Running Title: A CRISPR-Cas9-based tool to study DSBs dose-dependently

25 **Abstract**

26 The integrity of DNA is put at risk by different lesions, among which double strand
27 breaks (DSBs) occur at low frequency, yet remain one of the most life-threatening harms. The
28 study of DSB repair requests tools provoking their accumulation, and include the use of
29 chemical genotoxins, ionizing radiations or the expression of sequence-specific nucleases.
30 While genotoxins and irradiation allow for dose-dependent studies, nuclease expression
31 permits assessments at precise locations. In this work, we have exploited the repetitiveness of
32 the Ty transposon elements in the genome of *Saccharomyces cerevisiae* and the cutting activity
33 of the RNA-guided Cas9 nuclease to create a tool that combines sequence specificity and dose-
34 dependency. In particular, we can achieve the controlled induction of 0, 1, 15 or 59 DSBs in
35 cells with an otherwise identical genetic background. We make the first application of this tool
36 to better understand the behavior of the apical kinase of the DNA damage response Tel1 in
37 the nuclear space. We found that Tel1 is capable of forming nuclear foci, which are clustered
38 by condensing when DSBs occur in Ty elements. In striking contrast with other DSB-related
39 protein foci, Tel1 foci are in tight contact with the nuclear periphery, therefore suggesting a
40 role for the nuclear membrane in their congregation.

41

42 **Introduction**

43 Cells are confronted to an enormous amount of spontaneous DNA damage arising
44 from natural sources, such as reactive oxygen, reactive carbonyl and nitrogen species,
45 products of lipid peroxidation or the spontaneous chemical lability of the DNA. In addition,
46 there are external sources of damage such as ionizing radiations, chemicals in food, air and
47 water as well as ultraviolet light. Last, rare exposure as that occurring during chemotherapy
48 and radiotherapy is intentionally aimed at forming damage to the DNA. The lesions resulting
49 from these attacks are of a heterogeneous nature, and can include nucleotide base opening,
50 adducts, crosslinks and single-stranded DNA breaks. DNA double strand breaks (DSBs) can
51 also occur, albeit in lower proportion, yet remaining one of the most life-threatening lesions
52 (1).

53 This higher deleteriousness is in great part due to the fact that, contrary to single strand
54 breaks, DSBs more frequently lack an appropriate undamaged, complementary strand to

55 exploit as a repair template. In fact, DSB repair can efficiently occur without such a support
56 through the process of Non-Homologous End Joining (NHEJ) by sealing the broken ends back
57 together (2). This process could be error-prone because short deletions or insertions may occur
58 at junctions, and translocations take place by the joining between two ends from different DSBs
59 (2). Alternatively, if a sequence similar to the broken one exists elsewhere in the genome, it can
60 be used as a template to guide the information retrieval needed to reconstitute the interrupted
61 sequence at the DSB. This process is Homologous Recombination (HR) and, like NHEJ, is not
62 without drawbacks. The homologous sequence needed to support repair may be available in
63 the replicated sister chromatid or in the homologous chromosome. Further, some sequences
64 are repeated and spread throughout the genome. Given that the resolution of the homology
65 copy may end up with an exchange of the neighboring sequences, a process known as
66 crossing-over, repair involving ectopic repeated sequences or the homologous chromosome
67 could respectively lead to genome rearrangements or loss of heterozygosity and thus only the
68 repair with the sister chromatid warrants a faithful repair (2).

69 The study of DSB repair necessitates of tools capable of provoking their accumulation.
70 In this sense, genotoxic agents of chemical nature or different types of ionizing radiation are
71 used to damage the genomes of model organisms in a sequence-unspecific manner. A more
72 controlled strategy relies on the expression of proteins whose enzymatic activity creates DSBs
73 at specific DNA target sequences. These can be endonucleases such as restriction enzymes,
74 commonly used *in vitro* for molecular biology (3–8), and meganucleases known to bear a well-
75 defined, rare sequence only present from once to a few times in a given genome (9–13). For
76 example, much of our understanding about DSB repair mechanisms comes from the analysis
77 of HO-mediated DSB in yeast *Saccharomyces cerevisiae* (11). On the one hand, the use of
78 standard restriction enzymes permits the creation of a relatively high number of breaks, at
79 known positions, with ends of a well-defined structure. On the other hand, the use of specific
80 meganucleases cutting at single locations allows to focus the study of molecular events with a
81 high degree of precision while ensuring that no break occurring elsewhere influences the
82 outcome of that DSB event. Yet, a limitation of these sequence-targeted tools is that, contrary
83 to the effects obtained when using increasing doses of genotoxins, they cannot be used for
84 dose-dependent studies. In this sense, in a recent elegant study, Gnügge and Symington
85 engineered yeast strains in which the expression of restriction enzymes could be induced,

86 using a battery of enzymes that can cut an increasing number of sites in the genome, ranging
87 from 20 to 96 (14). However, the different *in vivo* enzymatic activities manifested by each
88 enzyme prevent the use of this system for dose-dependent comparative studies. An alternative
89 work exploited the repetitiveness of the transposable Ty elements in *S. cerevisiae* genome to
90 insert 2, 7 or 11 sites that can be cut upon controlled induction of the HO endonuclease (15).
91 Yet, engineering this system was tedious because it implied multiple rounds of cloning,
92 retrotransposition and Southern blot analysis. This system was used to assess molecular events
93 in DSB repair such as resection and checkpoint activation, as monitored by Southern and
94 western blot, respectively (15,16), and the sensitivity of these techniques allowed to assess
95 dose-dependent differences. Yet, if less sensitive techniques important in the field of DSB
96 sensing and repair need to be used, a system with such a restricted number of breaks may not
97 be sufficient.

98 In this work, we have exploited the repetitiveness of the Ty transposon elements in the
99 genome of *S. cerevisiae* and the guide RNA-driven sequence specificity of Cas9 cutting activity.
100 In particular, we have targeted an increasing number of Ty elements by designing specific
101 guide RNAs (gRNAs) that could recognize one or several Ty classes. Upon the controlled
102 induction of Cas9 expression, we can achieve an increasing number of enzymatic DSBs (0, 1,
103 15 or 59) *in vivo*. Because Cas9 and the gRNAs are expressed from plasmids, DSBs can be easily
104 induced in cells grown in otherwise identical conditions and with an identical genetic
105 background. Thus, we have generated a versatile tool that overcomes the lack of dose-
106 dependency of expressing restriction enzymes while achieving the maximum number of DSBs
107 in an easily applicable manner, atypical in systems using sequence-specific nucleases.

108 We applied this tool to assess the behavior of the Tel1 apical kinase of the DNA damage
109 response in space and time after DSB induction. Contrary to later-acting factors of the DSB
110 repair cascade, fluorescence microscopy is not commonly used to study the very early-acting
111 factors, especially those involved in DSB sensing. Here, we report that Tel1 molecules
112 congregate in the shape of foci in response to diverse sources of DSBs. We report that Tel1 can
113 form up to 8 foci per cell, in striking contrast with other DSB-related proteins, and they can be
114 clustered by condensin when DSBs occur in Ty repetitive elements. We also show that Tel1
115 foci manifest in tight contact with the nuclear periphery, therefore suggesting a role for the
116 nuclear membrane in their congregation.

117

118 **Materials and Methods**

119 **Reagents** used in this work for cell treatments were zeocin, R25001 ThermoFisher
120 Scientific; camptothecin (CPT), C9911 Sigma-Aldrich; and DAPI, D9542 Sigma-Aldrich.

121

122 **Culture and treatments:** *Saccharomyces cerevisiae* cells carrying plasmids for the
123 expression of the gRNA used to cut the genome and for the expression of the Cas9
124 endonuclease were grown at 25°C in the appropriate selection medium (-uracil, -leucine).
125 Typically, cells were grown in 2 % glucose; prior to the induction of Cas9 expression, cells were
126 shifted to 2 % glycerol and grown overnight at 25°C to ensure complete glucose consumption.
127 When DNA damage was induced using zeocin (100 µg/mL), cells bearing a control plasmid
128 were grown at 25°C in minimal medium with appropriate selection (uracil). Spot assays were
129 carried out in medium selecting the gRNA plasmids (-uracil) and the inducible Cas9
130 expression vector (-tryptophan) containing either 2 % glucose or 2 % galactose as a carbon
131 source. Sensitivity spot assays were carried out using YEPD medium supplemented with
132 either DMSO (control) or with 40 µM CPT. For Nup57 tagging with the red fluorophore
133 tDIMER at its genomic *locus*, the plasmid pRS305-NUP57-tDIMER (17) (gift from O. Gadal,
134 Toulouse, France) was linearized with *Bgl*III and transformed into strain MM-144. Pus1 was
135 tagged with mCherry using the plasmid YIplac211-mCherry-PUS1 (18) (a gift from S.
136 Siniosoglou, Cambridge, UK), which was linearized at the *URA3 locus* with *Bgl*III and inserted
137 by HR in this same *locus* in the strain of interest. To accomplish experiments with the *smc2-8*
138 mutant, cultures were split 2h prior to the experiment and cells incubated at the permissive
139 (24°C) or the restrictive (37°C) temperature.

140

141 **Pulsed Field Gel Electrophoresis (PFGE):** Agarose plugs containing
142 chromosomal DNA were made as described (19). Chromosomes were separated at 13°C in a
143 0.9% agarose gel in 0.5× TBE using a Rotaphor apparatus (Biometra) with the following
144 parameters: interval from 100 to 10 s (logarithmic), angle from 120 to 110° (linear), and voltage

145 from 200 to 150 V (logarithmic) during 24 h. The gel was subsequently stained with ethidium
146 bromide for 1 h and washed in water for 30 minutes, then photographed under UV light. For
147 subsequent Southern blot, DNA from gels was transferred to Genescreen Plus membranes
148 (Perkin Elmer). Hybridization was achieved using multiple radioactive probes specific for:

149 - chromosome III:

150 *ARS307* locus; PCR primers 5'-ATTCATTGCGTCTCTGTATTT-3' and 5'-TTTGAAGATCCTATAACCGTG-3'.

151 - chromosome IV:

152 *SLX5* locus; 5'-GGTAATAACCAAGTCGAAATTGTC-3' and 5'-CAAAGCACAATTGCACCTCTGATC-3'.

153 *FOB1* locus; 5'-CATTTAGTCAAACGGGTGTTA-3' and 5'-AAATTTTGGAGCATTCTCTG-3'.

154 *RAD9* locus; 5'-GCAGCTCCCCATCAAATAAG-3' and 5'-TGAATCTCGTTATTGCTCCTT-3'.

155 *MUS81* locus; 5'-AACTTTTTCAGTTTTTGTCTGTAATG-3' and 5'-GGGATGACTATATTCAAATTGCTA-3'.

156 - Ty1 and Ty2; PCR primers 5'-AAATCTGCAAGACAACATGC-3' and 5'-ATCCTATTACATTATCAATCC-3'.

157 Hybridized membranes were read using a PhosphorImager (Typhoon IP, GE). Three
158 independent biological replicates were performed for Cas9 induction time course experiments.

159

160 **Fluorescence Microscopy:** 1 mL of the culture of interest was centrifuged, the
161 supernatant thrown away and the pellet resuspended in the remaining 50 μ L. 3 μ L of this cell
162 suspension were directly mounted on a microscope slide for immediate imaging of the
163 pertinent fluorophore-tagged protein signals. Imaging was achieved using a Zeiss Axioimager
164 Z2 microscope and visualization, co-localization and analysis done using Image J. For time-
165 lapse microscopy experiments, we used cells bearing the x59-cuts gRNA and the inducible
166 Cas9 plasmids that had been induced for Cas9 expression in liquid culture by addition of
167 galactose for 5h40. A total of 10 μ L were then spotted on the bottom of a previously prepared
168 FluoroDish (selective minimal medium supplemented with 2% galactose and 1% agarose was
169 casted on FluoroDishes [FD35-100; World Precision Instruments] that had been previously
170 treated with a 0.1% [wt/vol] polylysine solution for 10 min at room temperature, then air-
171 dried). Samples were observed in a Metamorph-controlled Nikon TIRF PALM STORM
172 microscope in a culture chamber at 30°C. Lasers were used at 5% of their power, and pictures
173 were shot every 20 min for 140 min.

174

175 **Telomere length measurement:** Telomere length was measured by PCR after
176 end labeling with terminal transferase (20,21). End-labeling reactions (40 μ L) contained 120 ng
177 genomic DNA, x1 New England Biolabs™ Terminal Transferase Buffer, 1 mM dCTP, 4 units
178 Terminal Transferase (New England Biolabs™) and were carried out at 37°C for 30 minutes
179 followed by heat inactivation at 75°C for 10 minutes. 1/5th volume of 5 M NaCl, 1/80th volume
180 of 1 M MgCl₂ and 1 volume of isopropanol were added to the reaction and DNA was
181 precipitated by centrifugation at 17000×g during 15 min. Precipitated DNA was resuspended
182 in 40 μ L of ddH₂O. The end-labeled molecules were amplified by PCR using the primer 5'-
183 GCGGATCCGGGGGGGGGGGGGGGGGG-3' and 5'-TGTGGTGGTGGGATTAGAGTGGTAG-3' (X) and 5'-
184 TTAGGGCTATGTAGAAGTGCTG-3' (Y'), respectively. PCR reactions (50 μ L) contained between 40 ng
185 and 80 ng of DNA, 1x myTaq buffer, and primers 0.4 μ M each. Amplification was carried out
186 with 5 U of MyTaq polymerase (Meridian Biosciences®). The conditions were 95°C, 5 minutes;
187 followed by 35 cycles of 95°C, 1 minute; 56°C (Y reaction) / 60°C (X reaction), 20 seconds; 72°C,
188 5 minutes. Reaction was ended with 5 minutes at 72°C. Samples were visualized in a 2 %
189 agarose gel containing 1× GelRed (Ozyme®).

190

191 **Serial dilution spots assays:** Exponentially growing cells of the indicated
192 genotype were serially diluted 10-fold and 3 μ L of each dilution spotted onto the indicated
193 plates, incubated at 30°C for 2 or 3 days and imaged.

194 **Analysis of DNA content by flow cytometry:** 430 μ L of culture samples
195 at 10⁷ cells/mL were fixed with 1 mL of 100% ethanol. Cells were centrifuged for 1 minute at
196 16000 xg and resuspended in 500 μ L 50 mM Na-Citrate buffer containing 5 μ L of RNase A (10
197 mg/mL, Euromedex, RB0474) and incubated for 2 hours at 50°C. 6 μ L of Proteinase K
198 (Euromedex, EU0090-C) were added and after 1 hour at 50°C, cell aggregates were dissociated
199 by sonication (one 3 s-pulse at 50% potency in a Vibracell 72405 Sonicator). 20 μ L of this cell
200 suspension were incubated with 200 μ L of 50 mM Na-Citrate buffer containing 4 μ g/mL

201 Propidium Iodide (FisherScientific). Data were acquired and analyzed on a Novocyte Express
202 (Novocyte).

203

204 **Quantifications, Graphical Representations and Statistical Analyses:** The

205 number of nuclei displaying foci of the analyzed proteins as well as the number of foci present

206 per nucleus were determined visually by the experimenter. Counting was not done in a

207 blinded manner, but three different researchers were implicated in the quantification of

208 experiments to challenge reproducibility. GraphPad Prism was used both to plot the graphs

209 and to statistically analyze the data. The mean value of nuclei displaying foci was calculated

210 for each independent experiment, and the SEM (standard error of the mean) was used to

211 inform on inter-experiment variation. The SEM estimates how far the calculated mean is from

212 the real mean of the sample population, while the SD (standard deviation) informs about the

213 dispersion (variability) of the individual values constituting the population from which the

214 mean was drawn. Given that the goal of our error bars was to describe the uncertainty of the

215 true population mean being represented by the sample mean, we chose to plot the SEM. To

216 plot probability distributions, we converted the actual observations from each category

217 (number of foci) into frequencies by dividing by the total number of observations. To establish

218 the cutting efficiency, band intensities were determined from non-saturated Southern blot

219 images using ImageJ. The signals emanating from cut bands were divided by the addition of

220 signals emanating from both cut and uncut bands, and expressed as a percentage.

221

222 **Strains, plasmids and oligos:** The strains used in this study are presented in

223 [Table 1](#) and were obtained either by classical methods for integration, transformation and

224 crosses, or by CRISPR-Cas9 technology in the case of Tel1 yEGFP-tagging. The plasmids used

225 in this study are presented in [Table 2](#). The relevant sequences for CRISPR-Cas9 manipulations

226 are described in [Table 3](#). We have also designed, but not characterized, guide RNAs targeting

227 2 Ty4, 3 Ty3, 44 Ty1 and 163 Delta elements. Plasmids and sequences are available upon

228 request.

235

236 Results

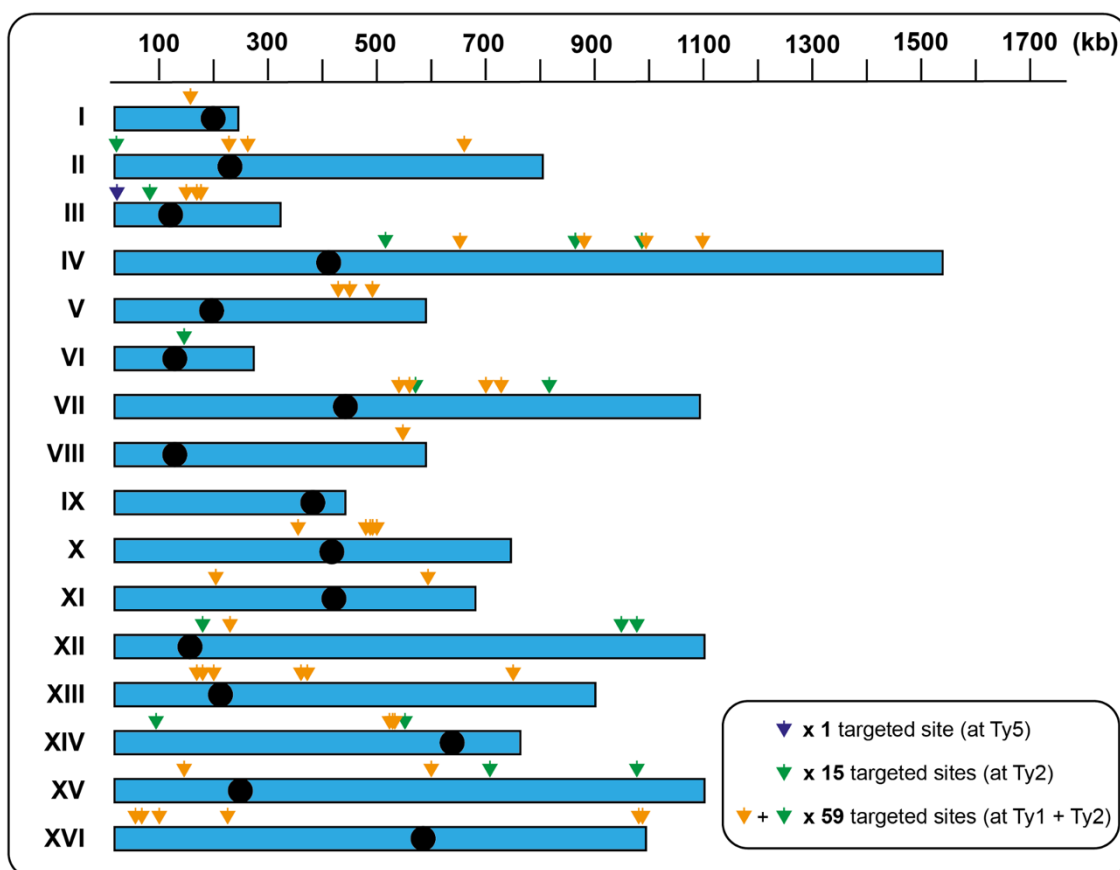

237 A genetic system to create DNA double strand breaks in an inducible and dose-dependent 238 manner

239 In order to generate multiple DSBs, we targeted repeated DNA by using the CRISPR-
240 Cas9 technology (25). Among the most abundant classes of repeats in *S. cerevisiae* are
241 retrotransposons (Ty elements), which represent about 3% of the genome (26), and whose
242 targetability by the CRISPR-Cas9 technology has already been demonstrated in a study aimed
243 at engineering translocations in a controlled manner (27). Based on the sequenced genome of
244 the W303 yeast strain (28), we designed guide RNAs (gRNAs) to target the ORF of the sole
245 complete Ty5 element (1 targeted site), of the 15 copies of Ty2 (15 targeted sites) and of both
246 the closely related Ty1 and Ty2 (59 targeted sites) (Fig 1A). The sequences for the gRNAs were
247 cloned in multicopy expression plasmids, different from the one expressing the Cas9 nuclease
248 under the control of the galactose-inducible GalL promoter (22,23).

249 To assess the performance of the system, we initially tested viability upon inducing
250 Cas9 expression in wild-type cells simultaneously expressing no guide RNA (gRNA) and thus
251 not inducing DSBs (x 0), or the gRNAs leading to the potential cleavage of the genome at 1 site
252 (x 1), 15 sites (x 15) or 59 sites (x 59), respectively. We spotted serial dilutions of cells either in
253 medium containing glucose (no Cas9 expression) or increasing concentrations of galactose
254 (low, mild and strong Cas9 expression). We observed that the viability of wild-type cells
255 expressing x 1 gRNA was only mildly affected compared with no guide RNA (x 0). This result
256 is not surprising taking into account that the x 1 gRNA is targeting Cas9 to the sole Ty5
257 element, which is located very close to the left telomere of chromosome III. Cleavage of

258 chromosome III at this location generates a telomere-proximal fragment that does not contain
259 essential genes and could be lost, while the other fragment containing the centromere could
260 be efficiently repaired by *de novo* telomere addition or telomere recombination. In contrast to
261 the effect of the x 1 gRNA, the viability of wild-type cells expressing x 15 or x 59 gRNAs was
262 strongly affected by the increased number of targeted sites (x 0 < x 1 < x 15 < x 59) and by the
263 increased expression of Cas9 (Fig 1B, WT). These results suggest that DSBs are readily induced
264 by the expression of Cas9 in a dose-dependent manner.
265

266

267 **Figure 1. Design of the CRISPR-Cas9-based system to induce DSBs in a dose-dependent**
 268 **manner**

269 **A.** Scheme of the sixteen *S. cerevisiae* chromosomes (blue boxes), in which the black circles
 270 mark the relative position of the centromeres. Color-coded arrows mark the approximate Ty
 271 positions targeted by the designed gRNAs. In more detail, the x 1 gRNA targets the single Ty5

272 (dark blue arrow), the x 15 gRNA targets the Ty2 sites (green arrows), and the x 59 gRNA
273 targets both Ty2 and Ty1 sites (orange and green arrows).

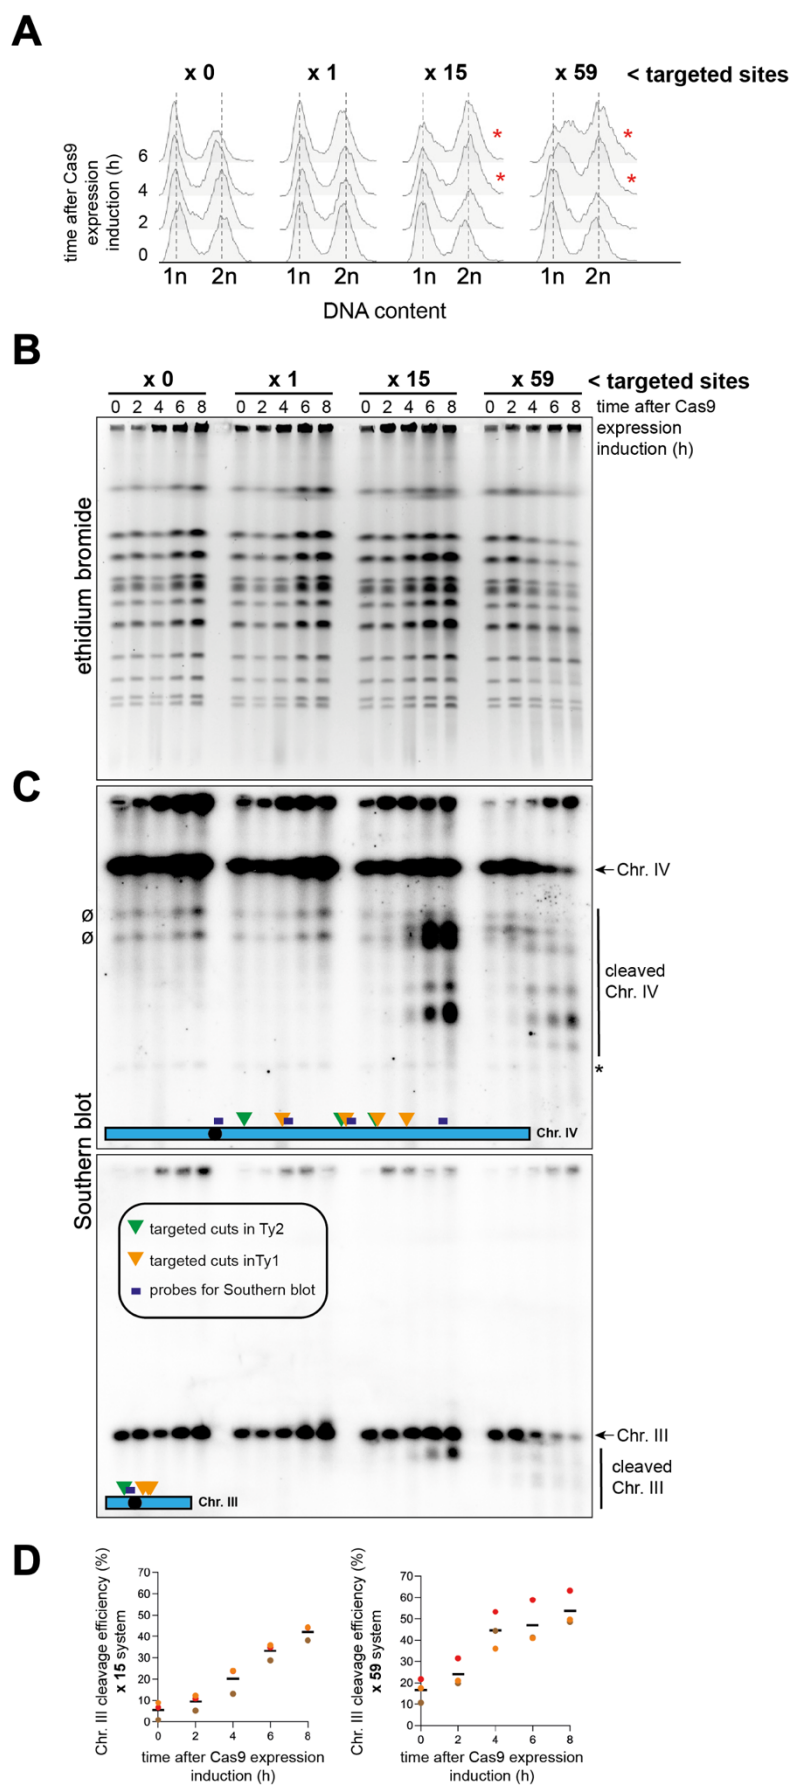

274 **B.** *S. cerevisiae* wild-type, *lig4Δ* and *rad52Δ* cells were transformed with the vector bearing an
275 inducible Cas9 and with the vector expressing the relevant gRNA to achieve the desired
276 number of breaks. 10-fold serial dilutions of cells exponentially growing in glucose to prevent
277 Cas9 expression were spotted onto selective minimal medium plates supplemented with the
278 following carbon source: either glucose, to monitor the loading control; or increasing amounts
279 of galactose complemented with sucrose to modulate Cas9 expression. Growth plates were
280 incubated 3 days at 30°C and imaged. The experiment was repeated three times.

281

282 Our next objective was to provide a physical and more quantitative characterization of
283 the system. To this end, we grew wild-type cells overnight until they reached exponential
284 phase in medium selective for the Cas9 and gRNAs plasmids and with glycerol as the carbon
285 source, allowing a robust and controlled induction of Cas9 upon galactose addition. Cells were
286 recovered and processed for flow cytometry and Pulsed Field Gel Electrophoresis (PFGE)
287 analyses before induction of Cas9 expression and every 2 hours thereafter during 8 hours. The
288 analysis of DNA contents by flow cytometry showed a mild but progressive accumulation of
289 cells in G₂/M in the x 15 and x 59 systems (Fig 2A, red asterisks). While these results are
290 consistent with the activation of the DNA damage checkpoint, which halts the cell cycle
291 progression in G₂/M in response to DSBs (29), the modest cell cycle halt suggests either low
292 cleavage efficiency and / or fast repair (see below).

293 Separation of chromosomes by PFGE allows for the detection of broken DNA
294 molecules. No broken DNA molecules could be detected at any of the time-points of the x 0
295 kinetics. However, modest smeared signals were visible in the ethidium bromide-stained gels
296 at late times of the x 15 and x 59 gRNA kinetics (Fig 2B). Yet, the strongest evidence of
297 molecules being broken emanated from the latest time-points in the x 59 system, when signals
298 corresponding to full chromosomes started to fade away. To provide formal proof of the
299 breaks, the DNA was transferred and the membranes subjected to Southern blotting using
300 either a probe directed to the chromosome III or a mix of four probes directed against several
301 locations distributed between the potential break sites on the chromosome IV. As a result, a
302 time- and dose-dependent pattern of broken chromosome fragments could be observed (Fig

303 [2C](#)), confirming the proficiency of the system. Analysis of the fragments released from
304 chromosome III in the x 15 and x 59 systems allowed us to quantify Cas9's cleavage efficiency.
305 It revealed a progressive increase over time reaching mean values between 43 and 54% 8 h
306 after Cas9 induction ([Fig 2D](#)). We conclude that the CRISPR-Cas9-based system produces
307 DSBs with a good efficiency.
308

309

310 Fig 2. Physical characterization of the DSB-inducible system

311 **A.** *S. cerevisiae* wild-type cells were transformed as in [Fig 1B](#) and a culture of cells growing
312 exponentially in selective minimal medium with glycerol as the carbon source was prepared.
313 A sample was taken at time 0 (before induction). After the addition of 2% galactose, samples
314 were taken at the indicated time points to assess cytometry profiles. n and $2n$ refer to the DNA
315 content, thus serving as an estimate of the number of cells in G_1 and G_2 phases of the cell cycle,
316 respectively. The red asterisks indicate the time-points at which an increase in the number of
317 cells in G_2/M is detected when compared to the no-cut condition.

318 **B.** *S. cerevisiae* wild-type cells were transformed as in [Fig 1B](#), and a culture of cells growing
319 exponentially in selective minimal medium with glycerol as the carbon source was prepared.
320 A sample was taken at time 0 (before induction). After the addition of 2% galactose, samples
321 were taken at the indicated time points. Cells were processed for Pulsed Field Gel
322 Electrophoresis (PFGE). This technique allows for the separation of chromosomes. The PFGE
323 gel was dyed with ethidium bromide.

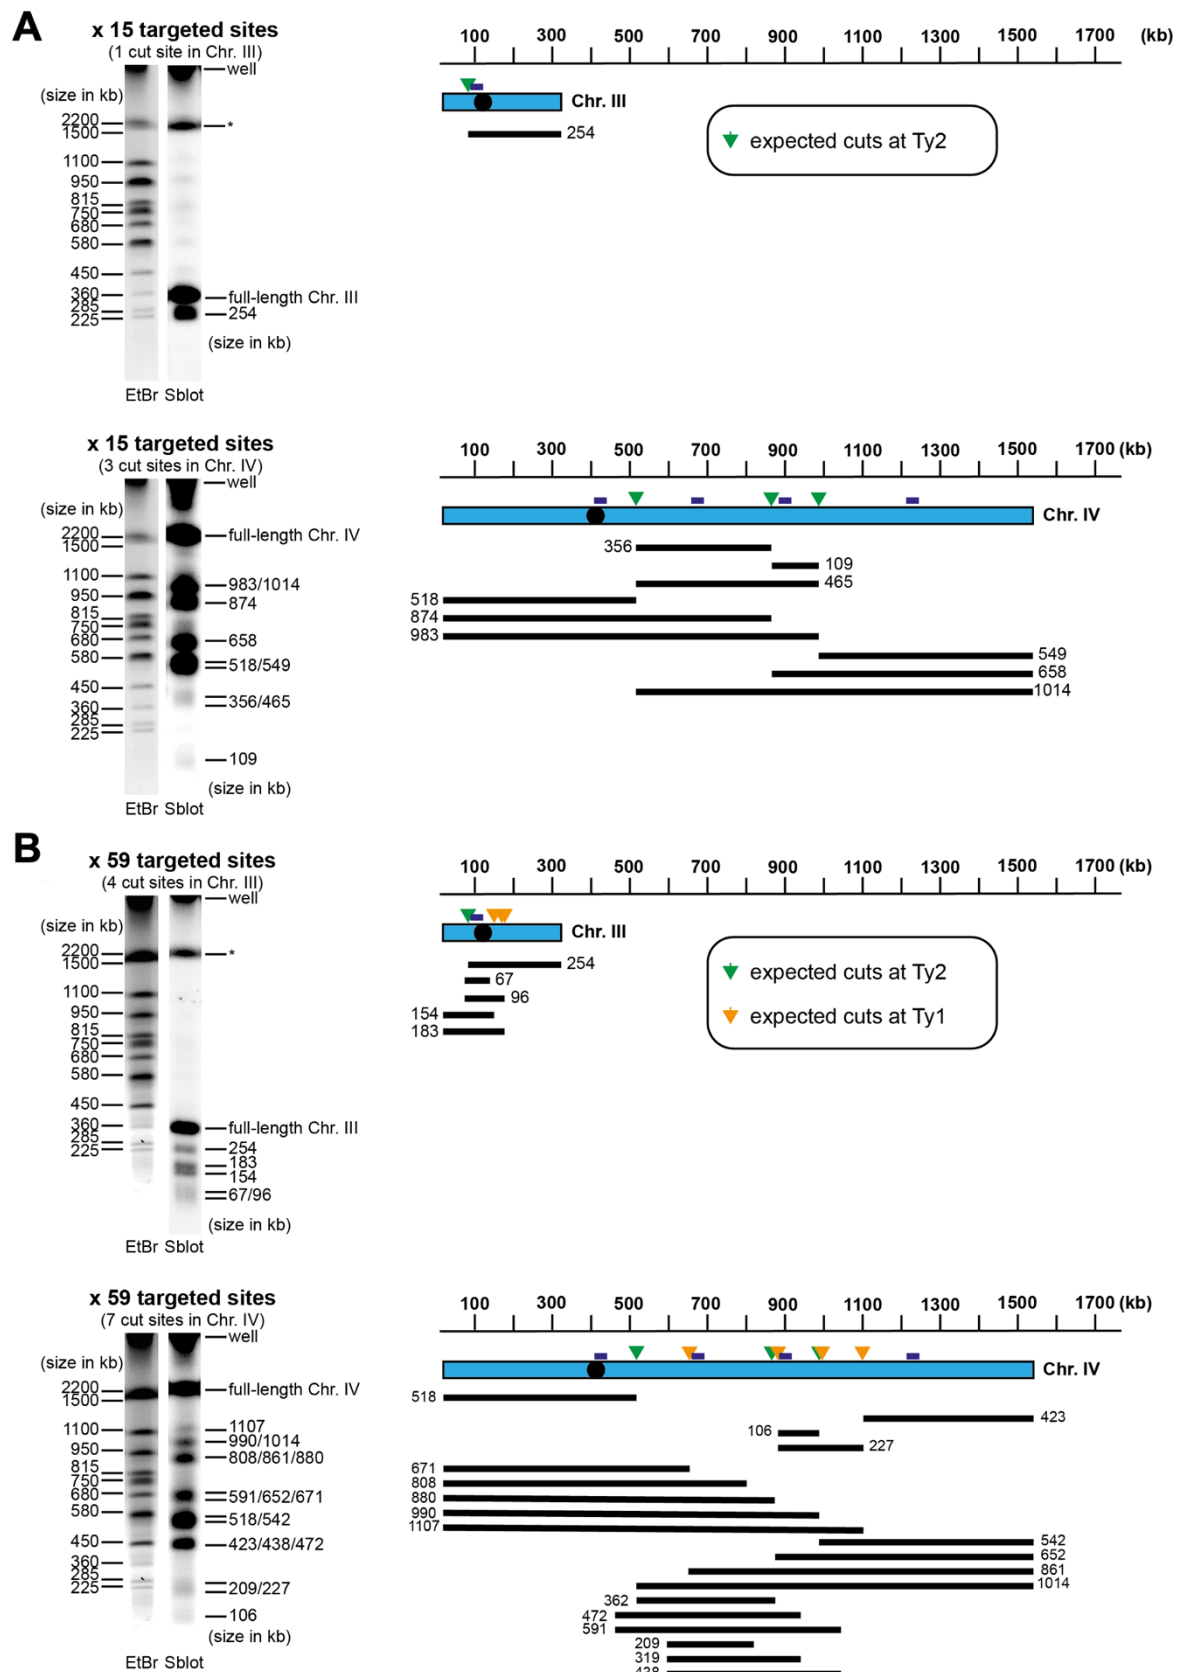

324 **C.** Southern blot against the DNA from the PFGE shown in **(B)** using one probe targeting
325 chromosome III and four probes targeting chromosome IV. Bands corresponding to full-length
326 chromosomes III and IV are indicated. The asterisk indicates a remaining band corresponding
327 to chromosome III after incomplete stripping of the radioactive probe from the membrane,
328 while the symbol \emptyset points at unspecific signals present at all time-points.

329 **D.** Quantification of chromosome III cleavage efficiency after Cas9 induction in the x 15 and
330 the x 59 systems. The mean values (dark bar) and the individual values (circles) from three
331 independent experiments (indicated by different colours) are plotted for each time point of the
332 time course experiment shown in **(C)**.

333

334 We subsequently conducted a deep restriction analysis of chromosome cleavage in
335 order to verify whether Cas9 could cleave all the potential cut sites in Ty elements, as indicated
336 in [Fig 1A](#). We used the known sizes of the full-length chromosome bands from the ethidium
337 bromide-stained gel to infer the sizes of the chromosome fragments that appeared 8h after
338 Cas9 induction on the Southern blot membrane ([S1 Fig](#)). We could not perform this analysis
339 with the x 1-cut system since cleavage of chromosome III should happen very close to the
340 telomere and generate a fragment which size is not distinguishable from the full-length
341 chromosome after separation by PFGE. In the x 15 system, the chromosome III is expected to

342 be cleaved once, generating a ~254 kb fragment, which we could detect by using a probe
343 targeting this fragment (Fig 3A). In this same system, 3 cuts are expected in chromosome IV.
344 These cuts can generate various fragments corresponding to the complete or partial cleavage
345 of the chromosome IV (Fig 3A). The Southern blot analysis revealed the presence of bands
346 corresponding to all the expected sizes of the chromosome fragments (Fig 3A). We performed
347 the same analysis for the x 59 system, in which four cuts in chromosome III and seven cuts in
348 chromosome IV are expected. Again, we could identify chromosome fragment bands
349 corresponding to all expected restriction patterns thanks to various probes targeting the
350 regions between the cleavage sites (Fig 3B). This analysis thus indicates that Cas9 could
351 efficiently cleave chromosomes III and IV in all targeted regions, inferring that the CRISPR-
352 Cas9-based system is able to efficiently induce DSBs in every chromosome in a site-specific
353 and dose-dependent manner.
354

355

356 **Fig 3. Restriction analyses of chromosome cleavage**

357 **A, B.** Restriction analysis of chromosomes III and IV cleaved by Cas9 in the x 15 (**A**) and x 59

358 (**B**) systems. Full-length chromosome sizes (from ethidium bromide-stained gel; EtBr) and

359 inferred fragment sizes (from Southern Blot; Sblot) are indicated in kb. The asterisk indicates
360 a remaining band corresponding to chromosome IV after incomplete stripping of the
361 radioactive probe from the membrane. The approximate Ty positions targeted by the designed
362 gRNAs and the probes used for Southern blot analysis are indicated on chromosome schemes.
363 Restriction patterns are depicted, with expected chromosome fragments sizes, out of both full
364 and partial digestions, indicated in kb. Shown images come from the experiment shown in [S1](#)
365 [Fig.](#)

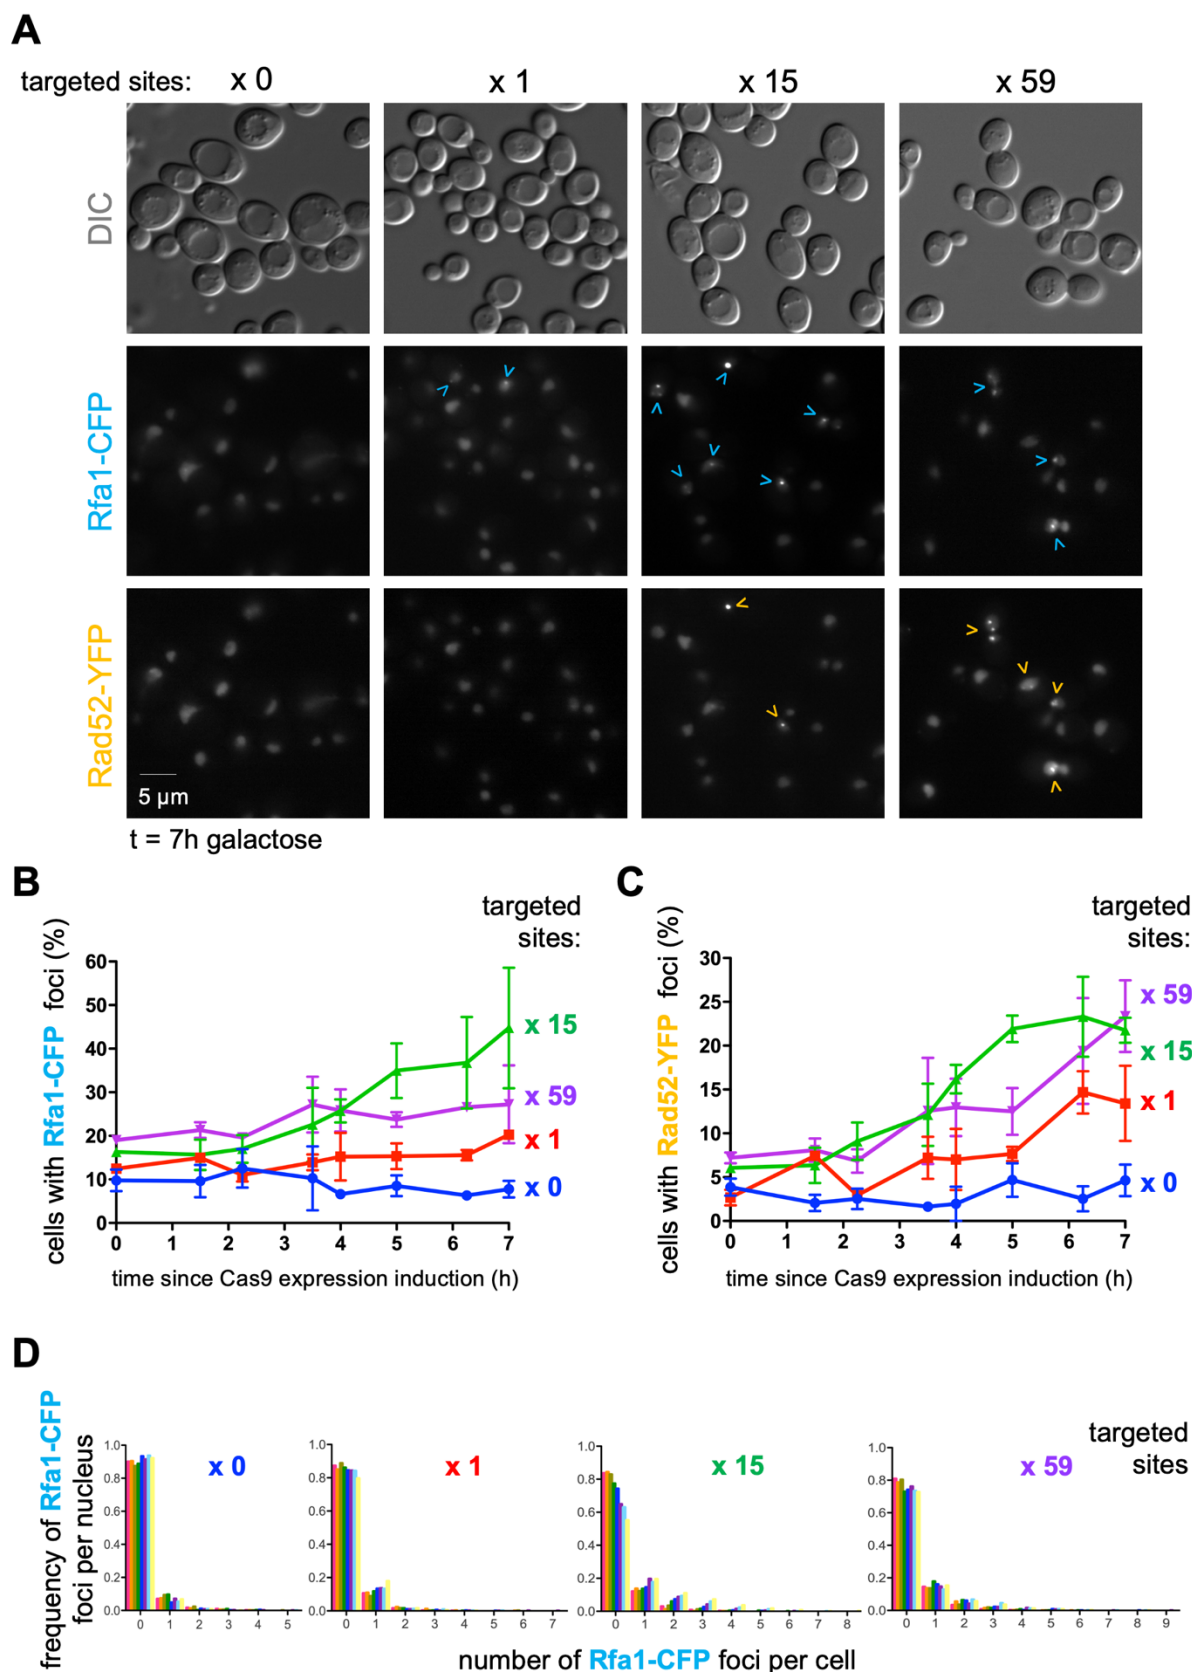

366

367 **The kinetics of DNA repair foci formation reflects the dose-dependent induction of DSBs** 368 **by Cas9**

369 DSB repair primarily occurs by Homologous Recombination (HR) or Non-
370 Homologous End Joining (NHEJ). In cycling *S. cerevisiae* cells, repair by HR is generally
371 favored over NHEJ by the availability of the sister-chromatid during DNA replication ([2,30](#)).
372 We wondered if the repair of DSBs in repeated Ty elements would follow this general rule.
373 We repeated the viability assay ([Fig. 1B](#)) by spotting cells either lacking Lig4, the DNA ligase
374 involved in NHEJ, or Rad52, the master regulator of HR. The loss of viability of *lig4Δ* cells
375 upon Cas9 expression was similar to wild-type cells, indicating that NHEJ is not involved in
376 cell survival to Cas9-induced DSBs. However, the lack of Rad52 in *rad52Δ* cells negatively
377 impacted the viability by about one order of magnitude compared to wild-type cells, even for
378 the 1 x system ([Fig. 1B](#)). These results indicate that HR is involved in the repair of Cas9-induced
379 DSBs in Ty elements, as expected for DSB repair outside repeated DNA sequences in cycling
380 cells.

381 In order to monitor the dynamics of repair by HR, we exported the system (Cas9 and
382 gRNAs plasmids) to an otherwise wild-type strain in which early HR actors are fluorescently
383 tagged. The Rfa1 component of the heterotrimeric RPA complex, binding exposed single
384 stranded DNA (ssDNA) at broken ends, was tagged with CFP at its C-terminus; Rad52, which
385 replaces RPA by Rad51 on ssDNA to initiate homology search, was tagged with YFP at its C-
386 terminus. As above, cells were grown overnight to mid-log phase in selective medium con-
387 taining glycerol, then galactose was added to induce Cas9 expression. Cells were visualized
388 through a fluorescence microscope and images acquired before Cas9 expression induction and
389 every hour during 7 hours thereafter. We counted the percentage of nuclei in the population

390 displaying Rfa1-CFP and Rad52-YFP foci (at least one focus) along time. The percentage of
391 nuclei basally displaying Rfa1 foci was of 10 % and fluctuated around this value for each time
392 point when Cas9 was expressed in the absence of any gRNA (Fig 4A,B, x 0). Likewise, the lack
393 of DSB induction maintained a basal level of 4 % of the nuclei displaying Rad52-YFP foci (Fig
394 4A,C, x 0). These data agree with previously reported basal levels of foci for these factors (31),
395 and further indicates that, in the absence of any gRNA, Cas9 alone does not trigger any accu-
396 mulation of DNA damage. Importantly, the expression of gRNAs driving an increasing num-
397 ber of DSBs permitted us to draw the following observations: First, the initial percentage of
398 foci-displaying cells increased with time when the x 1-, x 15- and x 59 targeted sites gRNAs
399 were present in the cells, confirming the proficiency of the system (Fig 4B,C). Second, the pro-
400 portion of nuclei displaying Rfa1 foci was consistently double than that of nuclei bearing
401 Rad52 foci, probably reflecting the increased residence time of resected filaments in compari-
402 son with the process of homology search (Fig 4B,C). Third, and as a general rule, gRNAs tar-
403 geting a higher number of sites led to an increased number of cells bearing Rfa1 and Rad52
404 foci (*i.e.* $x15 > x1 > x0$), with the higher mean values being of 45% of cells bearing Rfa1 foci and
405 27% showing Rad52 foci (Fig 4B,C). Surprisingly, from 5 hours onwards, creating 15 DSBs in
406 the genome triggered more Rfa1 foci accumulation than inducing 59 DSBs, and a much faster
407 (although equal in value) accumulation of Rad52 foci (Fig 4B,C). This may highlight the phe-
408 nomenon of interference at clustered DSBs. Indeed, DSBs concentrated at near-by locations, as
409 those induced in the x 59 system, are less efficiently repaired than isolated lesions (32). Finally,
410 we observed that increasing numbers of DSBs also increased the number of individual Rfa1
411 foci per nucleus (Fig 4D). This was not the case for Rad52 foci, which were previously de-
412 scribed to be repair centers capable of recruiting more than one DSB (33). Overall, these results
413 suggest that DSBs induced by Cas9 engage into HR in a dose-dependent manner.
414

415

416 Fig 4. Characterization of DNA repair foci formation in response to increasing Cas9-induced

417 DSBs

418 **A.** Wild-type cells transformed with the vector expressing an inducible Cas9 and the plasmid
419 expressing the gRNA driving the desired number of cuts grown to exponential phase in
420 selective minimal medium using glycerol as the carbon source. A sample was taken at time 0
421 before galactose was added to induce Cas9 expression, samples retrieved at the indicated
422 times, and cells inspected by microscopy. Representative images of Differential Interference
423 Contrast (DIC), Rfa1-CFP and Rad52-YFP channels are shown. Arrowheads point at foci
424 formed by the fluorescently tagged proteins.

425 **B.** Percentage of cells in the population displaying at least one focus of Rfa1-CFP in samples
426 from **(A)** at different times since galactose addition. Each point is the mean of three
427 independent experiments, and the error bars represent the SEM out of those three experiments.

428 **C.** Graph showing the percentage of cells in the population displaying at least one focus of
429 Rad52-YFP in samples from **(A)** at different times after galactose addition. Details as in **(B)**.

430 **D.** Graphs showing the frequency of Rfa1-CFP foci in a given nucleus at a given time as
431 calculated from the experiments presented in **(C)**. The probability distribution is calculated
432 upon merging the three experiments presented in **(C)**. All three independent experiments had
433 a similar profile. At least 200 cells were counted per time-point, condition and experiment.

434

435 **Time-lapse fluorescence microscopy reveals multiple rounds of Rad52 foci formation in** 436 **G₂/M cells**

437 Because some DSBs may be repaired while others are formed, we posited that the
438 frequency of cleavage and the percentage of repair events could be higher than we calculated.
439 To test this hypothesis, we used time-lapse live fluorescence microscopy to look at continuous
440 Rad52 foci formation. Cells bearing the x 59 system were induced for Cas9 expression in liquid
441 medium containing galactose for 5h40, then mounted on an imaging device under an agarose
442 pad prepared in selective minimal medium with galactose to keep Cas9 expression on. 300
443 and 540 individual cells were monitored in two independent experiments every 20 min for 140
444 min (therefore reaching 8h post-galactose addition). Illustrative examples of individual cells
445 are shown evolve in time in [Fig 5](#). We observed two types of Rad52-YFP populations
446 contributing differently to Rad52 foci counts. One population of cells displayed only one event
447 of Rad52 foci formation. These events were long-lasting with a duration of at least 60 min and
448 even beyond 140 min ([Fig 5](#)). These events readily contribute to the observed percentage of

449 positive cells when performing classical experiments in which multiple pictures of a culture
450 are taken at a given time (as in [Fig 4C](#)). Yet, a second population exists in which two events of
451 Rad52 foci formation were observed during the time-lapse experiment. These events were
452 short-lasting, for their duration ranged from less than 20 min to maximum 60 min. In these
453 cells, a lapse of time frequently exists during which no foci can be seen, then new foci appear,
454 indicative of a new round of cut(s) and repair ([Fig 5](#)). When displaying Rad52 foci-containing
455 cells according to their cell cycle stage, as estimated from their shape and bud growth, the
456 population bearing long-lasting Rad52 foci were likely early-S phase cells, showing no or small
457 buds. On the contrary, the cells displaying short-lived Rad52 foci corresponded to G₂/M cells.
458 These results suggest that DSBs induced early during the cell cycle could not be quickly
459 repaired by HR and that the completion of DNA replication may be required for HR to proceed
460 further. Once in G₂/M, DSBs could undergo fast repair due to the availability of sister
461 chromatids, allowing new rounds of cleavage by Cas9 and Rad52 foci formation. Importantly,
462 since the foci displayed by the same cell could stem from different cutting events, we reckon
463 there is an underestimation of the real cleavage frequency when calculated from snapshots
464 taken every hour, as those shown in [Fig 4C](#). Finally, we analyzed the karyotypes of 46
465 independent survivor colonies coming from wild-type cells that had endured 8 hours of Cas9
466 induction with the x 59 system and did not observe any gross chromosomal rearrangements
467 ([S2 Fig](#)). We conclude that the repair of the DSBs induced by Cas9 is faithful, despite the fact
468 that DSBs occurs in repeated Ty elements dispersed throughout the genome. These results are
469 consistent with the relatively low frequency of genomic alterations observed after targeting
470 Cas9 to Ty1 elements in haploid yeasts ([34](#)).

> First Rad52-YFP event
 > Second Rad52-YFP event

471
 472 **Fig 5. Time-lapse microscopy analysis of Rad52 foci formation after Cas9-induced DSBs**
 473 *S. cerevisiae* wild-type cells in which Rad52 was YFP-tagged were transformed with the vector
 474 bearing an inducible Cas9 and with the vector expressing the x 59 gRNA, kept in selective
 475 medium plus glycerol as the source of carbon, then changed to galactose to induce Cas9
 476 expression. After 5h40, cells were mounted on a microscope device and immobilized using an
 477 agarose pad embedded in the same medium. Images of multiple positions were acquired every

478 20 min for 140 min. Individual cells followed this way are shown evolving in time. The first
479 Rad52-YFP foci to be detected are indicated by pink arrowheads, while secondary events are
480 indicated by yellow ones. The first and last time-point brightfield images are also shown. On
481 the vertical axis, the cells have been intentionally ordered by their morphology, with those in
482 early S-phase at the top and those in late S-phase or G₂/M at the bottom.

483

484 **Exploiting the dose-dependent DSB system to study DSB signaling by Tel1**

485 Fluorophore-tagging of multiple proteins has allowed the establishment of the
486 temporal kinetics from DSB sensing till late steps of its repair (31,35). Yet, compared to the
487 number of works assessing the formation, persistence, dissolution or frequency of foci of DNA
488 repair proteins such as Rad52, the study of very early acting factors such as DSB sensors has
489 been under-assessed. DSBs sensing is orchestrated by the early arrival of the MRX (MRN in
490 humans) complex and its immediate binding by the apical kinase of the DNA Damage
491 Response Tel1 (ATM in humans). Mre11 and Tel1 foci can form at any stage of the cell cycle,
492 persist if resection is not implemented, as in *SAE2* deletion mutants (31,36) and, in agreement
493 with their early role, do not depend on the ssDNA-coating complex RPA (31). Still, in contrast
494 to Mre11 foci, which have attracted more interest (16,36), Tel1 study by microscopy has been
495 assessed in only one study (31). This little interest may relate to the fact that the absence of
496 Tel1 hardly sensitizes cells to genotoxic agents, with the exception of Topoisomerase 1
497 trapping by camptothecin (CPT) (37), presumably because its deficiency is often compensated
498 by the other apical kinase Mec1 (38,39). Yet, accurate sensing, proper processing and timely
499 checkpoint activation upon DSBs depend on Tel1, and therefore the alternative orchestration
500 by Mec1 may not reflect the physiological pathway that the lesions should have triggered.
501 Moreover, it has been observed that Tel1 signaling becomes critical in the absence of Mec1 in
502 response to an increasing number of simultaneous DSBs (16).

503 We have tagged Tel1 with yeast-enhanced-GFP (yEGFP) at its N-terminus, a location
504 reported to preserve its function (31,40), while conserving its natural promoter. In agreement,
505 strains bearing this modification were as proficient as their isogenic wild-type in tolerating
506 CPT, in contrast to *tel1Δ* cells (Fig 6A). Tel1 function in DSB signaling is key in preserving
507 telomere length, which can be measured by subjecting genomic DNA samples to terminal
508 transferase treatment followed by PCR-driven telomere amplification (20,21). We monitored

509 both X and Y' telomere length and observed similar sizes in wild-type and in derived yEGFP-
510 Tel1 cells, in marked contrast with the shorter products observed in *tel1Δ* cells (Fig 6B). Thus,
511 we concluded that the fluorescent yEGFP tag at the N-terminus of Tel1 does not alter its biol-
512 ogy and can be used to assess functional questions.

513 Inducing DSBs with the CRISPR-Cas9 dose-dependent system led to Tel1 forming
514 nuclear foci (Fig 6C) whose round morphology and size did not differ from those reported
515 after DSBs induction with ionizing radiations (31), or other DNA damage-related foci, for
516 example of Rad52/Rfa1 (Fig 4A). The basal level of cells presenting Tel1 foci in the population
517 was low, at around 4% (Fig 6D), suggesting that the basal localization of Tel1 at telomeres does
518 not lead to foci formation. The progressive accumulation of DSBs, dependent on time and on
519 gRNA type, matched a parallel increase in the percentage of cells in the population displaying
520 Tel1 foci (Fig 6D, $x_0 < x_1 < x_{15} < x_{59}$). The maximum obtained value of 20 % (x_{59} targeted
521 sites at 6 h) was in striking concordance with the percentage of cells displaying Rad52 foci in
522 the same condition. However, the increase of Tel1 foci happened earlier than the one of Rad52
523 foci (compare with Fig 4C), hinting at Tel1 role in damage sensing. Finally, positive cells rarely
524 displayed more than one Tel1 focus, even after 6 hours of induction of the x_{59} system (Fig 6C,
525 one rare example of three foci per nucleus has been included; quantification in Fig 6E). We
526 conclude that N-terminal tagging of Tel1 with yEGFP represents a performant tool allowing
527 to monitor early events of DSB repair in agreement with its described role in the first steps of
528 DSB signaling.

529

530 Fig 6. Characterization by microscopy of Tel1 foci formation in response to DSBs

531 **A.** 10-fold serial dilutions of *S. cerevisiae* cells of the indicated genotypes spotted onto YPED
532 rich medium plates supplemented either with DMSO (untreated) or with 40 μ M CPT,
533 incubated 2 days at 30°C and imaged.

534 **B.** Telomeres (X and Y') length was measured by PCR-mediated amplification (see M&M) from
535 genomic DNA extracted from the indicated strains. *tel1* Δ cells were included as a control for
536 their telomere shortening phenotype. yEGFP-Tel1 cells, whether additionally bearing
537 mCherry-Pus1 or not, display wild-type-length telomeres.

538 **C.** Representative images of yEGFP-Tel1 cells subjected to Cas9-driven DSBs with the x 59
539 gRNA, as described in (D). The contour of the nucleus has been superimposed using the
540 signals provided by DNA staining with DAPI. yEGFP-Tel1 foci are indicated by yellow
541 arrowheads.

542 **D.** yEGFP-Tel1 cells transformed with the vector expressing an inducible Cas9 and the plasmid
543 expressing the gRNA driving the desired number of DSBs grown to the exponential phase in
544 selective minimal medium using glycerol as the carbon source. Cell samples collected at time
545 0 before galactose was added to induce Cas9 expression and at the indicated times after
546 induction were inspected by microscopy in search of Tel1 foci. The graph shows the percentage
547 of cells displaying, at least, one Tel1 focus. Each point is the mean of three independent
548 experiments, and the error bars represent the SEM out of those three experiments. At least 150
549 cells were considered per time, condition and experiment.

550 **E.** The mean number of Tel1 foci per cell (as established by counting the total number of foci
551 divided by the total number of cells) was calculated out of at least 150 cells for each time point
552 and condition. This experiment was done three times, and the plotted value is the mean out of
553 those three experiments. The error bars correspond to the SEM associated to them

554

555 **Tel1 can form multiple foci at the nuclear envelope upon induction of DSBs**

556 We noted that we always observed Tel1 foci in the periphery of the nucleus (Fig 6C).
557 To know whether this characteristic was specific to DSBs induced by Cas9 at Ty elements, we
558 compared Tel1 foci formation upon Cas9-induced DSBs to chemical induction of DSBs by the
559 clastogen zeocin (41). We grew cells in the same conditions as for the Cas9-DSB-inducing
560 system experiments. We acquired images of these untreated cells and then at intervals till 100
561 min of exposure to 100 μ g/mL zeocin. We could observe that Tel1 foci formed at the same

562 frequency in the population as when DSBs were induced by Cas9, although much faster (Fig
563 7A). A maximum value of 24 % was reached at 40 min that was invariably maintained till 100
564 min. Monitoring the percentage of cells bearing Rad52-YFP foci demonstrated an only-slightly
565 delayed kinetics (Fig 7B). Unexpectedly, we observed that zeocin induced a much higher
566 number of Tel1 foci per cell than Cas9. In fact, we observed that the frequency of cells with
567 more than one (up to 8) Tel1 focus per nucleus increased as time passed by under zeocin
568 treatment (Fig 7C). This could be due to zeocin triggering many more DSBs than Cas9 per
569 genome at any given moment. Alternatively, though not exclusively, we reasoned that Ty
570 elements are often inserted near tRNA genes, and that tRNA genes have been described to be
571 clustered in the nuclear space by condensin (42). Single Tel1 foci observed with the Cas9
572 system could thus relate to DSB clustering by condensin. To test this possibility, we used the
573 thermo-sensitive condensin mutant *smc2-8*, which has been shown to disperse the clusters of
574 tRNA genes (42). Our results show that the proportion of cells containing Tel1 foci increased
575 in the *smc2-8* mutant bearing the x 59 system upon Cas9 induction when cultured at the
576 restrictive temperature of 37°C compared to the permissive temperature of 24°C (Fig 7D).
577 Specific comparison at Cas9-expressing time-points of the percentage of cells displaying 2 Tel1
578 foci or more demonstrated a significant increase at such restrictive temperature (Fig 7E).
579 Together, these data indicate that the difference in Tel1 foci number following treatment with
580 zeocin compared to CRISPR-guided DSBs is due, at least in part, to the particular spatial
581 organization of Ty elements in the nucleus.
582

583

584 **Figure 7. Tel1 can appear in the form of more than one focus per nucleus**

585 **A.** An otherwise wild-type strain tagged with yEGFP at the N-terminus of Tel1 and with
 586 mCherry at the N-terminus of Pus1 (to visualize the nucleoplasm) was transformed with an

587 empty vector allowing its growth in minimal selective medium. Cells were exposed to 100
588 $\mu\text{g}/\text{mL}$ zeocin and samples retrieved for analysis by fluorescence microscopy at the indicated
589 times. The graph shows the percentage of cells in the population displaying at least one focus
590 of yEGFP-Tel1 at different times. Each point is the mean of three independent experiments,
591 and the error bars represent the SEM out of those three experiments. At least 150 cells were
592 considered per time, condition and experiment.

593 **B.** Details as in (B) but to score the formation of Rad52-YFP foci.

594 **C.** The foci count data obtained from the cells harbouring at least one focus presented in the
595 three experiments described in (B) were exploited to build a frequency distribution. In brief,
596 the number of Tel1 foci per nucleus was counted and a frequency histogram was drawn. Since
597 the three independent experiments provided similar profiles, all the values were merged to
598 build a more robust distribution. The graph illustrates the frequency at which a nucleus
599 displays the indicated number of Tel1 foci for cells not being exposed to zeocin, or exposed for
600 120 or for 210 minutes (pink, orange and green bars, respectively).

601 **D.** *smc2-8* yEGFP-Tel1 cells bearing the x59 gRNA and inducible Cas9 vectors were grown to
602 the exponential phase in selective medium plus glycerol, to prevent Cas9 expression. The
603 culture was then split, and half set at 24°C, half at 37°C, for 2h. Then, each culture was again
604 split into two, of which one half remained unprocessed (no cut), the other half to which 2%
605 galactose final was added to induce Cas9 expression and genome cleavage. Images to monitor
606 yEGFP-Tel1 foci formation were acquired at the indicated time-points, and the percentage of
607 such foci calculated for three independent experiments (mean and SEM are shown).

608 **E.** The percentage of cells from (E) displaying two or more yEGFP-Tel1 foci is presented as a
609 bar plot for each given condition. The total percentage of the addition of these categories was
610 compared at each meaningful time-point between the permissive (24°C) and the restrictive
611 (37°C) temperatures using a paired *t*-test analysis, as indicated.

612
613 Interestingly, the higher number of Tel1 foci induced by zeocin reinforced the earlier
614 observation that they always form near the nuclear periphery (Fig 8A). To investigate further
615 the tight proximity to the nuclear envelope, we simultaneously monitored Tel1 foci and the
616 nucleoporin Nup57, marked in its C-terminus with a tDIMER-RFP moiety. Tel1 foci were

617 recurrently found close to Nup57-tDIMER signals (Fig 8B), with a maximum distance between
618 the maximal intensities of both adjacent signals close to the resolution limit, 0.2 μm (Fig 8C).

619 Altogether, we report here that yEGFP-Tel1 represents a tool to monitor the very early
620 steps of DSB signaling, irrespective of whether they are enzymatically or chemically induced.
621 Furthermore, the subnuclear distribution of Tel1 foci near the nuclear envelope, which is
622 different from the distribution of Rad52-YFP or Rfa1-CFP foci, suggests the existence of yet
623 unknown aspects of initial DSB processing in the nuclear space.

624

625

626 **Fig 8. Characterization of the proximity of Tel1 foci to the nuclear envelope**

627 **A.** An otherwise wild-type strain was tagged with yEGFP at the N-terminus of Tel1 and with
628 mCherry at the N-terminus of the nucleosoluble protein Pus1 in order to define the

629 nucleoplasm. The subcellular localization of Tel1 was assessed by fluorescence microscopy in
630 response to 100 $\mu\text{g}/\text{mL}$ zeocin. Images of both channels as well as their merging are shown.

631 **B.** An otherwise wild-type strain was tagged with yEGFP at the N-terminus of Tel1, and with
632 tDIMER-RFP at the C-terminus of the nucleoporin Nup57 with the goal of defining the nuclear
633 periphery. The relative position of Tel1 foci with respect to nucleoporin signals was assessed
634 by fluorescence microscopy after exposing the cells for 2 h to 100 $\mu\text{g}/\text{mL}$ zeocin. Images of the
635 Differential Interference Contrast (DIC), RFP and GFP channels, as well as their merge are
636 shown. The asterisk marks the cell used to create the graph shown in **(C)**.

637 **C.** A straight line (indicated in green color) was drawn from left to right onto the chosen image
638 and the pixel intensity along it plotted for both the Nup57-tDIMER and yEGFP-Tel1 images.
639 The vertical arrows indicate the points of maximal intensity, thus highlighting the proximity
640 of Tel1 signals to the nuclear periphery.

641

642 Discussion

643 In this work, we have expanded the toolbox in the field of DSB sensing and repair.
644 First, we have taken advantage from the repetitiveness of the transposon elements in the
645 genome of *S. cerevisiae* to design gRNAs capable of driving Cas9 action at specific sites in the
646 genome. Upon Cas9 expression induction, we can compare otherwise identical genomes being
647 broken at an increasing number of locations by the same enzyme. We have validated
648 genetically, physically and functionally the performance of this system. Second, we used this
649 tool to characterize the behavior of the apical kinase of the DNA damage response Tel1 in
650 space and time. We found that Tel1 molecules congregate in the shape of foci clustered by
651 condensin in response to Cas9-induced DSBs in transposon elements. We also show that
652 zeocin-induced DSBs can lead to the formation of up to 8 Tel1 foci per cell, which distribute in
653 tight contact with the nuclear periphery.

654 Previous works have used the repetitiveness of the Ty elements in *S. cerevisiae* genome
655 to insert 2, 7 or 11 restriction sites that can be cut upon controlled induction of the HO
656 endonuclease (15,16). While the design behind our system is reminiscent of this one, we
657 managed to devise a wider range of induced DSBs, thus permitting further studies on the dose-
658 dependency. Indeed, the Ty-HO system was used to assess, by Southern blot, the role of Mre11
659 on resection as well as, by monitoring the phosphorylation of the downstream effector Rad53,

660 the role of Tel1 in DNA damage signaling (15,16). Given the sensitivity of Southern and
661 western blotting, a maximum of 7 cuts was enough to assess functional differences. Yet, our
662 system provides an enlarged palette of induced DSBs suitable for less sensitive studies or to
663 extend the study of DSB repair genome-wide. 60% of the human genome being composed of
664 transposable elements, targeting these repetitive elements with the CRISPR-Cas9 technology,
665 as we performed in the yeast genome, would provide a useful tool to produce enzymatic dose-
666 dependent DSBs in human cells.

667 More than 13 proteins working in the cascade of DSB sensing and repair have been
668 fluorescently labelled and their *in vivo* foci formation ability scored by microscopy (31,35,43).
669 With the exception of post-Spo11 cutting during meiosis, with up to 15 Rad52 foci measured
670 per cell (44), these proteins mostly gather in a single focus irrespective of the number of DSBs.
671 For example, even at doses as high as 160 krad, which induces up to 80 DSBs per cell, haploid
672 *S. cerevisiae* cells as the ones used in this study eventually form a maximum of 2 Rad52 foci
673 (44). Of all this set, the only protein openly reported to simultaneously form multiple nuclear
674 foci is Rfa1 (45). The difference in whether the factor gathers under a single focus or as multiple
675 foci may come from the nature of the lesion to be repaired, the DNA-binding properties of the
676 factor under consideration, or other physical properties ruling its ability to phase-separate
677 (45,46). A striking finding of our study is the evidence that Tel1 can form multiple (up to 8)
678 foci per cell upon zeocin addition. Given that Tel1 exerts an early and main role in damage
679 sensing, prior to any engagement of DNA repair activities, the notion arises of whether lesion
680 recognition and lesion repair concur under different regimes of protein nucleation. For
681 example, lesion recognition could occur through a gathering process restricted locally, thus
682 giving rise to more detectable events. Later on, from the moment resection by nucleases would
683 take place, the subsequent steps would be ruled by different nucleation abilities (47).

684 Analysis of numerous nuclei imaged from distinct angles led us to propose that Tel1
685 foci form at the periphery of the nucleus. A deeper analysis of Tel1 foci proximity with the
686 nuclear periphery by visualizing a fluorescently tagged nucleoporin further supported this
687 notion. The fact that Tel1 foci form in close contact to the nuclear periphery raises the
688 possibility that a nucleation factor presumably exists close to, or even at, the nuclear
689 membrane that serves to scaffold them. It also suggests that the nuclear periphery could be
690 implicated in DSB sensing. Tel1 and the other DNA damage response apical kinase, Mec1, are

691 Phosphatidyl Inositol 3-kinase-like kinases. Although these kinases are thought not to bear the
692 ability to phosphorylate phosphatidylinositol (PI) moieties any longer (48), they have kept
693 their ability to interact with such molecules. Indeed, the Mec1 human homolog, ATR, was
694 reported to be assisted by phosphoinositides in order to correctly nucleate in the shape of foci
695 upon DNA damage (45). Furthermore, ATR demonstrates ability to sense lipids at membranes
696 (49), and to act at the nuclear membrane to phosphorylate its targets in response to mechanical
697 cues (50). Moreover, Tel1 has been recently reported to bind various lipid moieties inserted
698 within membranes (51), making it very tempting to suggest that Tel1 is being guided at lipid
699 hotspots at the inner nuclear membrane either to exert its DNA breaks sensing activity, or to
700 regulate downstream steps of DSB repair. In a further attempt to venture into this direction,
701 we note a striking similarity of the Tel1 foci arrangement and the discrete spots described
702 along the nuclear-vacuole junction marked by the fatty acids metabolism-related enzyme
703 Mdm1 (52). It will be worth exploring in a near future whether this Tel1 nucleation also relates
704 to the metabolism of lipids.

705

706 **Acknowledgements**

707 We thank Philippe Pasero for strains, Olivier Gadal for the vector harboring *NUP57-tDIMER*, and Symeon
708 Siniossoglou for the vector permitting mCherry-Pus1 tagging. We thank Pascale Lesage and Emmanuelle Fabre for

895 **S2 Fig. Analysis of chromosome integrity after DSB repair.** Cells bearing the Cas9 and the
896 x59-cuts gRNA plasmids were first exposed to galactose as to induce Cas9 expression for 8 h,
897 then seeded onto rich medium plates containing glucose, in order to repress Cas9 expression
898 and allow survival following DSB repair. 23 colonies from two independent experiments were
899 used to prepare DNA in plugs and assess survivors' karyotype by Pulsed Field Gel
900 Electrophoresis (PFGE). **A**, ethidium bromide gels. **B**, Southern blot after these electrophoreses
901 using a probe specific for Ty1 and Ty2 elements. C: karyotype from cells taken before Cas9
902 expression induction.
