1 **Abstract**

2 Cooperative molecular switching at the solid state is exemplified by spin crossover
3 phenomenon in crystals of transition metal complexes. Time-resolved studies with temporal
4 resolutions that separate molecular level dynamics from macroscopic changes, afford clear
5 distinction between the time scales of the different degrees of freedom involved. In this work
6 we use 100 ps X-ray diffraction to follow simultaneously the molecular spin state and the
7 structure of the lattice during the photoinduced low spin to high spin transition in microcrystals
8 of $[\text{Fe}^{\text{III}}(\text{3-MeO-SalEen})_2]\text{PF}_6$. We show the existence of a delay between the crystalline
9 volume increase driven by the propagation of collective volumic strain waves, and the
10 cooperative macroscopic switching of molecular state. Such behaviour is different from the
11 expectation that phase transformation only requires atomic displacements in the unit cell, that
12 can occur simultaneously with propagation of a volumic strain. Model simulations and
13 discussions of the physical picture explain the phenomenon with thermally activated kinetics
14 governed by local energy barriers separating the molecular states.

15

1 **Introduction**

2 Dynamical processes induced by a laser pulse in materials are intrinsically multi-scale in time
3 and space. The difference of time scale is significant between the electronic processes, typically
4 occurring within femtoseconds, the coherent atomic displacements ranging from few 10's of
5 femtoseconds to picoseconds reflecting the period of optical phonons, the volume expansion,
6 and finally the slower kinetics dictated by activation energies. It is noteworthy that the
7 macroscopic crystal deformations, such as global volume change, require collective atomic
8 motions driving lattice deformations over long distances, i.e. acoustic wave propagation. The
9 time scale is thus limited by the speed of sound in the crystal. The strain waves are triggered
10 by laser-induced internal stress, generated by ultrafast lattice heating and/or instantaneous
11 electronic change [*Thomsen1986, Wright1994*]. Recovery of the mechanical equilibrium with
12 the sample environment occurs through wave propagation over the relevant length of the
13 system (crystal size, light penetration depth, ...). The associated acoustic time scale falls in the
14 picosecond range for nanometers, and in the nanosecond range for micrometers in many
15 materials of interest. Moreover, there may exist activation barriers at the local scale, which can
16 further slow down the atomic rearrangements. As opposed to conventional time-averaging
17 experiments, ultrafast time-resolved experiments are typically used to delineate the dynamics
18 of the different degrees of freedom, such as change of electronic distribution, atomic
19 reorganizations, as well as cell deformations [*Lorenc2009*]. They are key to understanding the
20 non-equilibrium dynamics on material scale, and to harnessing the mechanisms that govern the
21 properties of materials [*Bargheer2004, Baum2007, Braun2007, Morrison2014*].

22 The opportunity to photo-induce a phase transition with a laser pulse [*Nasu1997, Nasu2004*]
23 has opened up a vast field of research ranging from the melting of charge, spin and structural
24 orders in electronically correlated materials [*Zhang2014, Basov2017*] to molecular switching

1 in the solid state [*Lorenc2009, Cailleau2010, VanderVeen2013a, VanderVeen2013b*].
2 Recently, some attention has been turned to phase transitions that explore the possibility of
3 combining the ultra-fast with the ultra-small [*Sagar2016, Park2017, Ridier2019*]. We
4 previously reported the size effect on an elastically-driven cooperative dynamical response in
5 a switchable molecular crystal, a spin crossover (SCO) iron complex [*Bertoni2016a*]. Owing
6 to a positive elastic feedback from the expanding lattice on the volume-changing bistable
7 molecules, the number of switched molecules is significantly enhanced and the lifetime of their
8 photo-induced state is prolonged. The time scale of such dynamics showed to be scaling with
9 the size, namely becoming shorter in micro- and nano-crystals than in bulk single-crystals (>
10 100 μm). This suggested a central role of propagating volume expansion for the cooperative
11 transformation at the scale of a crystallite [*Bertoni2016b*].

12 At thermal equilibrium, volume change and spin state switching occur together. In contrast, the
13 out-of-equilibrium dynamics triggered by a laser pulse implies a sequence of processes. To
14 establish the respective evolution of the elastic deformation of crystalline volume and the
15 switching of molecular spin state, a simultaneous measurement of the two purportedly coupled
16 parameters is required. To address this challenge, we used time-resolved X-ray diffraction (tr-
17 XRD) on small crystallites. Our findings were corroborated with extended Monte Carlo
18 simulations.

19 **Experimental Results**

20 Phase transition and volume change in bulk single crystal

21 In this study, we focus on an SCO compound $[\text{Fe}^{\text{III}}(\text{3-MeO-SalEen})_2]\text{PF}_6$. The SCO materials
22 serve as prototypical examples of cooperative switching between two molecular electronic

1 states, Low Spin (LS) and High Spin (HS). The sample was previously identified as suitable
2 candidate for the photo-induced out-of-equilibrium studies in solid state from the angle of
3 elastic properties that lead to strong cooperativity [*Bertoni2016a*]. The crystalline structure of
4 this material was characterized in previous studies (S1, [*Tissot2011*, *Tissot2012*]). At the
5 molecular level, the switching of electronic state of Fe^{III} system, from LS (S = 1/2) to HS (S =
6 5/2) causes an increase of molecular volume, due to elongation of the Fe-Ligand bonds by
7 around 0,15 Å between LS and HS states. The molecules in this compound are arranged in a
8 closed packed network [*Tissot2011*] (figure 1a). It is known that the relative stability between
9 different macroscopic phases in such SCO crystals is ensured by the elastic intermolecular
10 interactions of various strengths, resulting in more or less cooperative transformations
11 [*Rat2017*, *Buron2012*]. In the present case, a strongly first order phase transition is observed
12 around 162 K, with a thermal hysteresis of 3 K, between the low temperature LS phase and the
13 high temperature HS phase [*Tissot2011*]. This phase transition is isostructural, as it does not
14 imply any change of symmetry (same space group P-1 and Z=2 for each phase), in a way similar
15 to the gas-liquid transition [*Chernyshov2004*]. The volume is a totally symmetric parameter
16 and plays central role for an isostructural phase transition. At thermal equilibrium, both the unit
17 cell volume and the concentration of HS molecules show correlated jumps at the phase
18 transition. This is usually observed for two totally symmetric degrees of freedom involved in
19 changes associated with a phase transition without symmetry change [*Landau1980*].

20 We performed XRD measurements on a single crystal (see Methods and S2) between 100 K
21 and 250 K, in order to quantify accurately the volume jump (volume discontinuity at the first
22 order phase transition). The measured temperature evolution of the unit cell volume is
23 displayed in figure 1b. It shows a significant volume jump of 1.6% (22 Å³ per unit cell) at
24 transition temperature T_↑ = 166 K (both consistent with the values reported in the previous
25 studies [*Tissot2011*]). Below and above this discontinuity, the thermal expansion is also

1 significant in both LS and HS phases. The same measurement allowed for accurate
2 determination of the thermal dependence of all six unit cell parameters for each triclinic phase.
3 Their extrapolated evolution can be described with a linear function of temperature T for both
4 phases (S2). The volume expansion coefficients for HS and LS phases were found to be
5 respectively $0.31 \text{ \AA}^3/\text{K}$ and $0.16 \text{ \AA}^3/\text{K}$ (figure 1b). It is a considerable thermal expansion,
6 leading to volume increase of 33 \AA^3 between 100 and 250 K, in comparison with 22 \AA^3 jump
7 originating from the transition.

8 Powder XRD study at thermal equilibrium of micro-crystals

9 In the following, we will discuss measurements performed on micro-crystals of $[\text{Fe}^{\text{III}}(\text{3-MeO-}$
10 $\text{SalEen})_2]\text{PF}_6$ embedded in a polymer thin film (see Methods). The small crystallites are plate-
11 shaped, with average dimensions $3.5 \mu\text{m} \times 0.35 \mu\text{m} \times 0.13 \mu\text{m}$ [*Tissot2012*]. The size is very
12 much dependent on the synthesis conditions. Smaller crystallites are possible to obtain, but
13 these were chosen to ensure diffraction patterns of sufficient quality for a quantitative analysis.
14 The crystallites were dispersed in polyvinylpyrrolidone (PVP) polymer matrix and the
15 composite films were spin-coated on a glass substrate, as described in [*Bertoni2012*].

16 The powder XRD measurements were performed at ESRF, ID09 beamline. XRD images were
17 recorded on a 2D detector in quasi-grazing reflection geometry at 0.2° incidence angle (see
18 Methods). This experimental geometry was used to reduce the diffuse background due to
19 scattering from the glass substrate and thereby enhance the diffraction from the thin film
20 sample. A typical diffraction image is shown in figure 1c. The diffraction rings from the
21 polycrystalline sample are clearly visible, with a patterning due to preferred orientation of the
22 micro-crystals. Indeed, since the micro-crystals are plate-shaped, they tend to align with the
23 shortest dimension (crystallographic *c* axis) perpendicular to the film surface. Several micro-
24 crystals can also stack in-depth.

1 Temperature-dependent steady states measurements were first performed to characterize the
2 XRD signatures of the phase transition in the polycrystalline sample. The measured diffraction
3 patterns are shown in figure 1d. Strong diffuse background, mainly attributed to PVP (figure
4 1c) was removed, and the important peak broadening was ascribed mainly to a large X-ray
5 footprint at the small angle incidence. The latter made the analysis challenging, yet as detailed
6 below, the full-pattern refinement was possible. This allowed for retrieval of key parameters,
7 namely the phase fraction and the volume change very accurately.

8 To this end, we applied the Pawley approach [*Pawley1981*] using the Topas software
9 [*Coelho2018*], and a similar method to the one recently applied for powder diffraction studies
10 of photo-induced structural changes [*Azzolina2019, Mariette2021*]. The refinements details
11 are provided in Methods. In short, this method constrains the Bragg peak positions according
12 to the refined unit cell parameters, but allows the Bragg peak intensities to vary freely. At room
13 temperature, the sample is fully in the HS phase. At 100 K, it was not possible to fit the pattern
14 satisfactorily considering LS phase only, therefore a biphasic state had to be considered, in
15 contrast with the bulk single crystal. We ensured the stability of the refinement further by
16 parametrization of the unit cell and peak intensities, as detailed hereafter. Firstly, to describe
17 the volume evolution of both phases as a function of temperature T , the respective six unit cell
18 parameters were forced to follow the thermal expansion determined with the single crystal
19 study and shown in the figure S2. Consequently, the temperature T was the only parameter
20 required to describe the evolution of all unit cell parameters. Secondly, the relative Bragg peak
21 intensities I_{hkl} were fixed for both phases: $I_{hkl,HS}$ and $I_{hkl,LS}$ were estimated from the refinements
22 of the patterns at room temperature ($RT = 293$ K) and 100 K. Thirdly, the complete powder
23 patterns of a biphasic state (LS, HS) were fitted with X_{HS} as the only refined parameter. In such
24 a case, X_{HS} accounts both for intensity changes and peak shifts, since the thermal expansion is
25 phase-dependent.

1 The refined X_{HS} is plotted in figure 1f as a function of temperature. A clear change of slope is
2 observed around the transition temperature in the bulk single crystal. Above this temperature,
3 the sample is almost fully in the HS phase. The observed X_{HS} evolution correlates very well
4 with the $M \cdot T$ product (M , magnetisation and T , temperature) measured by SQUID
5 (Superconducting QUantum Interference Device, see Methods) probing the evolution of the
6 fraction of molecules in the HS state. The spin state conversion in these micro-crystals shows
7 two peculiar features: a gradual conversion (compared to abrupt in bulk), and incomplete
8 conversion at low temperature. The residual X_{HS} at $T = 100$ K is equal to $(34 \pm 3) \%$ is
9 consistent with the previous reports [**Bertoni2012**]. These two features are explained in terms
10 of size/strain effects and non-homogeneous stress due to surface interaction with polymers,
11 resulting in a broad regime of phase coexistence [**Tissot2012, Laisney2020**]. The refined X_{HS}
12 also allows to calculate the average volume:

$$13 \quad V_{\text{average}}(T) = V_{\text{HS}}(T) * X_{\text{HS}}(T) + V_{\text{LS}}(T) * (1 - X_{\text{HS}}(T)) \text{ (eq. 1)}.$$

14 Concurrence of the gradual spin-state conversion and thermal expansion leads to a very smooth
15 evolution of the average volume. Yet, the average volume V_{average} changes slope around 160 K
16 (figure 1e).

17 Thus parametrized powder pattern refinement allows extracting accurate values for both
18 $X_{\text{HS}}(T)$ and $V_{\text{average}}(T)$ simultaneously, and the ensuing discussion is hinged upon it. We should
19 nonetheless mention some underlying assumptions. First hypothesis is that the LS and HS
20 phases can be treated as separate diffracting domains. Explicitly, X_{HS} quantifies the fraction of
21 ordered HS domains, rather than counting the HS molecules. The excellent correlation between
22 X_{HS} and the fraction obtained with SQUID (counting individual molecules) supports our
23 assumption. The second hypothesis is that other structural distortions on temperature within a

1 given phase have negligible contribution to the changes of I_{hkl} . This is substantiated with
2 measurements on a single crystal (figure S2) and therefore seems reasonable too.

3 Time-resolved XRD study of photoinduced dynamics

4 The tr-XRD images were recorded at 100 K with the setup described above. The crystallites
5 were excited with 1 ps pump laser at 800 nm, as in previous optical studies [*Bertoni2016a*].
6 The experimental time resolution was limited by the X-ray pulse duration to 100 ps. The details
7 about the setup and data reduction are given in Methods.

8 The time-resolved patterns covering several decades in time are shown in figure 2a. Photo-
9 induced changes can be seen on these patterns for all positive delays, and they are emphasized
10 in the difference patterns (figure 2b). The comparison with steady state diffraction patterns
11 measured at low and high temperature allows for a qualitative description. The shape of the
12 difference patterns can be explained by a weight transfer of the diffracted intensity from LS-
13 to HS-Bragg peaks. However, the peak shift to smaller q due to volume expansion would
14 produce a similar difference pattern. Therefore, separating these two possible contributions
15 requires more quantitative analysis as described below. A closer inspection of the difference
16 patterns also gives some insight into the dynamics. First changes occur within the 100 ps time
17 resolution. Thereafter, the difference patterns change shape, suggesting a sequence of processes
18 with structurally distinct signatures.

19 In order to analyze the underlying structural dynamics, the same method of full-pattern
20 refinement as in the temperature study was applied to the tr-XRD patterns. The refinement
21 results are shown in figure 2c. The parametrized model was similar to that used in the
22 temperature study. However, in addition to X_{HS} , the lattice temperature becomes an adjustable

1 parameter T_{lattice} , to account for the heating and non-equilibrium lattice expansion (see
2 Methods).

3 The time evolution of the structural parameters obtained for the highest excitation density (380
4 $\mu\text{J}/\text{mm}^2$) reveals multistep dynamics. A small increase of ΔX_{HS} estimated at 7%, accompanied
5 by a small volume increase, is observed at the early step (i.e., within 100 ps time resolution).
6 Even if the initial volume rise cannot be accurately determined due to the 100 ps time
7 resolution, the maximum of volume expansion is sufficiently pronounced and well resolved at
8 around 300 ps. At this delay, for high excitation density, the refinement yields a value of $\Delta T_{\text{lattice}}$
9 $= (90 \pm 5)$ K, corresponding to $\Delta V_{\text{average}} = 19 \text{ \AA}^3$. During this second step, ΔX_{HS} increases
10 very little, even at high excitation density. At such excitation, a more pronounced increase of
11 ΔX_{HS} occurs during a third step on the nanosecond time scale, with a plateau between $t = 20$
12 ns and $t = 300$ ns, corresponding to the maximum transformation $\Delta X_{\text{HS}} = 23\%$. Finally, ΔX_{HS}
13 and volume decrease simultaneously, and recovery of the values at thermal equilibrium occurs
14 on a sub-millisecond time scale. The most striking observation is the decoupling in time
15 between the dynamics of volume change and ΔX_{HS} : the increase of ΔX_{HS} occurs two orders of
16 magnitude later than the increase of volume. Importantly, their respective dependence on the
17 excitation density is very different. Irrespectively of excitation density, either low or high, the
18 volume expansion exhibits a maximum around 300 ps. In contrast, ΔX_{HS} exhibits a continuous
19 decrease in the ns range at low excitation density, and a pronounced increase to a clear
20 maximum at 20 ns for high excitation density (figure 2c). This observation is in agreement with
21 previous measurements of the ΔX_{HS} by transient optical absorption, and it demonstrates that
22 the nonlinear increase of ΔX_{HS} sets in with a threshold [*Bertoni2016a*]. However, no significant
23 increase of average volume is observed when ΔX_{HS} reaches its maximum.

1 The validity of such analysis of non-equilibrium dynamics whereby I_{hkl} and the lattice
2 expansion are *a-priori* assumed, can be questioned. Both affect mainly the refined X_{HS} . In
3 particular, the newly formed HS molecules might be homogeneously distributed within the
4 crystal, rather than organized into separate diffracting phases. This homogeneous distribution
5 would lead to a change of the average structure factor of each phase [*Collet2011*], that is not
6 taken into account in our analysis. Yet, as already stressed, the evolution of ΔX_{HS} obtained by
7 such analysis is consistent with previous optical measurements (figure 2c) that yield ΔX_{HS}
8 directly whether or not there is a phase separation. This very good agreement strengthens the
9 validity of the assumptions made for analyzing the tr-XRD patterns.

10 **Monte-Carlo simulations of mechanoelastic model**

11 In order to rationalize the experimental results, we applied the mechanoelastic model, also
12 referred to as ball-and-spring model, that had been successfully used in previous studies to
13 simulate the out-of-equilibrium self-amplification [*Enachescu2017, Bertoni2019*]. In this two-
14 dimensional model, molecules are mimicked with spheres (balls) whose radii reflect LS or HS
15 state (10% increase in radius from LS to HS molecules, as observed on the Fe-Ligand bond
16 length). The balls are connected by springs, which replicate elastic interactions occurring in the
17 solid state through the lattice (figure 3a). When molecules (balls) switch, they induce a local
18 deformation of neighboring springs through a change of radii, that will propagate to the
19 adjacent molecules (balls). Hence, the elastic force network accounts for both short- and long-
20 range interactions in the model. The probabilities for switching a given molecule from LS to
21 HS state, and the reverse, depend on the temperature and the local pressure through Arrhenius-
22 like activation.

1 The elastic stresses originate not only from the molecular swelling upon LS to HS switch, but
2 also from the lattice heating. The latter leads to the so-called thermo-elastic stresses that trigger
3 thermal expansion [*Thomsen1986, Matsuda2015, Ruello2015*]. It originates from the energy
4 transfer between the photoexcited molecules and the thermal bath of lattice phonons
5 [*Lorenc2012*]. Because the simulations rely on a harmonic potential, such phenomenon cannot
6 be reproduced by a temperature increase alone, which only modifies the probability of
7 switching. For this work, the Monte-Carlo (MC) model was extended to account for the thermal
8 expansion by allowing distances between molecules to increase without changing the spin state.
9 To factor this aspect of non-equilibrium thermodynamics in MC simulations, the springs were
10 allowed to stretch beyond the HS and LS equilibrium distances at a given temperature (figure
11 3b). This mimics thermal lattice expansion. In practice, we started with a simulation assuming
12 a homogeneous increase of temperature, with 15% increase for HS and LS spring lengths.
13 Following this very first MC step, the spring lengths recover equilibrium positions
14 exponentially, with the same time constant as the recovery of equilibrium temperature. Such
15 extension of the insofar used model is a very simple yet satisfactory approximation that allows
16 independent treatment of volume change and spin transition.

17 **Discussion on the physical picture of photo-induced multistep dynamics**

18 We now consider the implications of the observed multistep structural dynamics and propose
19 a comprehensive scheme for the macroscopic photo-switching. In particular, we discuss the
20 origin of a significant delay between the volume expansion process and the transformation
21 from LS to HS phase.

22 The initial step of photo-excitation by a 100 fs laser pulse was described previously
23 [*Camarata2014*]. Direct photo-excitation from LS to HS molecular state is forbidden, so the

1 800 nm light is used to photo-excite a LS molecule to a short-lived intermediate singlet state,
2 followed by an ultrafast intersystem crossing towards the HS state [*Hauser1986*]. The latter is
3 structurally relaxed on the ps time scale. The switched molecules are uniformly distributed in
4 each microcrystal, since the thickness of microcrystals is much smaller than the penetration
5 depth of laser light (approximately 5 μm at 800 nm [*Bertoni2016a*]). Initial ΔX_{HS} is small and
6 it scales linearly with the excitation density [*Bertoni2016a*], here estimated at 7% for the high
7 excitation density (figure 2c). Importantly, the absorbed photon energy (1.55 eV) is much
8 higher than the energy difference between HS and LS ground states (tens of meV). In
9 consequence, most of the absorbed energy is dissipated through lattice heating. Complementary
10 time resolved mid-IR measurements (S3) to monitor the vibrational population of nascent HS
11 molecules show that it is reasonable to assume that the transfer of heat to the lattice is complete
12 within few ps.

13 During this initial process at the molecular scale, the volume is constrained, and uniformly
14 distributed stresses are generated through both the swelling of switched molecules and the
15 lattice heating. Subsequently, volume starts to expand through a coherent propagative process
16 occurring at the microcrystal scale. Strain waves are launched directly from the surface of
17 microcrystals to recover mechanical equilibrium with the environment, which is reached when
18 the internal and the atmospheric pressure become equal [*Thomsen1986, Wright1994,*
19 *Ruello2015*]. Such strain wave picture is supported by the observation of a maximum of the
20 volume expansion occurring at 300 ps, irrespective of the excitation density. It corresponds to
21 the travel time of the volumic deformation through a microcrystal [*Schick2014*]. Thus, taking
22 a sound velocity $v \sim 4 * 10^3 \text{ m.s}^{-1}$ estimated from previous measurements on similar samples
23 [*Parpiiev2017*] and $L \sim 1.3 \mu\text{m}$ the average crystal dimension, the associated acoustic time
24 scale is $\tau = L/v = 1.3 * 10^{-6} / 4 * 10^3 = 330 \text{ ps}$. Moreover, the initial photo-switching of 7% of the
25 molecules causes the average volume jump of only 1.5 \AA^3 (figure 1e), significantly smaller

1 than the observed volume change of 19 \AA^3 at the maximum of volume expansion (figure 2c). It
2 indicates that the lattice heating is dominant in this process. The estimated temperature rise at
3 the surface due to imparted laser energy (S4), $\Delta T_{\text{lattice}} = 105 \text{ K}$, corroborates the experimentally
4 found $\Delta T_{\text{lattice}} = 90 \text{ K}$. After 300 ps, $\Delta V_{\text{average}}$ decreases continually, due to heat transfer to the
5 polymeric environment.

6 Even for the high excitation density, no significant increase of ΔX_{HS} is observed during the
7 acoustic step. It contrasts with $\Delta X_{\text{HS}} = 23 \%$ on the 10-100 ns time scale, in agreement with
8 previous optical measurements (figure 2c). A clear decoupling in time between the dynamics
9 of volume expansion and molecular switching may be explained by a characteristic feature of
10 SCO compounds, namely the existence of energy barriers between LS and HS state at
11 molecular scale. They activate slower kinetics determined by Arrhenius-like probabilities, as
12 introduced in the mechanoelastic model. Our simulations suggest that the delay of the
13 activation is indeed independent of the size of the simulation box (S5.2), unlike the time taken
14 by the strain wave to travel through a microcrystal. At 300 ps, the molecular state is not
15 equilibrated with the lattice thermal bath, and remains essentially frozen by local energy
16 barriers. The volume expansion redistributes pressure in a way that favors HS over LS (S5.1),
17 yet it does not cancel the effect of the energy barrier between these two states and the
18 transformation can only occur on longer time scale. Moreover, the occurrence of the second
19 increase of ΔX_{HS} depends in a non-linear fashion on the excitation density. No such increase
20 is observed at low excitation (figure 2c), in accordance with the threshold effect evidenced by
21 optical measurements. It is a manifestation of cooperative response during the phase
22 transformation: intermolecular interactions give rise to self-amplification by internal feedback.
23 By contrast, a linear elastic response for the propagating volume is observed. The delay by
24 almost two temporal decades between the two processes is relatively long. It is fair to assume
25 that achieving a phase transition at the macroscopic scale requires more time than does the

1 switching of independent molecules [*Boukheddaden2000*]. Also, it is noteworthy that no
2 additional volume increase is observed when ΔX_{HS} reaches maximum. It is possible that part
3 of the thermal energy stored in the lattice is spent on phase transformation. Consequently, the
4 lattice temperature and volume would decrease and counterweight the increase of volume
5 originating from phase transformation.

6 Finally, after this step which occurs only at high excitation density (figures 2b and 3c), $\Delta V_{\text{average}}$
7 and ΔX_{HS} relax simultaneously on 10 μs time scale (50% decrease) to recover equilibrium with
8 the environment. This is about 2 decades longer compared to a faster recovery under the effect
9 of the low excitation, below the threshold. It is hence justified to conclude that the phase
10 transformation associated with a sufficiently expanded volume prolongs the lifetime of the
11 transient high spin state.

12 The complete photo-induced cycle is drawn schematically in figure 4. It delineates time scales
13 for multiscale dynamics triggered by a laser pulse at a molecular level and on the macroscopic
14 scale. It emphasizes that the mechanisms involved in spin state switching through the excited
15 state and the ground state are different. The photophysics of the excited state was largely
16 covered in the literature, yet the cycle at the macroscopic level barely starts there. The figure
17 depicts temporal decoupling at the macroscopic scale between the fast collective dynamics of
18 volume dilation and the slow thermally activated kinetics of the LS-to-HS transformation.

19 **Conclusion**

20 First and foremost, these results demonstrate the capacity of time-resolved X-ray powder
21 diffraction to simultaneously determine the photoinduced dynamics of average unit cell
22 parameters and phase fraction in a molecular switchable material. A strongly discriminating
23 quantitative structural analysis [*Freyer2013, Mariette2021*] allowed to establish

1 unambiguously a sequence of events by which photo-induced spin state switching occurs from
2 molecular to material scale. In particular, the experimental results support a scheme for the
3 multiscale dynamics at a macroscopic scale whereby the volume expansion and the increase of
4 switching molecules are clearly separated in time. The time scale of the dynamics of volume
5 expansion agrees with a propagative picture of collective atomic motions such as elastic waves,
6 while the cooperative self-amplification upon phase transformation takes place later. A model
7 simulation accounting for thermally activated kinetics, governed by local energy barriers
8 separating LS and HS molecular state, reliably reproduced all important experimental features
9 (figure 3a and 3b). The situation is fundamentally different from that encountered in systems
10 with no local energy barriers. In such a case, the transformation implies only ultrafast structural
11 dynamics of atomic displacements on the optical phonon time scale. Those dynamics follow
12 the propagation of volume expansion as observed recently in another isostructural
13 transformation [*Mariette2021*]. In the case of SCO, the volume must be sufficiently expanded
14 to promote the thermally activated transformation towards the HS phase at the macroscopic
15 scale. Should energy barrier be very low, the macroscopic transformation would be limited by
16 the propagation of volumic strain wave on the acoustic time scale.

17 In conjunction with the earlier optical studies that revealed size dependent switching time
18 [*Bertoni2016a*], and *a priori* expectation that in the ever so smaller nanoparticles the
19 macroscopic switching of the molecular state can be indefinitely fast, the new results point to
20 a bottleneck in the switching dynamics. Hence, our findings define the ultimate time scale for
21 macroscopic transformation of molecular state in nanoscale objects for this class of solids.
22 They do not obey the rule “the smaller the faster” [*Ridier2019*]. This finding could motivate
23 an optimised material design, scalable with size dependent dynamics and intrinsic energetics.
24 A new perspective for the design of functional spin-crossover nano systems could reside in
25 chemical leverage of the energy barriers by tuning the ligand field, or other methods.

1 METHODS

2 Single crystal X-ray diffraction

3 Temperature-dependent X-ray diffraction (XRD) study was performed on [Fe^{III}(3-MeO-
4 SalEen)₂]PF₆ single crystal using a laboratory SuperNova Agilent Technologies 4-circle
5 diffractometer, with Cu-K_α microsource ($\lambda = 1.5406 \text{ \AA}$) and EosS2 CCD camera. The sample
6 was cooled down using 800 Plus nitrogen flow cryostat from Oxford Cryosystems. To obtain
7 good precision of cell parameter change with temperature, a set of short scans within 2 \AA
8 resolution was taken from 100 K to 250 K, with 2 to 5 K steps. Data reduction was performed
9 with CrysAlisPro software [*CrysAlisPro2018*]. The single crystal had a plate shape, with a long
10 dimension around 100 μm .

11 Samples

12 The Fe^{III} compound was prepared in the form of a powder of pure microcrystals as previously
13 reported [*Tissot2012*]. The microcrystals (typical dimensions of 3.5 μm , 0.35 μm , 0.13 μm
14 from TEM) were processed in polyvinylpyrrolidone (PVP, MM = 45000 gmol⁻¹) thin films
15 formed by spin-coating on glass substrate [*Bertoni2012*].

16 X-ray diffraction on polycrystalline sample

17 Experimental setup

18 X-ray diffraction experiment was performed at ESRF, ID09 beamline during hybrid mode ($\frac{7}{8}$ th
19 continuous filling + 1 isolated electron bunch). The isolated electron bunch was used in the
20 experiment. The ID09 setup was discussed in detail previously [*Cammarata2009*]. Briefly, fast
21 rotating choppers were used to isolate X-ray single pulses (each 100 ps long) at 40 Hz repetition

1 rate. The X-rays energy was centered at 18 keV ($\lambda = 0.6888 \text{ \AA}$) with 1.5% bandwidth. The
2 beam size at sample position was 0.1 (horizontal) x 0.02 (vertical). Diffracted X-rays were
3 integrated on a Rayonix MX170-HS CCD detector. Each image was recorded with 1000 shots
4 exposure.

5 For the thermal study at equilibrium, sample was cooled down using a nitrogen cryostream
6 700Plus from Oxford Cryosystems and diffraction images were measured with 1 K steps from
7 293 K to 100 K.

8 For the time-resolved study, a synchronized laser (800 nm) at 40 Hz was used to excite the
9 sample with 11° incident angle. Laser Beam size was $1.2 \times 0.23 \text{ mm}^2$, leading to a laser
10 footprint on sample of $(6.3 \times 0.23) \text{ mm}^2$. The sample was cooled down to 100 K. Diffraction
11 patterns were measured with $60 \mu\text{J}/\text{mm}^2$ and $380 \mu\text{J}/\text{mm}^2$ laser excitation, for time delays in
12 the following lists, respectively:

13 *[-50 ps, 0 ps, 50 ps, 100 ps, 300 ps, 1 ns, 3 ns, 10 ns, 30 ns, 100 ns, 300 ns, 1 μs , 3 μs , 10 μs ,
14 100 μs , 300 μs , 1 ms]*

15 *[-50 ps, 0 ps, 50 ps, 100 ps, 200 ps, 300 ps, 700 ps, 1 ns, 1.5 ns, 3 ns, 5 ns, 7 ns, 10 ns, 30 ns,
16 100 ns, 300 ns, 1 μs , 3 μs , 10 μs , 30 μs , 100 μs , 300 μs , 1 ms]*

17 Measurements were performed with shuffled delays, to detect any drift effects during the
18 experimental time.

19 **Data Reduction**

20 The diffraction images were azimuthally integrated using pyFAI [*Ashiotis2015*]. Background
21 was subtracted using scikit-ued python library [*Rene2017*]. Negative reference patterns (-5 ns)
22 were used to calculate differential patterns and averaging with *trx* python library
23 [*Cammarata2017*].

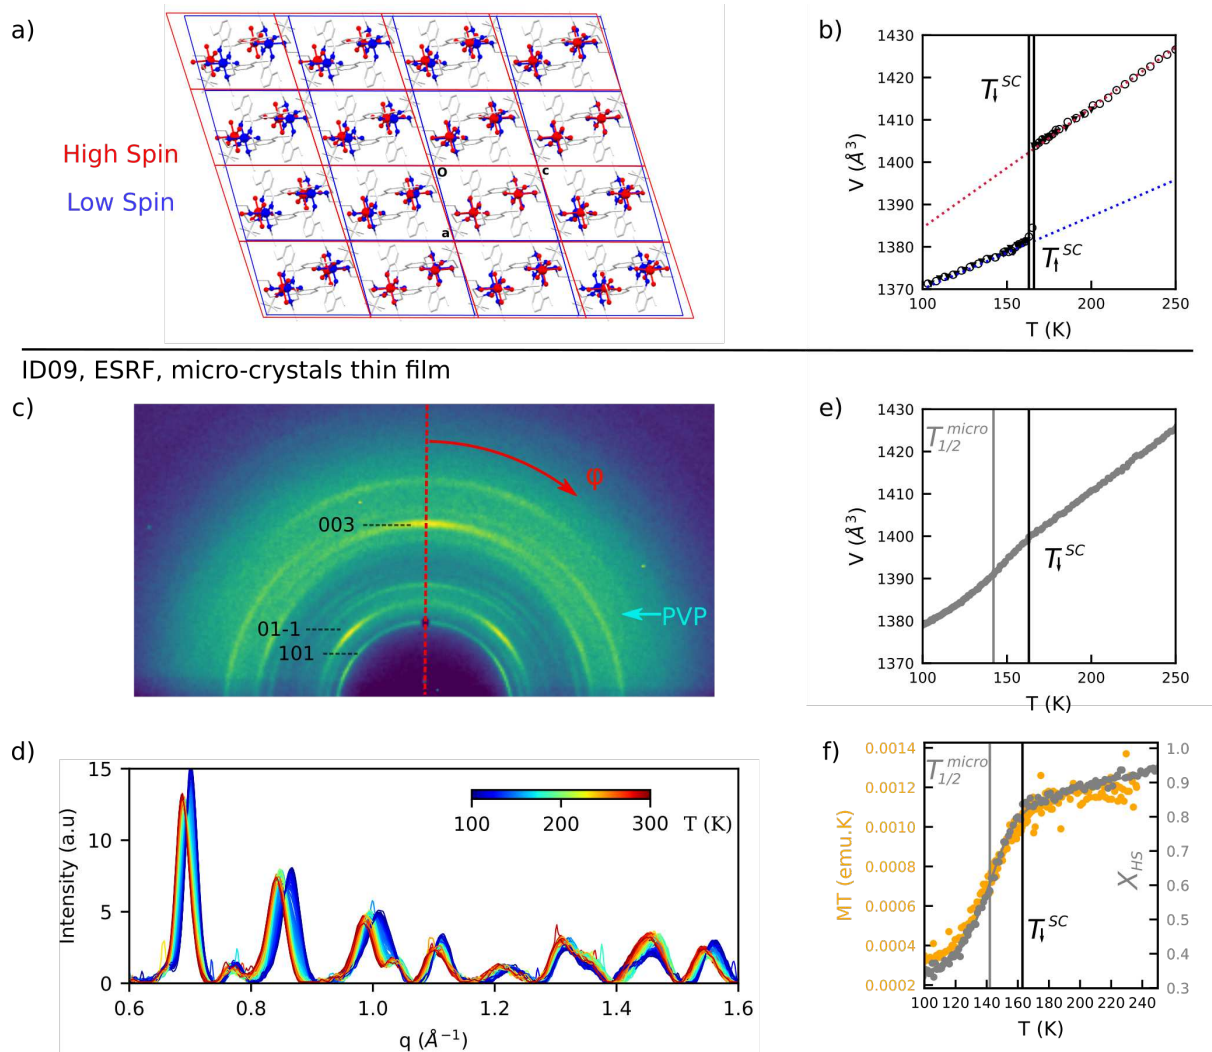

1 Powder patterns refinement

2 Full powder pattern refinements were performed after the data reduction step described above.
3 Peak profiles and sample displacement were described from a fundamental parameter approach
4 using expressions derived in [Rowles2017] with the TOPAS software [Coelho2018]. The
5 incident wavelength was fixed $\lambda = 0.6888 \text{ \AA}$ ($E = 18 \text{ keV}$) with $\Delta E/E = 1.5\%$ (FWHM
6 gaussian). The beam height at sample position was fixed to $20 \mu\text{m}$. Sample displacement was
7 refined once and fixed for a given temperature / time scan. α_i was set to 0.2° for all scans, and
8 refined value remained within $0.2^\circ \pm 0.05^\circ$ interval. Background subtracted patterns were
9 refined on $[0.3 - 1.9] \text{ \AA}^{-1} q$ range. Typical R_w was $(19 \pm 2) \%$.

10 Magnetic susceptibility

11 Magnetic measurements were carried out using a Quantum Design SQUID magnetometer
12 (MPMS5S Model) calibrated against a standard palladium sample. Data were collected
13 between 250 and 50 K, at a rate of 0.67 K/min with a small number of microcrystals
14 embedded in PVP, once removed from the glass substrate.

3 **Figure 1.** a) $[\text{Fe}^{\text{III}}(3\text{-MeO-SalEen})_2]\text{PF}_6$ molecular lattices in LS (100 K, blue) and HS (293 K,

4 red) state, shown in the (a, c) plane. Ligands (in gray) are shown for the LS structure only. b)

5 XRD measurement on a single crystal: temperature evolution of the unit cell volume (T

6 decreasing, plain black triangles, T increasing, open circles) for extraction of thermal expansion

7 parameters of the HS (red dotted line) and LS (blue dotted line) unit cell (SI Method,

8 [Tissot2011]). Vertical black lines represent transition temperatures for T decreasing ($T_{\downarrow}^{\text{SC}}$)

9 and T increasing (T_{\uparrow}^{SC}). c) to f) Synchrotron x-ray powder diffraction on micro-crystals

10 measured at ESRF, ID9 beamline: c) Diffraction image measured at $T = 293$ K. d) 1D powder

11 patterns after azimuthal averaging of diffraction images (a) for the different temperature

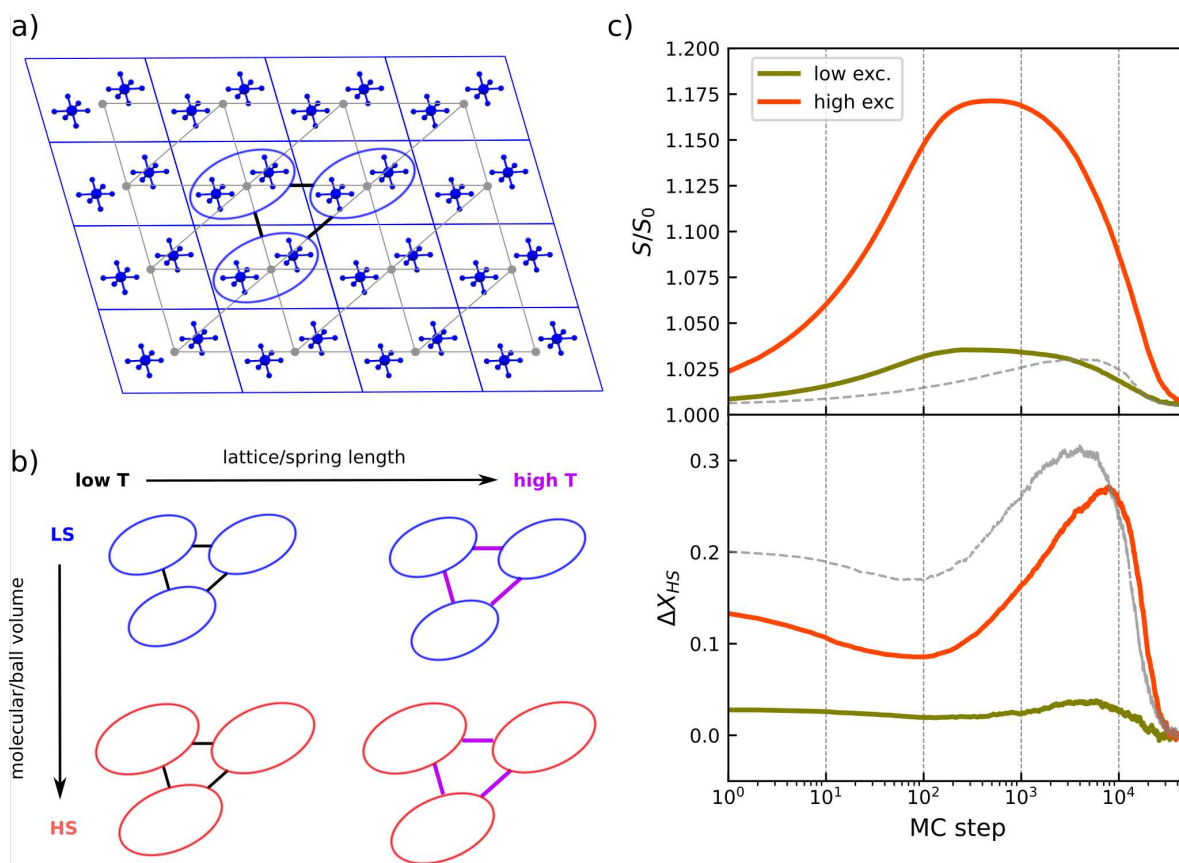

1 measured from $T = 293 \text{ K}$ to $T = 99 \text{ K}$ (upon cooling). e) and f) Temperature evolution of the
2 mean unit cell volume as extracted from the powder pattern refinement. e) In yellow:
3 temperature evolution of the magnetic moment-temperature product MT as extracted from
4 SQUID measurements; in grey: evolution of the HS fraction as extracted from the powder
5 pattern refinement. Gray solid line is a guide for the eyes. b), e) and f): The vertical black and
6 gray lines indicate transition temperatures $T_{\downarrow}^{\text{SC}}$ and $T_{1/2}^{\text{micro}}$ in the single crystal and small
7 crystallites, respectively.

1

2 **Figure 2.** a) TR powder patterns and corresponding difference patterns measured under high
 3 fluence $380 \mu\text{J}/\text{mm}^2$ (multiplied by 2 and shifted by 4 for clarity). Blue to red colors correspond
 4 to increasing time delay from negative to positive (detailed delays in Methods). b) Integrated
 5 pattern of crystalline film. Top and middle: Steady state integrated patterns measured at $T =$
 6 293 K (HS state, in red) and $T = 99 \text{ K}$ (in blue), offset for clarity by arbitrary values. Black
 7 lines are the result of powder pattern refinements (see Methods) and grey lines correspond to
 8 the residual (difference between experimental and refined patterns). Bottom: Time-resolved
 9 differential pattern measured at 99 K from -50 ps to 1 ms after photo-excitation under high

1 fluence $380 \mu\text{J}/\text{mm}^2$ (multiplied by 4 for clarity), showing the characteristic shape for volume
2 expansion (peak shifts towards lower q values). Red and blue vertical lines indicate the position
3 of major HS and LS Bragg peaks, respectively. c) Time evolution of the volume (top) and
4 relative HS fraction (middle) as extracted from powder pattern refinement. Bottom: time
5 evolution of the relative photo-induced HS fraction extracted from optical spectroscopy
6 (adapted from [*Bertoni2016a*]). In orange: high excitation density ($380 \mu\text{J}/\text{mm}^2$ and 410
7 $\mu\text{J}/\text{mm}^2$ for XRD and OD measurements, respectively), in dark green: low excitation density
8 ($60 \mu\text{J}/\text{mm}^2$ and $100 \mu\text{J}/\text{mm}^2$ for XRD and OD measurements, respectively).

1
 2 **Figure 3.** a) $[\text{Fe}^{\text{III}}(3\text{-MeO-SalEen})_2]\text{PF}_6$ molecular lattice in LS state, displayed in the (a,c)
 3 plane, for clarity ligands are hidden. The rounded blue contours encircle two molecules per
 4 unit cell. In MC simulations, elastic interactions are modelled by springs connecting the unit
 5 cells; diagonal springs prevent structural collapse in simulations. b) Schematic representation
 6 of ball and spring model accounting for thermal volume expansion. The rounded blue and red
 7 contours replicate molecules in LS and HS state, respectively; short black and long magenta
 8 sticks replicate the thermal load on the springs c) Simulations of evolution of X_{HS} (bottom) and
 9 of the surface (equivalent to volume in 2D box, top) following high (20%, orange) and low
 10 (5%, dark green) fractions of switched sites at MC's step zero. Dotted grey lines correspond to
 11 previous model, without initial spring length increase. In that case, the increase of HS fraction
 12 and the volume were not separated in time.

13

1

2 **Figure 4.** Photoexcitation cycle of a single crystallite upon spin-crossover. Top: laser induced
 3 charge transfer promotes LS molecules (not shown for clarity) residing in LS lattice (blue) to
 4 a hot HS state (shape and color coded consistently with figure 3) in less than 100 fs. Vibrational
 5 cooling of hot molecules with LS lattice (color coded consistently with figure 3) takes place on
 6 the picosecond time scale. Bottom: volume expansion of heated lattice in 100's ps, and
 7 coexistence of LS molecules (not shown) in thermally dilated LS lattice (blue) with photo-
 8 switched HS molecules (red) in thermally dilated HS lattice (red). HS and LS lattices
 9 superimposed to emphasize their likely coexistence (only average volume measured with
 10 XRD). Shift of the switching regimes: LS molecules residing in the ground state switch to the
 11 HS state according to LS/HS occupancy probabilities modified by lattice expansion; the delay
 12 between expansion (300 ps, or less for nano-crystallites) and the switching (ns time-scale), due
 13 to incompressible Arrhenius-type kinetics sketched in the insert.

1 ACKNOWLEDGEMENTS

2 ML gratefully acknowledges the Agence Nationale de la Recherche for financial support under
3 grant ANR-16-CE30-0018 (“Elastica”). MLB thanks Amandine Bellec for her assistance in the
4 profilometry measurement. Parts of this research were carried out in the frame of the IM-LED
5 LIA (CNRS).
