A}^{(l-1)}\|_F}, \tag{14}$$

which decreases to 10^{-15} at the 500th alternate step. Estimated temporal signals and spatial maps were normalised by the criteria given in [19] for comparison with the provided ground truth. The normalised mean squared error (NMSE) and normalised mean absolute error (NMAE) for the estimated spatial maps and time activity curves were calculated. In addition, we also provide spectral angle distances (SAD) for the estimated time activity curves. The formulae for NMAE, NMSE and SAD are given in Appendix B. The quantitative results on the synthetic scintigraphy data are given in table IV. We observe that the signals estimated by our method are close to those obtained by RUDUR, and DL-C-SUnSAL is slightly better for the first two ROIs but fails to estimate the TAC for ROI3. The NMSE and NMAE for spatial maps calculated using the two methods are given in table V. The errors on the spatial maps were calculated by restricting the pixels of the estimated maps to the initial ROIs. Errors are generally lower in the case of DL-C-SUnSAL for the estimated spatial maps and globally well controlled for RUDUR.

TABLE V: Errors between the estimated spatial maps for the different regions and the ground truth. The errors given here were calculated by restricting the pixels of the estimated spatial maps to the initial ROIs. Best estimations for different cases have been highlighted in bold.

The spatial maps unmixed by our method are presented in Fig. 3 (c) and those estimated by RUDUR and DL-C-SUnSAL are displayed in Fig. 3 (d) and Fig. 3 (e) respectively. Visually the maps estimated by RUDUR and the proposed method are very similar in the interior of ROIs although the errors are lower in the case of RUDUR. The pixels outside the ROIs were not treated by the algorithm proposed in this work, so they were not taken into account to evaluate performances. The last row(f) shows the TACs estimated by the proposed method (in blue). We observe in Fig. 3 that our solution is near the target solution (in dashed black) for all the sources and is close to the solution provided by RUDUR. For ROI3, DL-C-SUnSAL suffers from the lack of ROI-based constraint and is more sensitive to the noise for TAC estimation.

V. Application on semi-real and real data

In this section, we discuss the application of our algorithm to sources unmixing of (semi-real) resting state (rs) 3D fMRI data and on a real dataset of hyperspectral astronomic images. In these two applications, in addition to the 3D + time or hyperspectral data, a high resolution segmentation map is available as a standard, with a registration on the low resolution images containing the sources to be separated.

A. Semi real rs-fMRI dataset

Resting state functional Magnetic Resonance Imaging (rs-fMRI) has been widely used for studying brain functional connectivity [30]. Rs-fMRI allows the observation of changes in cerebral activity by analysing the blood-oxygen-level-dependent (BOLD) signal [31]. At rest, only spontaneous activity is measured, and a set of anatomical regions with the same fluctuations are considered part of a common network. We apply the algorithm on a single subject rs-fMRI. The motivation to work on single subject has been detailed in [17]. Extended analysis of this particular example is given here, with regard to the pure pixel hypothesis which is not verified for all sources here. The benefit of integrating a high resolution (HR) anatomical atlas in the single-subject case has also been demonstrated in this previous work.

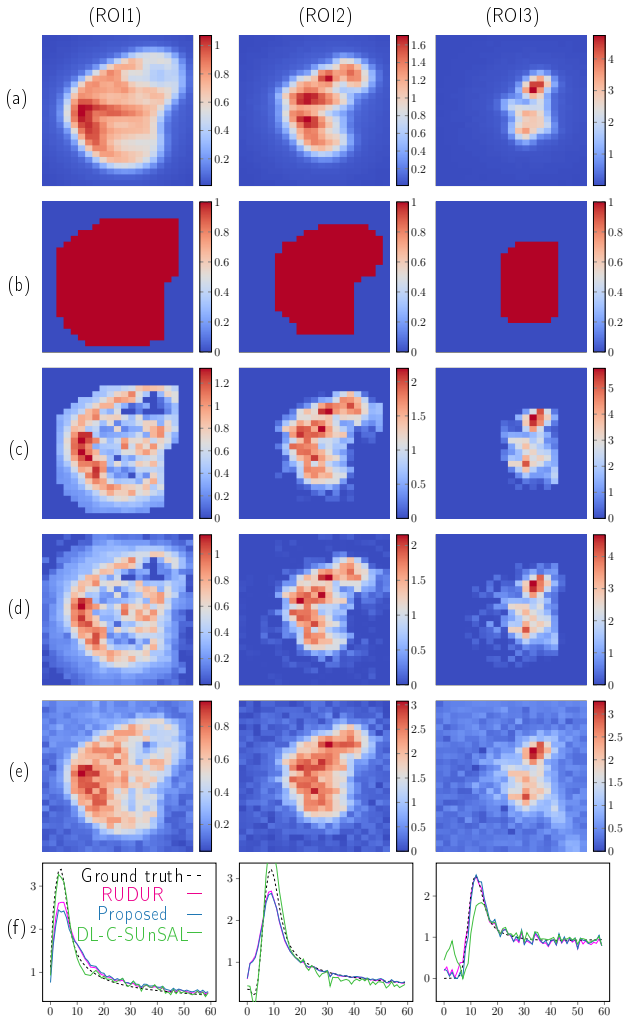

Fig. 3: Scintigraphic data. (a) Ground truth for spatial maps, (b) Initial ROIs , (c) Spatial maps estimated by the proposed algorithm, (d) spatial maps estimated by RUDUR, (e) spatial maps estimated by DL-C-SUnSAL (f) TACs estimated by RUDUR, DL-C-SUnSAL and our method.

In order to test the proposed unmixing method, we use data acquired in a preclinical study with an Alzheimer mouse model; the studies on this data are given in [32], [33]. The data consist of a 3D+t rs-fMRI and a 3D anatomical image registered to the rs-fMRI image. The anatomical image has a dimension of $256 \times 256 \times 34$ and $0.08299 \times 0.07812 \times 0.4\ mm$ resolution. Functional images have a spatio-temporal dimension of $147 \times 87 \times 27 \times 500$ with $0.1445 \times 0.2299 \times 0.5\ mm$ spatial resolution and 2s for the temporal resolution. The high resolution (HR) segmentation map comes from the mouse Allen Brain Atlas (ABA) [34], shown in Fig. 4. This very HR atlas provides a 3D MRI volume (template) and a structural annotation volume, both at $25 \times 25 \times 25\ \mu m$ resolution with $228 \times 160 \times 264$ voxels. The annotations identify more than 600 different anatomical structures in the mouse brain.

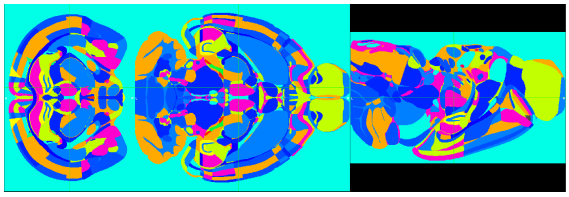

Fig. 4: Rs-fMRI data unmixing. 3D representation of the segmentation map associated with the Allen Mouse Brain Atlas [34]. Each colour represents a label associated with an anatomical region.

1) Validation dataset: A validation dataset is created by introducing a set of synthetic temporal signatures in seven small regions of the real Alzheimer mice dataset. The seven regions, labelled ACAd1, ACAd5, ACAd6a, ACAv1, ACAv5, ORBl1 and PL1, have been arbitrarily chosen in the prefrontal cortex. A first synthetic signal is obtained by averaging the real signals of the regions ACAd1 and ACAd5, which were already highly correlated in the real data. This signal is then modified to create signals with arbitrary high correlation or anti-correlation for the regions ACAd1, ACAd5, ACAd6a, ACAv1, ACAv5, ORBl1 and PL1 (see details on these signals in [17]). These correlations do not have a physical significance, they are used as ground truth for evaluation of the proposed algorithm performances [17].

The classical fMRI preprocessing pipeline of slice timing and co-registration is applied on the rs-fMRI

dataset. Also, the confounding signals are regressed before analysing the data. The next step consists in registering the spatially well-resolved ABA template to the artificially augmented anatomical image (which is already perfectly aligned with the rs-fMRI data). The registration of the ABA mouse template to the anatomical images provides the deformation field that is applied to the HR segmentation map to transport the different labelled regions on the augmented rs-fMRI data. The spatial resolution of rs-fMRI data is augmented by subdividing each original voxel into $3 \times 6 \times 2$ high resolution voxels. The registration of the anatomical image to the augmented rs-fMRI leads to an increase in its own resolution.

Synthetic signals are introduced in the standardised artificially augmented fMRI data, which are then reduced to the initial low resolution. These synthetic signals are thus mixed with the real signals in the voxels containing a portion of the seven selected regions. Since the atlas has a much higher spatial resolution than the fMRI or structural MRI data (up to a factor of 20 in one of the dimensions), the temporal signatures of the different anatomical regions are highly mixed within each low resolution fMRI voxel. Let us note that the pure pixel assumption is not verified in the regions where the signals were added. The minimum and maximum number of overlapping regions on the voxels of each region is given in table VI.

	ACAd1	ACAd5	ACAd6a	ACAv1	ACAv5	PL1	ORBl1
Min	4	2	4	4	6	4	2
Max	9	12	18	12	17	10	10

TABLE VI: Minimum and maximum number of regions overlapping on the voxels for fMRI regions where signals were added.

2) Algorithm details: The unmixing problem corresponds to the formulation given in eq. (4). Finally, DL algorithm detailed in Algorithm 3 is performed at the (low) resolution of the initial fMRI data $\mathbf{Y} \in \mathbb{R}^{N \times P}$, where N = 490 temporal samples and P = 21024 voxels after extracting the brain. The initial abundance matrix $A^{(0)} \in \mathbb{R}^{R \times P}$ is constructed as follows. Let's say that each voxel $i \in \{1,\ldots,\mathrm{P}\}$ was subdivided into J high resolution voxels during the artificial augmentation step.

For each voxel i of $\mathbf{Y}$ and all regions $r \in \{1,\ldots,R\}$, the element $(A^{(0)})_{r,i}$ will contain the proportion of high resolution voxels in voxel i, occupied by region r. If region r is not transported to the low-resolution voxel i then $(A^{(0)})_{r,i} = 0$. Matrix $\tilde{A}$ which supports the spatial constraint $\mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A})$ in eq. (3) is defined as: $(\tilde{A})_{r,i} = 1$ when $(A^{(0)})_{r,i} > 0$ and 0 elsewhere.

3) Results and discussion: The proposed DL method is applied to the validation data set. Empirically, the algorithm converges to an acceptable solution for $\mathbf{A}$ and $\mathbf{U}$ after 500 iterations, see Fig. 5, corresponding to a gain on the optimisation $\kappa_l < 10^{-3}$ (eq. (14)). For the estimation of $\mathbf{A}$, the FISTA algorithm requires a stopping criterion or a maximum number of iterations. In our implementation, FISTA is stopped when $\|\mathbf{a}_i^{(k-1)} - \mathbf{a}_i^{(k)}\|_2 < 10^{-8}$ or $k > 100$. DL-C-SUnSAL is not compared to the proposed approach as in section IV-A, the results proved that proposed method has a better performance than DL-C-SUnSAL for the cases which could occur in fMRI datasets but with much more significant overlaps for the ROIs. Additionally, DL-C-SUnSAL and RUDUR do not respect the boundaries of ROIs, which is important in this case. Moreover, the optimisation problem of RUDUR has a positivity constraint on the timecourses and cannot be used here.

The mean squared error (MSE) of the estimated timecourses are given in table VII. Despite the strong mixing in the voxels of the seven regions, our algorithm pro-

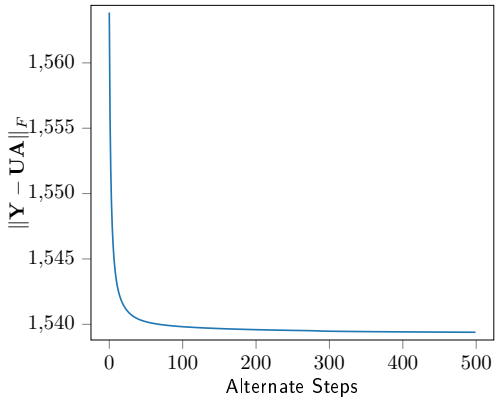

Fig. 5: Rs-fMRI data. The figure shows that $\|\mathbf{Y}-\mathbf{UA}\|_F$ converges; as is seen by the flattening of the curve in the last iterations.

	ACAd1	ACAd5	ACAd6a	ACAv1	ACAv5	PL1	ORBl1
MSE	0.0887	0.0578	0.0341	0.0292	0.0221	0.0266	0.0398

TABLE VII: Errors (NMAE and NMSE) and spectral angle distances (in degrees) between the estimated timecourses and the ground truth for the scintigraphy dataset. Best estimations for different cases have been highlighted in bold.

vides a very good estimate of the synthetic timecourses introduced in the data. In neurosciences applications, these timecourses are then used to build functional brain networks.

B. Hyperspectral astronomic data

In order to confront our algorithm with an unmixing problem on real data, we finally consider the problem of unmixing sources in hyperspectral astronomic data. Some datasets in this domain comprise of hyperspectral datacubes and an external information on the spatial location of the sources. We studied datacubes from the MUSE instrument, the Multi Unit Spectroscopic Explorer [35], installed at the Very Large Telescope, which produces hyperspectral observations of the deep sky. In these hyperspectral images, we can observe hundreds or even thousands of galaxies. Depending on their age, chemical composition, type, distance, etc, these galaxies have different spectra. These spectra may contain emission lines, continuous components, etc. One of the main objectives of MUSE data analysis is the detection of very distant galaxies, which therefore emit very low light flux. Spectrum of distant galaxies consists of a single emission line, the Lyman-α emission line, which is a marker of the strong presence of hydrogen in the galaxy. They are difficult to detect due to their distance and their very faint intensity compared to closer galaxies, and a strong noise affects the data. Moreover, if two galaxies are aligned in the direction of observation, their spectra will blend inside pixels of MUSE images.

Recently two articles [21], [36] were published around a MUSE dataset called Ultra Deep Field (UDF) which corresponds to an area of the sky previously observed by the Hubble Space Telescope (HST). The HST observation is a spatially well-resolved image, of spatial resolution 0.1×0.1 arcsec, for which there is a segmentation map presented in [37]. Due to the difference in resolution of the MUSE data, which is only 0.7×0.7 arcsec, two distinct sources in the HST image, may overlap in the MUSE data creating a mix in the spectra. In [21], [36], the information provided in the Rafelski catalogue is exploited to perform the deblending and prove that MUSE, despite its lower spatial resolution, allows, thanks to the spectral information, to unmix two spatially close or even superimposed sources. We have selected the same portion of the image that is presented in figure 21 of [21] where the objects identified by ID#4451, ID#4460 and ID#4465 in [37] are spatially superimposed in the MUSE observation. This gives a 25×25 pixels image with spectra composed of 3681 samples from 4750 to 9350 Angström (1 Ang = 0.1 nm).

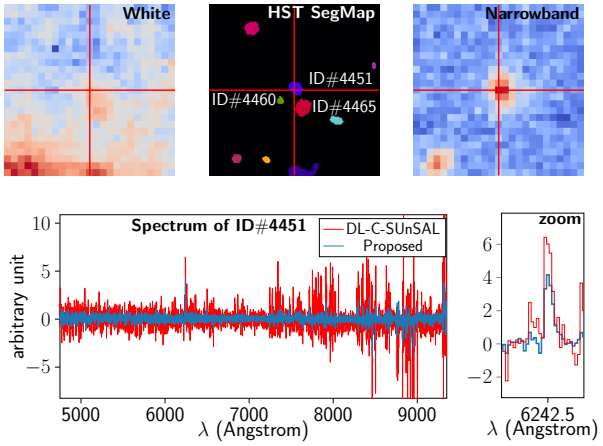

Fig. 6: UDF Hyperspectral astronomic data. On top, from left to right, MUSE reconstructed white light image, HST Rafelski segmentation map and narrowband image centered on $\lambda = 6242.5$ Ang (position of the emission line in estimated spectrum of source ID#4451). The central Rafelski source denoted by red crosshair is ID#4451. Bottom, from left to right: estimated spectrum by the proposed method and its comparison to DL-C-SUnSAL for source ID#4451 over the whole wavelength range and zoom on the Lyα emission line estimated at $\lambda = 6242.5$.

A total of 9 galaxies are present in this field of view, with three of them that are spatially close in the HST segmentation map represented at the middle of the first row in Fig. 6. The source ID#4465 is brighter than galaxies ID#4451 and ID#4460. Its contribution is visible on the white light image, obtained by averaging the datacube with respect to the wavelength axis. A visible source on the white light image indicates that its spectrum contains a continuous component plus, possibly, some emission lines. Contribution of source ID#4451 is embedded in source ID#4465's one. The objective of this section is to show that knowing the spatial location of such a blended source provides enough information to unmix spectra of the different superimposed sources with our algorithm.

For defining the spatial constraint $\mathcal{I}_{M(\tilde{\mathbf{A}})}$ required by our model, the HST segmentation map provided by [37] is used. This map is perfectly registered on the MUSE data. Then by degrading the spatial resolution from 0.1 arcsec to 0.7 arcsec, we obtain binary masks for all the objects present in the field. For the three central sources, the obtained binary masks are shown on the first row of Fig. 7. Mixing of the galaxy spectra corresponds to an additive mixing, hence the *sum-to-one* constraint is dropped, and we note:

$$
\begin{aligned}
f_{\mathbf{U}}(\mathbf{U}) &= \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\|_F^2 + \frac{\mu_\sigma}{2}\|\mathbf{U}\|_F^2, \\
h_{nd}(\mathbf{U}) &= 0, \\
f_{\mathbf{A}}(\mathbf{A}) &= \frac{1}{2}\|\mathbf{Y} - \mathbf{U}\mathbf{A}\|_F^2, \\
g_{nd}(\mathbf{A}) &= \mathcal{I}_{\mathbb{R}^+}(\mathbf{A}) + \mathcal{I}_{M(\tilde{\mathbf{A}})}(\mathbf{A}).
\end{aligned}
$$

One hundred alternated optimisation steps allow to reach a gain eq. (14) equal to 10^{-10}. It should be noted that the background is considered here as a source, its mask is available in the segmentation map and it is processed in the same way as for the galaxies, to degrade its resolution to the resolution of the MUSE data. The DL-C-SUnSAL algorithm was tested on the dataset with the same initialisation and provided a much noisier spectrum. Even-though similar conclusions can be drawn for the Lyα emission line in the estimated spectrum, its presence is not distinguishable from the other emission lines, especially at the end of the spectrum. The absence of a hard spatial constraint in DL-C-SUnSAL resulted in larger estimated spatial maps, and this can be observed in Fig. 7. The failure of DL-C-SUnSAL is due to the presence of a stronger noise at the end of the spectrum.

It is impossible to compare quantitatively the results obtained with a ground truth, since no such information exists for the MUSE data. However, same conclusions as in [21] can be drawn about the spectrum estimated by our algorithm for source #4451: at wavelength $\lambda = 6242.5$

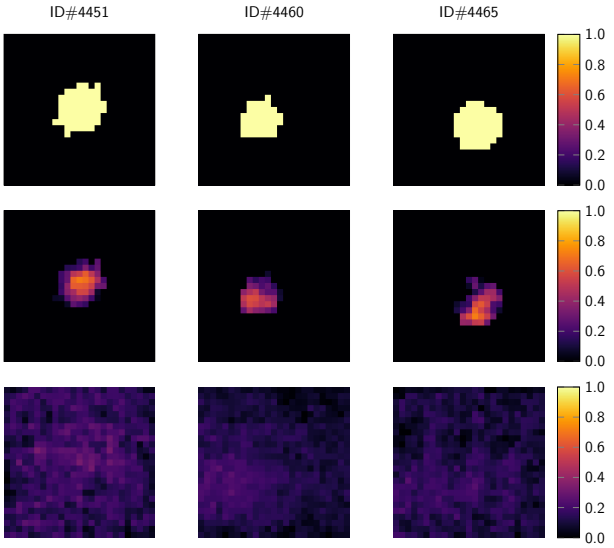

Fig. 7: Hyperspectral astronomic data. Top row, from left to right, binary mask of sources ID#4451, ID#4460 and ID#4465. Middle row, from left to right, estimated abundance map of sources ID#4451, ID#4460 and ID#4465 by the proposed method. Bottom row, from left to right, estimated abundance maps of sources ID#4451, ID#4460 and ID#4465 by DL-C-SUnSAL method.

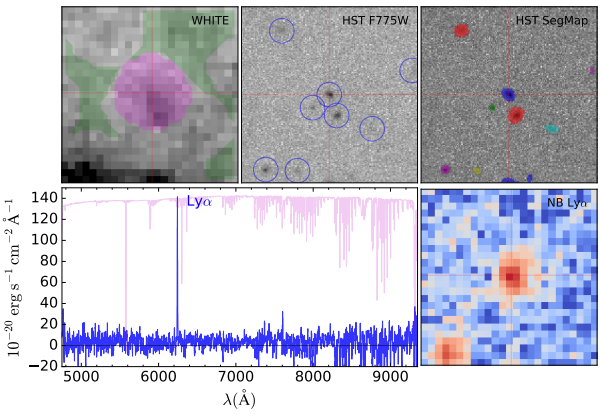

Fig. 8: Hyperspectral astronomic data. Reproduction of figure 21 from paper [21]. On top, from left to right, MUSE reconstructed white light image, HST image, and HST Rafelski segmentation map. The central Rafelski source denoted by red crosshair is ID#4451. Bottom left: PSF weighted estimated spectrum of source ID#4451 over the whole wavelength range (blue) and in mirror, the noise standard deviation (magenta). Bottom right: narrowband image centered on $\lambda = 6242.5$ Ang (position of the emission line in estimated spectrum of source ID#4451). Credit: Bacon *et al.* , A &A, vol. 608, p. A1, 2017, reproduced with permission © ESO.

Ang, there is an emission line corresponding to object #4451 of Rafelski's catalogue. This emission line has the characteristics of the Lyman-α line (Lyα), namely an asymmetric profile as illustrated in Fig. 6. These results are very similar to the ones presented in Figure 21 in [21] that is reproduced in Fig. 8 by courtesy of the authors. The similarity between results presented in Fig. 6 and Fig. 8 confirms the interest of our generic approach to solve this particular type of unmixing problem.

VI. Discussion

The last application shows the ability of the proposed algorithm to unmix hyperspectral data with a spatially constrained dictionary learning algorithm. It also underlines the necessity of having some external knowledge about the localisation of sources in higher spatial resolution to improve classical dictionary learning unmixing algorithm. In the case of MUSE data, such information coming from the segmentation of another telescope observation (here the Hubble Space Telescope) is rarely available. Moreover, a good segmentation of this additional image is also required. Besides, this *a priori* knowledge of sources spatial localisation must be precisely registered to the spectral/temporal data to unmix. As for the fMRI application, in [17] the authors showed that the estimated values were sensitive to the quality of the localisation maps provided. As these maps are used to define the regularisation term $\mathcal{I}_{M(\tilde{a}_i)}$, their precision influences the estimation of the temporal/spectral signatures and their abundances in strongly

mixed voxels: the better the precision of the localisation map, the better the estimation of the spectral/temporal information associated to each source.

From an algorithmic point of view, the strong points of the proposed approach are the small number of parameters to be set and its genericity. The algorithm has a single intrinsic parameter μ_σ used in the Tikhonov regularisation, it has only to be set to a very low arbitrary value, as explained in section II-B.

With the scintigraphy application, it has been shown that it is easy to adapt the unmixing problem by adding or removing constraints. In some applications, the proportions of each region have a natural smooth evolution from one pixel to another. A constraint for spatial smoothing within the regions could be introduced in a future variant of the algorithm. However, depending upon the nature of the added constraint, it would increase the complexity of the algorithm. For the current version, the constraints that are in the form of indicator functions would lead to the introduction of nested loops and consequently to a significant increase in calculation time.

Concerning the execution time of the algorithm, the main factors are the stopping criteria of the different nested iterative algorithms and the size of the images to be unmixed. Furthermore, the calculation time depends much more on the spatial dimension of the image than on the temporal/spectral dimension as the complexity lies in the estimation of $\mathbf{A}$, and to a lesser extent on the number of regions. The algorithm approached convergence for the astronomical data in a few minutes on a laptop, whereas 1.5 days CPU time was necessary for the fMRI data on a server with 32 cores, with a processing speed of each core around 1603 Mhz. The applications we presented do not require real-time processing, but a GPU implementation would lead to a significant gain in speed as the code is highly parallelisable.

VII. Conclusion

A method to unmix data consisting of an image and a temporal or spectral dimension has been presented. The proposed method proves effective in unmixing problems where some prior information related to the ROIs is available or where such information can be obtained from a registered high resolution image. It should be noted that the method does not take into consideration the morphology, the local structure or the texture of the sources, but only their approximate locations. The spatial constraints are classically expressed as an ℓ_1-penalty to promote sparsity of the mixture in each voxel. Problems with such constraints are generally solved by dictionary learning algorithms. The originality of the proposed approach lies in the replacement of this penalty by a constraint on the localisation of the different regions of interests. In some of the examples presented in the article, it has been shown that the algorithm can be easily adapted for specific applications by introducing or dropping constraints of *sum-to-one* on spatial maps or *positivity* on timecourses. State-of-the-art results have been obtained for three very different applications. The comprehensiveness of the method makes it possible to easily adapt it to other fields of application such as remote sensing applications for which incorporation of spatial information has been proved to enhance hyperspectral image unmixing performance [38]. The code will be available soon online for the community.

Appendix A
Formulae

The formulae for the different criteria used to analyse the experimental results are given below:

$$NMSE(U_r^{GT}, U_r) = \frac{\sum_{n=1}^{N}(U_{r,n}^{GT} - U_{r,n})^2}{\sum_{n=1}^{N}(U_{r,n}^{GT})^2}, \quad (15)$$

$$NMAE(U_r^{GT}, U_r) = \frac{\sum_{n=1}^{N}|U_{r,n}^{GT} - U_{r,n}|}{|\sum_{n=1}^{N}(U_{r,n}^{GT})|}, \quad (16)$$

$$SAD(U_r^{GT}, U_r) = \cos^{-1} \frac{\sum_{n=1}^{N} U_{r,n}^{GT} U_{r,n}}{\sqrt{\sum_{n=1}^{N} U_{r,n}^{GT\,2}} \sqrt{\sum_{n=1}^{N} U_{r,n}^{2}}}, \tag{17}$$

where U_r^{GT} is the ground truth temporal signal for r^{th} region, U_r is the estimated signal for the r^{th} region, N is the length of the temporal signal. NMAE and NMSE can be written in a similar manner to evaluate spatial maps.

ACKNOWLEDGMENT

The authors would like to thank IRIS platform [39] at ICube for the Alzheimer's data and equally R. Bacon for providing MUSE dataset.
