Abstract

Most commercial Finite Element codes rely on hypo-elastoviscoplastic constitutive equations for structural computations at large deformations. Such formulations are known to suffer from physical and thermodynamical flaws but their versatility and ease of implementation made them ubiquitous. The paper presents an alternative systematic and thermodynamically consistent extension of anisotropic thermo-elastoviscoplastic constitutive equations at finite strain. The formulation is based on the well-known multiplicative decomposition of the deformation gradient into a thermoelastic and an inelastic part. This decomposition introduces an isoclinic intermediate configuration. The present framework covers a wide range of multi-mechanism (MM) elastoplastic models so that it can advantageously replace the constitutive part of existing codes. The choice of suitable hyperelastic potential, hardening variables and anisotropy evolution laws are discussed. The concept of plastic spin is used and can be either derived from general representation theorems or obtained from the normality rule. The effect of the plastic spin is discussed in the light of examples involving anisotropic plasticity. The response of the proposed formulation is compared with hypoelastic models in the case of several structural applications. The implementation of this methodology in a commercial FE object-oriented code is detailed. We mainly show how to extend readily a wide range of small strain nonlinear constitutive models to finite deformations. The implementation is proved to be competitive with respect to existing hypo-elastoviscoplastic formulations in terms of

1. Introduction

Finite strain elastoplasticity, as observed in various materials, requires combined geometric and material nonlinear analysis of solids. Since the early sixties, a myriad of strategies have been developed to extend the well-established infinitesimal elastoplasticity theory to finite transformations [1, 2]. The widely used approach is the so-called hypoelastic formulations relying on additive decomposition of the total deformation rate into elastic and inelastic parts, and constitutive equations for objective stress rates [3, 4]. However, this framework has been the subject of much controversy. First, the constitutive equations are generally not integrable, which results in spurious energy dissipation in the elastic regime even prior to yield (see, e.g. [5, 6, 7] among others). In order to recover the integrability of hypoelastic formulations, a logarithmic rate has been put forward by [8, 9]. However, it was shown in [10] that the post-yield response of the logarithmic rate is inconsistent with the notion of elasticity. Second, the rate of elastic deformation is related to a non unique objective stress rate [11, 12]. In addition, some hypoelastic models are well-known to depend on the reference configuration, e.g. Green-Naghdi, and logarithmic rates [13]. Formulations relying upon the additive decomposition of the Green-Lagrange strain tensor were developed [1]. Given that the considered strain measure is symmetric, the latter model cannot describe full anisotropy. Another formulation based on the additive split of logarithmic strain was suggested by [14]. These formulations however imply a dependence of the choice of the reference configuration, meaning that the form of the constitutive laws is not left unchanged by the change of reference configuration [13].

Since the aforementioned models are unsatisfactory in describing finite deformations, several authors have put forward the necessity to introduce the multiplicative decomposition as a general way of describing the kinematics at finite strain [15, 16]. This decomposition assumes the existence of an intermediate configuration that is generally not unique. The concept of isoclinic intermediate configuration was proposed first by [17, 18]. Since then, several models relying upon the multiplicative decomposition and a hyperelastic potential for the stress have been developed (e.g [19, 20, 21, 22, 7]). It is noteworthy to mention that there exist different versions of the multiplicative decomposition, e.g. considering a decomposition in the reverse order [23, 24], decomposition assuming symmetric elastic part or symmetric plastic

part [16, 25]. Alternatively, a rigorous presentation of this theory has been proposed by [26] based on material isomorphisms. This approach defines a special class of materials described by elastic ranges that are independent of plastic deformation.

Constitutive modeling of kinematic hardening is still an active area of research even in the small strain regime [27]. Kinematic hardening models at finite strain can be generally classified into two main groups; both are regarded as extensions of the Armstrong-Frederick model [28]. The first one employs an evolution equation for the back stress, or the so-called 'Chaboche-type' model [29]. The second one involves an additional multiplicative decomposition of the plastic part of the deformation gradient into storage and dissipative parts [30, 19, 31, 32, 22]. The difference between different models becomes visible, particularly in cases where principal axes rotate, e.g. simple glide and torsion [33]. Significant differences are observed for the special case of linear kinematic hardening (Prager model) which leads to stress oscillations for Jaumann rate [33]. Meanwhile, many studies have shown that different extensions of the Armstrong-Frederick model yield, at least qualitatively, similar results [34, 35, 31]. The differences are mainly due to second-order effects for loading conditions involving large rotations, apparent in simple shear [31, 36].

At finite strain, the material does not undergo only macroscopic stretches and rotations but also rotations of its substructure described by some privileged directions called *directors*. The notion of plastic spin describes the evolution of material's directors with plasticity. As highlighted by several works (e.g. [37, 38]), the plastic spin is undetermined for isotropic materials and is often assumed to vanish. Several constitutive equations for the plastic spin has been proposed independently by [39, 40]. It has been argued that multiple plastic spins are required since each internal variable has a different nature and, consequently, a different rotating frame is required for each internal variable [41]. Furthermore, the plastic spin is useful to prevent stress oscillation, particularly in the case of the simple shear problem [40] when applied to elastoplastic materials with linear kinematic hardening. Constitutive modeling of plastic spin can be achieved through: (i) an additional ad-hoc constitutive equation [39, 42, 43] (ii) generalized normality conditions [18, 44, 45].

The additive hypo-elastoplastic models are widely used in finite element codes for the sake of computational ease. Small deformation material models are adapted to large deformation problems with appropriate tangent operators and stress/strain measures. To our knowledge, there is no finite element software supporting a systematic extension of infinitesimal models using the multiplicative decomposition. Meanwhile, this approach is already used, exclusively, for some particular models, e.g. in MSC Marc [46], or by using user material subroutines in ABAQUS [22, 7].

This work aims to propose a generic and systematic extension of small strain

models to finite deformations. The multiplicative decomposition of the deformation gradient into thermoelastic and inelastic parts is adopted. All constitutive equations are expressed in the local isoclinic intermediate configuration. Accordingly, the stress is related to the elastic strain through a hyperelastic law. Emphasis is put on the numerical implementation of the present formulation in a commercial finite element code provided with an object-oriented interface [47]. By this approach, small strain models, including isotropic and anisotropic plasticity models with various isotropic and kinematic hardening rules, can be re-used in the framework of the multiplicative decomposition. On the other hand, unlike usual hypoelastic models, various constitutive equations for the plastic spin can be formulated within this framework.

The manuscript is organized as follows. Section 2 presents a general thermodynamical framework for constitutive modeling of anisotropic finite strain thermoelastoviscoplasticity based on the multiplicative decomposition. Kinematic assumptions and a thermodynamically consistent derivation of constitutive equations for multi-mechanism modeling are regarded. Different models describing kinematic hardening are discussed. Two constitutive choices of plastic spin are presented. In section 3, we describe the implementation of the present formulation in a commercial finite element code by taking advantage of its oriented object interface. Special attention is paid to the integration of constitutive equations and the construction of tangent matrices. Two integration schemes are adopted: using the exponential mapping or correcting residuals in order to fulfill the plastic incompressibility condition. Finally, the response of some particular models is presented in sections 4 and 5 for a volume element and structural applications, respectively. Through these applications, comparisons are made with hypoelastic formulations presented in the appendix (6).

The notations used throughout are as follows. $\underline{\mathbf{a}}$, $\underline{\mathbf{A}}$, and $\underline{\underline{\mathbf{A}}}$ stand respectively for first, second and fourth order tensors. The transpose, inverse, transpose of inverse and time derivative of a second order tensor are denoted by $\underline{\underline{\mathbf{A}}}^T$, $\underline{\underline{\mathbf{A}}}^{-1}$, $\underline{\underline{\mathbf{A}}}^{-T}$, and $\dot{\underline{\underline{\mathbf{A}}}}$ respectively. Double contractions are denoted by $\underline{\underline{\mathbf{A}}} : \underline{\underline{\mathbf{B}}} = A_{ij}B_{ij}$ and $\underline{\underline{\mathbf{A}}} : \underline{\underline{\underline{\mathbf{B}}}} = A_{ijkl}B_{kl} \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j$, with $(\underline{\mathbf{e}}_i)_{i=1,2,3}$ being a Cartesian orthonormal basis. The following tensor products are used: $\underline{\underline{\mathbf{A}}} \otimes \underline{\underline{\underline{\mathbf{B}}}} = A_{ij}B_{kl} \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \otimes \underline{\mathbf{e}}_k \otimes \underline{\mathbf{e}}_l$, $\underline{\underline{\mathbf{A}}} \otimes \underline{\underline{\underline{\mathbf{B}}}} = A_{ik}B_{jl} \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \otimes \underline{\mathbf{e}}_k \otimes \underline{\mathbf{e}}_l$, $\underline{\underline{\mathbf{A}}} \bar{\otimes} \underline{\underline{\underline{\mathbf{B}}}} = A_{il}B_{jk} \underline{\mathbf{e}}_i \otimes \underline{\mathbf{e}}_j \otimes \underline{\mathbf{e}}_k \otimes \underline{\mathbf{e}}_l$.

2. General framework for elastoviscoplastic modeling at finite strains

2.1. Kinematics

The deformation gradient is multiplicatively split as

$$\underline{\underline{\mathbf{F}}} = \underline{\underline{\mathbf{F}}}^e \underline{\underline{\mathbf{F}}}^p \quad (1)$$

where $\underline{\underline{\mathbf{F}}}^e$ and $\underline{\underline{\mathbf{F}}}^p$ denote the thermoelastic and the inelastic parts, respectively, see Fig. 1. In contrast to $\underline{\underline{\mathbf{F}}}$, the parts $\underline{\underline{\mathbf{F}}}^e$ and $\underline{\underline{\mathbf{F}}}^p$ are not necessarily defined as gradients of one-to-one mappings. As a consequence of possible incompatibility of thermoelastic and plastic deformation fields, the intermediate configuration is local, *i.e.* it belongs to the immediate vicinity of a material point and is obtained from the current deformed configuration by a purely elastic unloading of this vicinity only. The volume changes due to elastic and plastic deformations are respectively denoted by

$$J_e = \det(\underline{\underline{\mathbf{F}}}^e) = \frac{\rho_e}{\rho}, \quad J_p = \det(\underline{\underline{\mathbf{F}}}^p) = \frac{\rho_0}{\rho_e} \quad (2)$$

and ρ , ρ_e and ρ_0 stand for the mass densities in current, intermediate and reference configurations, respectively. The decomposition (1), however, is not unique since any

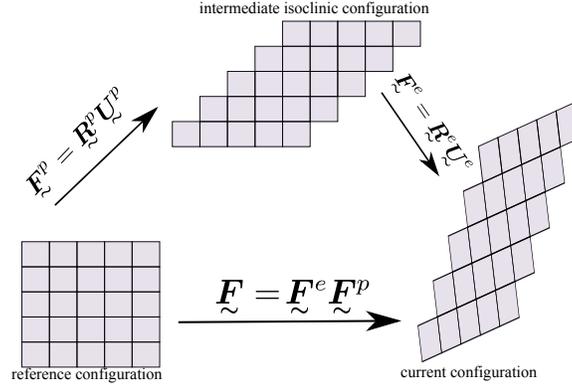

Figure 1: Illustration of the local isoclinic intermediate configuration

invertible transformation $\underline{\underline{\mathbf{H}}}$ can be introduced such that

$$\underline{\underline{\mathbf{F}}} = (\underline{\underline{\mathbf{F}}}^e \underline{\underline{\mathbf{H}}})(\underline{\underline{\mathbf{H}}}^{-1} \underline{\underline{\mathbf{F}}}^p) = \underline{\underline{\mathbf{F}}}^{e*} \underline{\underline{\mathbf{F}}}^{p*} \quad (3)$$

To remedy this concern, we shall define some material directors. These privileged directors are attached to some microstructural features and undergo a different transformation than the material. For solids, we can always define a triad of directors

describing its microstructure (fibers, crystal lattice vectors, ...). In general, an infinity of directors may be identified for a material. Nevertheless, if the relative spin of all directors with respect to a single triad of directors is known, the problem shall be simplified by considering only this triad. It leads to the concept of local isoclinic intermediate configuration, advocated in [18], where the material directors have the same inclination or orientation as in the reference configuration. The intermediate configuration is obtained by elastic virtual unloading, whereas the rigid-body rotation of directors is included in the thermoelastic part of the deformation gradient. The isoclinic local configuration is uniquely defined up to a symmetry operation belonging to the symmetry group of the material.

The velocity gradient is additively decomposed in the current configuration

$$\dot{\underline{\underline{F}}} \underline{\underline{F}}^{-1} = \underline{\underline{L}}^e + \underline{\underline{F}}^e \underline{\underline{L}}^p \underline{\underline{F}}^{e-1} \quad (4)$$

$\underline{\underline{L}}^e$ is the purely elastic part of the velocity gradient and $\underline{\underline{L}}^p$ is referred to as the plastic deformation rate in the intermediate configuration. The latter, in turn, can be split into symmetric and skew-symmetric parts as

$$\begin{cases} \underline{\underline{L}}^e = \dot{\underline{\underline{F}}}^e \underline{\underline{F}}^{e-1} = \underline{\underline{D}}^e + \underline{\underline{W}}^e \\ \underline{\underline{L}}^p = \dot{\underline{\underline{F}}}^p \underline{\underline{F}}^{p-1} = \underline{\underline{D}}^p + \underline{\underline{W}}^p \end{cases} \quad (5)$$

where $\underline{\underline{D}}^e = \text{sym}(\underline{\underline{L}}^e)$, $\underline{\underline{D}}^p = \text{sym}(\underline{\underline{L}}^p)$ are the elastic and the plastic strain rates, and $\underline{\underline{W}}^e = \text{skw}(\underline{\underline{L}}^e)$ and $\underline{\underline{W}}^p = \text{skw}(\underline{\underline{L}}^p)$ are the elastic and plastic spin tensors.

2.2. Thermodynamic framework

The local form of the Clausius-Duhem inequality expressed in the local current configuration is written as

$$\frac{\underline{\underline{\sigma}} : \underline{\underline{D}}}{\rho} - (\dot{\psi} + \dot{T}\eta) - \frac{1}{\rho} \underline{\underline{q}} \cdot \underline{\underline{g}} \geq 0, \quad \underline{\underline{g}} = \nabla_x T \quad (6)$$

where $\underline{\underline{q}}$ is heat flux, $\underline{\underline{g}}$ is the current spatial gradient of temperature, and ψ, η designate the Helmholtz free energy and entropy densities per unit mass. The volume density of internal forces w.r.t. the intermediate configuration is given by

$$J_e \underline{\underline{\sigma}} : \underline{\underline{D}} = \underline{\underline{\Pi}}^e : \dot{\underline{\underline{F}}}^e + \underline{\underline{M}} : \underline{\underline{L}}^p \quad (7)$$

where

$$\begin{cases} \underline{\mathbf{E}}^e = \frac{1}{2} (\underline{\mathbf{F}}^{eT} \underline{\mathbf{F}}^e - \underline{\mathbf{1}}) \\ \underline{\dot{\mathbf{E}}}^e = \underline{\mathbf{F}}^{eT} \underline{\mathbf{D}}^e \underline{\mathbf{F}}^e \\ \underline{\mathbf{\Pi}}^e = J_e \underline{\mathbf{F}}^{e-1} \underline{\boldsymbol{\sigma}} \underline{\mathbf{F}}^{e-T} \\ \underline{\mathbf{M}} = J_e \underline{\mathbf{F}}^{eT} \underline{\boldsymbol{\sigma}} \underline{\mathbf{F}}^{e-T} = \underline{\mathbf{C}}^e \underline{\mathbf{\Pi}}^e \end{cases} \quad (8)$$

$\underline{\mathbf{\Pi}}^e$ and $\underline{\mathbf{M}}$ denote the Piola and Mandel stress tensors, expressed in the intermediate configuration. The Mandel stress tensor $\underline{\mathbf{M}}$ is generally non-symmetric, in contrast to $\underline{\mathbf{\Pi}}^e$. By expressing the dissipation inequality in the intermediate configuration, we obtain

$$\underline{\mathbf{\Pi}}^e : \underline{\dot{\mathbf{E}}}^e + \underline{\mathbf{M}} : \underline{\bar{\mathbf{L}}}^p - \rho_e (\dot{\psi} + T\eta) - \frac{\underline{\mathbf{q}}_e \cdot \underline{\mathbf{g}}_e}{T} \geq 0 \quad (9)$$

where $\underline{\mathbf{q}}_e = J_e \underline{\mathbf{F}}^{e-1} \underline{\mathbf{q}}$ and $\underline{\mathbf{g}}_e = \underline{\mathbf{F}}^{eT} \underline{\mathbf{g}}$. The specific free energy density $\psi(\underline{\mathbf{E}}^e, T, \underline{\boldsymbol{\alpha}}_I)$ is a function of elastic strain $\underline{\mathbf{E}}^e$, temperature T and internal variables $\underline{\boldsymbol{\alpha}}_I$ which are scalar and/or tensor quantities accounting for hardening properties. It follows that

$$\dot{\psi} = \frac{\partial \psi}{\partial \underline{\mathbf{E}}^e} : \underline{\dot{\mathbf{E}}}^e + \sum_I \frac{\partial \psi}{\partial \underline{\boldsymbol{\alpha}}_I} \dot{\underline{\boldsymbol{\alpha}}}_I + \frac{\partial \psi}{\partial T} \dot{T} \quad (10)$$

The Clausius-Duhem inequality takes the form:

$$\left(\underline{\mathbf{\Pi}}^e - \rho_e \frac{\partial \psi}{\partial \underline{\mathbf{E}}^e} \right) : \underline{\dot{\mathbf{E}}}^e + \underline{\mathbf{M}} : \underline{\bar{\mathbf{L}}}^p - \rho_e \sum_I \frac{\partial \psi}{\partial \underline{\boldsymbol{\alpha}}_I} \dot{\underline{\boldsymbol{\alpha}}}_I - \rho_e \left(\frac{\partial \psi}{\partial T} + \eta \right) \dot{T} - \frac{\underline{\mathbf{q}}_e \cdot \underline{\mathbf{g}}_e}{T} \geq 0 \quad (11)$$

The following state laws are adopted

$$\underline{\mathbf{\Pi}}^e = \rho_e \frac{\partial \psi}{\partial \underline{\mathbf{E}}^e} \quad , \quad \eta = - \frac{\partial \psi}{\partial T} \quad (12)$$

so that the intrinsic dissipation remains as

$$\phi_{in} = \underline{\mathbf{M}} : \underline{\bar{\mathbf{L}}}^p - \rho_e \sum_I \frac{\partial \psi}{\partial \underline{\boldsymbol{\alpha}}_I} \dot{\underline{\boldsymbol{\alpha}}}_I \geq 0 \quad (13)$$

together with the condition $\underline{\mathbf{q}}_e \cdot \underline{\mathbf{g}}_e \leq 0$. The condition (13) is satisfied for any process if there exists a convex potential Ω w.r.t. $\underline{\mathbf{M}}$ and concave w.r.t. $\underline{\mathbf{A}}_I$ such that

$$\underline{\bar{\mathbf{L}}}^p = \frac{\partial \Omega(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I)}{\partial \underline{\mathbf{M}}} \quad , \quad \dot{\underline{\boldsymbol{\alpha}}}_I = - \frac{\partial \Omega(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I)}{\partial \underline{\mathbf{A}}_I} \quad (14)$$

\mathbf{A}_I are the thermodynamic forces associated with the state variables $\boldsymbol{\alpha}_I$:

$$\mathbf{A}_I = \rho_e \frac{\partial \psi}{\partial \boldsymbol{\alpha}_I} \quad (15)$$

In the case of time-independent plasticity, the flow rule in Eq. (14) is rewritten

$$\overline{\mathbf{L}}^p = \dot{\lambda} \frac{\partial f(\underline{\mathbf{M}}, \mathbf{A}_I)}{\partial \underline{\mathbf{M}}} \quad (16)$$

where $f(\underline{\mathbf{M}}, \mathbf{A}_I)$ is the yield function and $\dot{\lambda}$ denotes the plastic multiplier which can be determined by use of the consistency condition as

$$\dot{f}(\underline{\mathbf{M}}, \mathbf{A}_I) = \frac{\partial f}{\partial \underline{\mathbf{M}}} : \dot{\underline{\mathbf{M}}} + \frac{\partial f}{\partial \mathbf{A}_I} : \dot{\mathbf{A}}_I = 0 \quad (17)$$

For viscoplasticity with a threshold, from Eq. (16) and Eq. (14), a viscoplastic multiplier can be defined as

$$\dot{\lambda} = \frac{\partial \Omega(\underline{\mathbf{M}}, \mathbf{A}_I)}{\partial f(\underline{\mathbf{M}}, \mathbf{A}_I)} \quad (18)$$

The existence of a convex potential from which the flow rule and the evolution law of internal variables are derived is sufficient to satisfy the dissipation inequality in Eq. (13), but it is not necessary.

2.3. Thermo-hyperelasticity

A myriad of free energy potentials are available to model hyperelasticity at finite strains. A widely used free energy potential is the so-called St. Venant-Kirchhoff model, as a straightforward generalization of Hooke's law

$$\rho_e \psi^e(\underline{\mathbf{E}}^e) = \frac{1}{2} \underline{\mathbf{E}}^e : \underline{\underline{\mathbb{C}}} : \underline{\mathbf{E}}^e, \quad \text{with} \quad \underline{\mathbf{E}}^e = \frac{1}{2} (\underline{\mathbf{F}}^{eT} \underline{\mathbf{F}}^e - \underline{\mathbf{1}}) \quad (19)$$

where $\underline{\underline{\mathbb{C}}}$ is the fourth-order elasticity moduli. This non-polyconvex potential [48] fails to respond appropriately in some cases e.g. the stress needed to shrink a bar to zero volume goes to zero which is physically unreasonable [49]. This limitation is due to the fact that St. Venant-Kirchhoff model does not take into account the volume change appropriately. Several modified versions of this model are proposed in literature in order to circumvent the aforementioned limitation [50, 49, 51] e.g.

the isotropic neo-Hookean model

$$\rho_e \psi^e(\underline{\mathbf{E}}^e) = \frac{1}{2} \lambda (\log(J_e))^2 + \mu \left(\text{trace}(\underline{\mathbf{E}}^e) - \log(J_e) \right) \quad (20)$$

λ and μ are Lamé coefficients. We mention that the proposed formulation is not restricted to a unique hyperelastic model. The model in Eq. (19) is proposed by default. In particular this choice is sufficient to represent the elastic part of the elastoplastic behavior of metals and alloys which are characterized by small elastic strains.

Two approaches for introducing thermoelasticity at finite strain may be distinguished. In the first approach, two configurations of material sample are considered: The initial configuration at uniform reference temperature, and the deformed configuration characterized by non-uniform stress and temperature fields [26, 52, 53]. The second approach has been proposed by [54, 55, 52, 56] and by [57, 58, 19] in the framework of thermo-elastoplasticity, where a supplementary intermediate configuration is considered. In the purely thermoelastic case, the deformation gradient is then split multiplicatively into thermal and elastic parts as

$$\underline{\mathbf{F}} = \underline{\mathbf{F}}^{el} \underline{\mathbf{F}}^\theta \quad (21)$$

An alternative decomposition in the form of $\underline{\mathbf{F}} = \underline{\mathbf{F}}^\theta \underline{\mathbf{F}}^{el}$ is suggested by [59]. For isotropic materials, the two approaches yield identical or similar results [56]. When extended to anisotropic elastoplasticity, the latter approach gives rise to potential decompositions of the form $\underline{\mathbf{F}} = \underline{\mathbf{F}}^{el} \underline{\mathbf{F}}^\theta \underline{\mathbf{F}}^p$ and all permutations of this decomposition can be found in the literature¹ without unambiguous justification for the best-suited choice. That is why the first approach, see [53], which relies on a unified thermoelastic deformation $\underline{\mathbf{F}}^e$ is preferred in the following, so that superfluous sub-decompositions are avoided.

The thermoelastic part of the Helmholtz free energy ψ^{the} is defined as a function of the thermoelastic deformation tensor, still defined by Eq. (19), and temperature as

$$\rho_e \psi^{the}(\underline{\mathbf{E}}^e, T) = \rho_e \psi^e(\underline{\mathbf{E}}^e) - \Delta T \underline{\boldsymbol{\beta}} : \underline{\mathbf{E}}^e - C_\varepsilon T^2 \quad (22)$$

where $\underline{\boldsymbol{\beta}}$ is a second order tensor describing thermal properties and C_ε is the specific heat at constant strain. If the free energy definition (19) is adopted, the stress is

¹ $\underline{\mathbf{F}} = \underline{\mathbf{F}}^{el} \underline{\mathbf{F}}^p \underline{\mathbf{F}}^\theta$ according to [19] and $\underline{\mathbf{F}} = \underline{\mathbf{F}}^{el} \underline{\mathbf{F}}^\theta \underline{\mathbf{F}}^p$ in [57, 58]

obtained as

$$\underline{\mathbf{\Pi}}^e = \underline{\mathbb{C}} : (\underline{\mathbf{E}}^e - \underline{\boldsymbol{\alpha}}_T \Delta T), \quad \underline{\boldsymbol{\alpha}}_T = \underline{\mathbb{C}}^{-1} : \underline{\boldsymbol{\beta}} \quad (23)$$

where $\underline{\boldsymbol{\alpha}}_T$ denotes the thermal expansion second order tensor which, for isotropic materials, can be reduced to only one scalar parameter as $\underline{\boldsymbol{\alpha}}_T = \alpha_T \underline{\mathbf{1}}$. Due to the fact that in usual materials thermal expansion always remains small, the proposed framework closely related to the usual small strain formulation will be sufficient.

2.4. Multimechanism dissipation potential

The inelastic deformation observed on the macroscale has various origins at the level of material microstructure (dislocation slip, twinning, grain boundary sliding, viscosity and molecular orientation in polymers...). Each mechanism leads to a specific type of non-linearity and constitutive equations. To sum up the contributions of all mechanisms, the total dissipation potential is written in the form

$$\Omega(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I) = \sum_k^N \Omega_k(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I) \quad (24)$$

Ω_k denotes the potential associated with the individual viscoplastic mechanism k . Each mechanism is characterized by several internal variables summarizing, at a given time, the material state and the influence of the past thermomechanical loading. The yield surface is defined in the stress-hardening variable (and temperature) space. For a given temperature and hardening, the elastic range is limited by the yield surface. It is a part of the vector space of dimension 9 of non-symmetric second order tensors denoted by $\mathcal{D}_e = \{\underline{\mathbf{M}} / f(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I, T) \leq 0\}$. The condition $f(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I, T) = 0$ defines the yield surface and is chosen here of the form

$$f(\underline{\mathbf{M}}, \underline{\mathbf{X}}, R) = [\underline{\mathbf{M}} - \underline{\mathbf{X}}]_{eq} - R_0 - R(p, \underline{\boldsymbol{\alpha}}_I) \quad (25)$$

where $[\diamond]_{eq}$ denotes an equivalent stress measure involving appropriate invariants of the tensor inside the brackets, R_0 is the initial yield stress, R describes the isotropic hardening law depending on the accumulated plastic strain p and internal variables $\underline{\boldsymbol{\alpha}}_I$, and $\underline{\mathbf{X}}$ is the back stress. Considering for instance the case of two internal variables $\underline{\boldsymbol{\alpha}}_I = (\underline{\boldsymbol{\alpha}}, r)$ and using Eq. (15), the associated forces $\underline{\mathbf{X}}$ and R are obtained through

$$\underline{\mathbf{X}} = \rho_e \frac{\partial \psi}{\partial \underline{\boldsymbol{\alpha}}}, \quad R = \rho_e \frac{\partial \psi}{\partial r} \quad (26)$$

where $\underline{\boldsymbol{\alpha}}$ and r are the internal variables associated to kinematic and isotropic hardening, respectively. Multiple yield functions and multiple kinematic hardening variables

can be used in the context of multimechanism approach, as proposed in [60, 61]

It follows from Eq. (16) and (18) that the inelastic strain rate is the sum of the individual contributions of all mechanisms:

$$\bar{\underline{\mathbf{L}}}^p = \sum_k^N \frac{\partial \Omega_k(\underline{\mathbf{M}}, \underline{\mathbf{A}}_I)}{\partial \underline{\mathbf{M}}} \quad (27)$$

This method circumvents the decomposition of the inelastic deformation into various contributions, often used in the literature in the form $\underline{\mathbf{F}}^p = \underline{\mathbf{F}}^{pl} \underline{\mathbf{F}}^v \underline{\mathbf{F}}^d \underline{\mathbf{F}}^{tr} \dots$ including plastic (rate-independent), viscoplastic, damage or transformation deformations. Such decompositions and all their possible permutations are hard to justify or define unambiguously. In contrast, each mechanism contributes incrementally to the inelastic deformation rate and can generally not be time-integrated into one single deformation part.

2.5. Kinematic hardening

In small strain theory, the use of Armstrong-Frederick-Chaboche models is widely accepted [28, 62, 63]. This model was enriched by a static recovery term, initially proposed by [29]. This term allows for a full or partial recovery of the kinematic hardening variable. It has been demonstrated that the Armstrong-Frederick model does not admit a dissipation potential [27] when used with a standard yield function [64]. Accordingly, this model is non standard. *Generalized standard materials* (GSM following [44]) are characterized by a single potential to describe the yield function, the flow rule and the evolution laws for internal variables. Nonlinear kinematic hardening can be introduced in this GSM framework by modifying the yield function as follows [64]

$$f(\underline{\mathbf{M}}, \underline{\mathbf{X}}) = [\underline{\mathbf{M}} - \underline{\mathbf{X}}]_{eq} - R_0 + \frac{D}{2C} \mathbf{J}^2(\underline{\mathbf{X}}) \quad (28)$$

where C and D are material parameters related to kinematic hardening evolution and $\mathbf{J}(\diamond) = \sqrt{\frac{3}{2}(\diamond : \diamond)}$. Nevertheless, this modification Eq. (28) induces an isotropic hardening term in addition to the one describing the kinematic hardening effect. A different approach has been proposed in [65] by introducing a new class of materials called *implicit standard materials*. This framework allows recovering an associative model.

The extension of the Armstrong-Frederick model to finite strain range can be achieved in several ways. This issue was investigated thoroughly in [20, 31, 36]. A widely used approach is based on the multiplicative decomposition of the plastic part

of the deformation gradient [20, 31, 7, 46]

$$\underline{\mathbf{F}}^p = \underline{\mathbf{F}}_s^p \underline{\mathbf{F}}_d^p \quad (29)$$

The free energy, depending on $\underline{\mathbf{E}}^e$ and $\underline{\mathbf{E}}_s^p = \frac{1}{2}(\underline{\mathbf{F}}_s^{pT} \underline{\mathbf{F}}_s^p - \mathbf{1})$, is split into elastic and kinematic hardening contributions as

$$\rho_e \psi(\underline{\mathbf{E}}^e, \underline{\mathbf{E}}_s^p) = \rho_e \psi^e(\underline{\mathbf{E}}^e) + \rho_e \psi^{\text{kin}}(\underline{\mathbf{E}}_s^p) \quad (30)$$

The back stress acting on the local intermediate configuration is derived from

$$\underline{\mathbf{X}} = \rho_e \underline{\mathbf{F}}_s^p \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{E}}_s^p} \underline{\mathbf{F}}_s^{pT} \quad (31)$$

The dissipation inequality becomes

$$\underline{\mathbf{M}} : \underline{\mathbf{D}}^p - \rho_e \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{C}}_s^p} : \dot{\underline{\mathbf{C}}}_s^p \geq 0 \quad (32)$$

$$\left(\underline{\mathbf{M}} - 2\rho_e \underline{\mathbf{F}}_s^p \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{C}}_s^p} \underline{\mathbf{F}}_s^{pT} \right) : \underline{\mathbf{D}}^p + 2\rho_e \underline{\mathbf{C}}_s^p \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{C}}_s^p} : \underline{\mathbf{D}}_d^p \geq 0 \quad (33)$$

where

$$\underline{\mathbf{C}}_s^p = \underline{\mathbf{F}}_d^{p-T} \underline{\mathbf{C}}^p \underline{\mathbf{F}}_d^{p-1} \quad (34)$$

and

$$\dot{\underline{\mathbf{C}}}_s^p = 2\underline{\mathbf{F}}_s^{pT} \underline{\mathbf{D}}^p \underline{\mathbf{F}}_s^p - 2 \text{sym} \left(\underline{\mathbf{C}}_s^p \underline{\mathbf{D}}_d^p \right), \quad \underline{\mathbf{D}}_d^p = \text{sym}(\dot{\underline{\mathbf{F}}}_d^p \underline{\mathbf{F}}_d^{p-1}) \quad (35)$$

We denote by $\underline{\mathbf{X}} = 2\rho_e \underline{\mathbf{F}}_s^p \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{C}}_s^p} \underline{\mathbf{F}}_s^{pT}$ the back stress acting on the local intermediate configuration and by $\underline{\mathbf{M}}_d = 2\rho_e \underline{\mathbf{C}}_s^p \frac{\partial \psi^{\text{kin}}}{\partial \underline{\mathbf{C}}_s^p}$ a Mandel-like stress tensor. The evolution equations satisfying (33) are given by

$$\begin{cases} \underline{\mathbf{D}}^p = \dot{\lambda} \frac{\partial f}{\partial \underline{\mathbf{M}}} \\ \underline{\mathbf{D}}_d^p = \dot{\lambda} \frac{b}{c} \underline{\mathbf{M}}_d \end{cases} \quad (36)$$

where b and c are material constants. For time-dependent plasticity, the plastic multiplier is given by $\dot{\lambda} = \frac{\partial \Omega}{\partial f}$ where Ω is the dissipation potential. Otherwise, the

plastic multiplier $\dot{\lambda}$ is determined by applying the consistency condition $\dot{f} = 0$.

The proposed kinematic hardening model

As investigated in [31, 36], different extensions of the Armstrong-Frederick model lead to qualitatively similar results if the material parameters are selected appropriately. Another formulation of the kinematic hardening model with both static and dynamic recovery terms is adopted here avoiding any further decomposition of $\underline{\mathbf{F}}^p$ and resulting from the non-associative evolution equation as

$$\underline{\mathbf{X}} = \frac{2}{3}C\boldsymbol{\alpha}, \quad \dot{\underline{\mathbf{X}}} = \overline{\mathbf{D}}^p - \dot{\lambda}D\boldsymbol{\alpha} - \frac{3}{2}\left(\frac{\mathbf{J}(\underline{\mathbf{X}})}{M}\right)^m \frac{\underline{\mathbf{X}}}{\mathbf{J}(\underline{\mathbf{X}})} \quad (37)$$

where C , D , m and M are material parameters. The second term in the right describes the dynamic recovery and the third one is responsible for static recovery. This evolution equation must be complemented by the initial value of $\boldsymbol{\alpha}$.

Remark 1. *The kinematic hardening variable $\boldsymbol{\alpha}$ in Eq. (37) is symmetric provided that its initial value is symmetric. This rule can be generalized to a non-symmetric kinematic hardening variable by substituting $\overline{\mathbf{D}}^p$ in Eq. (37) by $\overline{\mathbf{L}}^p$*

$$\dot{\underline{\mathbf{X}}} = \overline{\mathbf{L}}^p - \dot{\lambda}D\boldsymbol{\alpha} - \frac{3}{2}\left(\frac{\mathbf{J}(\underline{\mathbf{X}})}{M}\right)^m \frac{\underline{\mathbf{X}}}{\mathbf{J}(\underline{\mathbf{X}})} \quad (38)$$

It follows that $\underline{\mathbf{X}}$ is generally not symmetric, like the Mandel stress tensor. We mention also that a model with non-symmetric internal variable of kinematic hardening has been proposed in [45].

A more accurate description of a large variety of experimental stress-strain curves is possible by combining several independent kinematic hardening variables [29] such that

$$\underline{\mathbf{X}} = \sum_{i=0}^{N_X} \underline{\mathbf{X}}_i, \quad \underline{\mathbf{X}}_i = \frac{2}{3}C_{ij}\boldsymbol{\alpha}_j \quad (39)$$

where N_X is the total number of kinematic hardening variables associated with (visco)-plastic mechanisms. C_{ij} is a matrix describing the interaction between kinematic hardening variables.

2.6. Plastic spin

We define the velocity gradient tensor $\overline{\mathbf{L}}$ as the pull back of $\underline{\mathbf{L}}$ to the intermediate configuration. It can then be split into purely elastic and plastic parts as

$$\overline{\mathbf{L}} = \underline{\mathbf{F}}^{e-1} \underline{\mathbf{L}} \underline{\mathbf{F}}^e = \overline{\mathbf{L}}^e + \overline{\mathbf{L}}^p \quad (40)$$

noting

$$\bar{\underline{\mathbf{L}}}^e = \underline{\underline{\mathbf{F}}}^{e-1} \dot{\underline{\underline{\mathbf{F}}}}^e \quad \text{and} \quad \bar{\underline{\mathbf{L}}}^p = \dot{\underline{\underline{\mathbf{F}}}}^p \underline{\underline{\mathbf{F}}}^{p-1} \quad (41)$$

Strain rate and spin tensors expressed in the intermediate isoclinic configuration are derived as

$$\bar{\underline{\mathbf{L}}} = \bar{\underline{\mathbf{D}}} + \bar{\underline{\mathbf{W}}}, \quad \bar{\underline{\mathbf{L}}}^e = \bar{\underline{\mathbf{D}}}^e + \bar{\underline{\mathbf{W}}}^e, \quad \bar{\underline{\mathbf{L}}}^p = \bar{\underline{\mathbf{D}}}^p + \bar{\underline{\mathbf{W}}}^p \quad (42)$$

The plastic deformation is induced by various mechanisms as mutual slips between material particles (crystals in metals, soil particles, etc.) without causing the rotation of the substructure defined by appropriate directors. Hence, the rotation and stretch of the substructure is induced only by the elastic distortion, including additional rigid body rotation, both included in $\underline{\underline{\mathbf{F}}}^e$. Accordingly, the spin of the substructure $\bar{\underline{\mathbf{W}}}^e$ is independent of plastic deformation. Therefore, $\bar{\underline{\mathbf{W}}}^e$ is given by subtracting the plastic spin from the total spin as follows

$$\bar{\underline{\mathbf{W}}}^e = \bar{\underline{\mathbf{W}}} - \bar{\underline{\mathbf{W}}}^p = \text{skw}(\underline{\underline{\mathbf{F}}}^{e-1} \dot{\underline{\underline{\mathbf{F}}}}^e) \quad (43)$$

One should note that if the plastic spin $\bar{\underline{\mathbf{W}}}^p$ vanishes, the spin of directors will coincide with the material rotation rate.

Two important classes of plastic spin constitutive laws are distinguished in the literature. The first one is derived from normality rules whereas the second one follows from the application of tensor representation theorems.

2.6.1. Plastic spin derived from the tensor representation theorem

A general explicit expression of plastic spin has been proposed independently by [40, 39] using the tensor representation theorem as

$$\begin{aligned} \bar{\underline{\mathbf{W}}}^p = & \beta_1(\underline{\underline{\mathbf{a}}}\underline{\underline{\mathbf{s}}} - \underline{\underline{\mathbf{s}}}\underline{\underline{\mathbf{a}}}) + \beta_2(\underline{\underline{\mathbf{a}}}^2\underline{\underline{\mathbf{s}}} - \underline{\underline{\mathbf{s}}}\underline{\underline{\mathbf{a}}}^2) + \beta_3(\underline{\underline{\mathbf{a}}}\underline{\underline{\mathbf{s}}}^2 - \underline{\underline{\mathbf{s}}}^2\underline{\underline{\mathbf{a}}}) \\ & + \beta_4(\underline{\underline{\mathbf{a}}}\underline{\underline{\mathbf{s}}}\underline{\underline{\mathbf{a}}}^2 - \underline{\underline{\mathbf{a}}}^2\underline{\underline{\mathbf{s}}}\underline{\underline{\mathbf{a}}}) + \beta_5(\underline{\underline{\mathbf{s}}}\underline{\underline{\mathbf{a}}}\underline{\underline{\mathbf{s}}}^2 - \underline{\underline{\mathbf{s}}}^2\underline{\underline{\mathbf{a}}}\underline{\underline{\mathbf{s}}}) + \dots \end{aligned} \quad (44)$$

where $\underline{\underline{\mathbf{s}}}$ is the stress measure, $\underline{\underline{\mathbf{a}}}$ denotes an internal variable and β_i are material parameters. $\underline{\underline{\mathbf{a}}}$ can be also regarded as structure variables [66, 67]. For instance, for a unidirectional composite described by a director $\underline{\underline{\mathbf{n}}}$ [68], $\underline{\underline{\mathbf{a}}} = \underline{\underline{\mathbf{n}}} \otimes \underline{\underline{\mathbf{n}}}$. This allows to describe the evolution of the material substructure or directors [43]. To the best of our knowledge, all the studies of models including plastic spin make use only of the first order approximation of Eq. (44). By doing so, the plastic spin expressed in terms of Mandel's stress tensor is given by

$$\bar{\underline{\mathbf{W}}}^p = \beta(\underline{\underline{\mathbf{M}}}\bar{\underline{\mathbf{D}}}^p - \bar{\underline{\mathbf{D}}}^p\underline{\underline{\mathbf{M}}}) \quad (45)$$

This model is used to describe the evolution of anisotropic axes [41, 43] where β is a parameter having the dimension of the inverse of stress. $\overline{\mathbf{W}}^p$ vanishes as long as $\underline{\mathbf{M}}$ and $\underline{\mathbf{D}}^p$ are coaxial.

2.6.2. Plastic spin derived from the normality rule

According to this approach, the plastic spin is derived naturally from the normality rule as the skew-symmetric part of $\underline{\mathbf{L}}^p$

$$\overline{\mathbf{W}}^p = \text{skw}(\underline{\mathbf{L}}^p) = \text{skw} \left(\frac{\partial \Omega(\underline{\mathbf{M}}, \mathbf{A}_I)}{\partial \underline{\mathbf{M}}} \right) \quad (46)$$

This model of plastic spin will be studied in the case of crystal plasticity (see section 4.6).

3. Implementation in an object oriented FEM code

3.1. Object oriented architecture

The full description of the implementation of a generic formulation of constitutive equations in an object-oriented code, like the Z-set software² used in the present work, is detailed in [47, 64]. The software is designed such that material models are implemented independently from the FEM. Therefore, the material library can be used by other FEM codes. This is made possible by proper interfaces between the FEM software and the material library Z-mat. The implementation of a generic material behaviour requires the following ingredients:

- **grad**: the imposed variable e.g. $\underline{\mathbf{F}}$. It allows driving the behaviour externally.
- **flux**: returned variable associated to a **grad** variable. It represents the response of the behavior law to the application of **grad** variable, e.g. the conjugate stresses $\underline{\boldsymbol{\sigma}}$, $\underline{\mathbf{P}}$
- **EP**: external parameters as temperature, humidity, grain size, ... EP are set by the user and thus always known in advance.
- **IV**: Integrated variables which are to be integrated over a given time increment in order to update **flux**, e.g. $\underline{\mathbf{F}}^e$, $\boldsymbol{\alpha}_I$, ...

²See www.zset-software.com

- **AV**: auxiliary variables do not define the material state directly, and they are kept for output. They may be useful in post-processing.
- **CO**: material parameters appearing as coefficients introduced in constitutive laws. They may depend on EP, IV and AV.

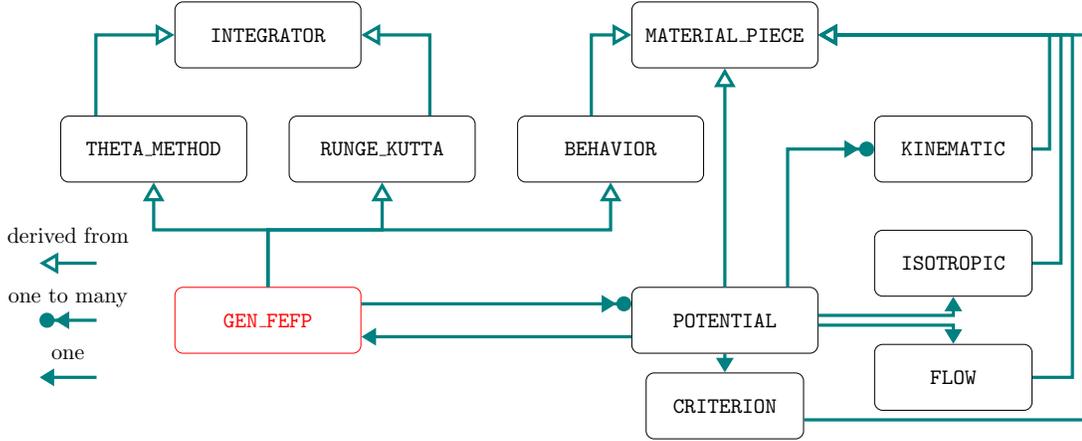

Figure 2: A diagram showing the organization of some objects used to build material behaviors.

Fig. 2 describes the implementation of a class named `GEN_FEFP` derived from `BEHAVIOR`. This class allows to consider various inelastic mechanisms through the class `POTENTIAL`. Each potential includes a flow rule (time-independent plasticity, Norton power law...), several isotropic and kinematic hardening rules. The internal variables associated with kinematic hardening (i.e. $\boldsymbol{\alpha}$) are held by the corresponding `KINEMATIC` object. Explicit and implicit integration of constitutive equations are handled by `RUNGE_KUTTA` and `THETA_METHOD` classes, respectively. The `CRITERION` object specifies the yield surface (von Mises, Tresca, Hill, ...). This implementation allows a minimum programming effort since all the required classes to build a material behavior (except `GEN_FEFP`) are already implemented and used in the framework of other formulations (small strain, hypoelasto-plasticity, ...).

3.2. Global resolution of equilibrium equations

The current (resp. reference) configuration of the body at time t (resp. t_0) is called V (resp. V_0) with boundary ∂V (resp. ∂V_0). The latter can be split into the sub-boundaries ∂V^u and ∂V^{tr} such that $\partial V = \partial V^u \cup \partial V^{tr}$ and $\partial V^u \cap \partial V^{tr} = \emptyset$, where Dirichlet and Neumann conditions are respectively prescribed. Corresponding surfaces ∂V_0^u and ∂V_0^{tr} are defined on the reference boundary of the body. The

space of kinematically admissible displacements field is the set of sufficiently regular displacement functions that satisfies

$$\mathcal{K} = \{\underline{\mathbf{u}}(\underline{\mathbf{x}}) | \underline{\mathbf{u}} = \tilde{\underline{\mathbf{u}}}(\underline{\mathbf{x}}) \quad \text{if} \quad \underline{\mathbf{x}} \in \partial V^u\} \quad (47)$$

knowing that $\tilde{\underline{\mathbf{u}}}$ is the prescribed displacement field on ∂V^u . Virtual displacements are set to zero over ∂V^u defining the space of virtual displacements as

$$\mathcal{V} = \{\underline{\boldsymbol{\eta}}(\underline{\mathbf{x}}) | \underline{\boldsymbol{\eta}}(\underline{\mathbf{x}}) = 0 \quad \text{if} \quad \underline{\mathbf{x}} \in \partial V^u\} \quad (48)$$

The surface tractions are prescribed over the region ∂V^{tr} .

Following [69] among others, the initial boundary value problem amounts to find a displacement field $\underline{\mathbf{u}} \in \mathcal{K}$ that satisfies

$$\mathcal{W}(\underline{\mathbf{u}}, \underline{\boldsymbol{\eta}}) = 0, \quad \forall \underline{\boldsymbol{\eta}} \in \mathcal{V} \quad (49)$$

where the virtual work functional under finite deformation is given by

$$\mathcal{W}(\underline{\mathbf{u}}, \underline{\boldsymbol{\eta}}) = \int_{V_0} (\underline{\mathbf{P}} : \nabla_x \underline{\boldsymbol{\eta}} - \underline{\mathbf{b}} \cdot \underline{\boldsymbol{\eta}}) dV - \int_{\partial V_0^{tr}} \underline{\mathbf{t}} \cdot \underline{\boldsymbol{\eta}} dS \quad (50)$$

where $\underline{\mathbf{b}}$ and $\underline{\mathbf{t}}$ denote the reference body force and surface traction fields, respectively. $\underline{\mathbf{P}}$ stands for the Boussinesq stress tensor. The linearization of Eq. (49) at a given state defined by the field $\underline{\mathbf{u}}^*$ is written

$$\mathcal{W}(\underline{\mathbf{u}}^*, \underline{\boldsymbol{\eta}}) + D\mathcal{W}(\underline{\mathbf{u}}^*, \underline{\boldsymbol{\eta}})[\Delta \underline{\mathbf{u}}] = 0, \quad \forall \underline{\boldsymbol{\eta}} \in \mathcal{V} \quad (51)$$

where $D\mathcal{W}(\underline{\mathbf{u}}^*, \underline{\boldsymbol{\eta}})[\Delta \underline{\mathbf{u}}]$ is the directional derivative of $\mathcal{W}(\underline{\mathbf{u}}^*, \underline{\boldsymbol{\eta}})$ in the direction of $\Delta \underline{\mathbf{u}}$. For convenience, the force and surface traction fields on ∂V_0^{tr} are assumed to

be independent of the displacement field. Then,

$$DW(\underline{\mathbf{u}}^*, \underline{\boldsymbol{\eta}})[\Delta \underline{\mathbf{u}}] = \frac{d}{d\epsilon} \left(\mathcal{W}(\underline{\mathbf{u}}^* + \epsilon \Delta \underline{\mathbf{u}}, \underline{\boldsymbol{\eta}}) \right) \Big|_{\epsilon=0} \quad (52)$$

$$= \frac{d}{d\epsilon} \left(\int_{V_0} \underline{\mathbf{P}}(\underline{\mathbf{F}}^* + \epsilon \Delta \underline{\mathbf{F}}) : \nabla_X \underline{\boldsymbol{\eta}} \right) \Big|_{\epsilon=0} \quad (53)$$

$$= \frac{d}{d\epsilon} \left(\int_{V_0} [\underline{\mathbf{P}}(\underline{\mathbf{F}}^*) + \Delta \underline{\mathbf{P}}(\underline{\mathbf{F}}^*, \epsilon \Delta \underline{\mathbf{F}})] : \nabla_X \underline{\boldsymbol{\eta}} \right) \Big|_{\epsilon=0} \quad (54)$$

$$= \int_{V_0} \left[\frac{\partial \underline{\mathbf{P}}}{\partial \Delta \underline{\mathbf{F}}} \Big|_{\underline{\mathbf{F}}^*} : \Delta \underline{\mathbf{F}} \right] : \nabla_X \underline{\boldsymbol{\eta}} \quad (55)$$

where

$$\Delta \underline{\mathbf{F}} = \nabla_X(\Delta \underline{\mathbf{u}}), \quad \underline{\mathbf{F}}^* = \underline{\mathbf{1}} + \nabla_X \underline{\mathbf{u}}^* \quad (56)$$

The Boussinesq stress tensor $\underline{\mathbf{P}}$ is related to Kirchhoff's stress tensor $\underline{\boldsymbol{\tau}}$ by

$$\underline{\mathbf{P}} = \underline{\boldsymbol{\tau}} \underline{\mathbf{F}}^{-T} \quad (57)$$

The tangent modulus is computed as

$$\underline{\mathcal{A}} \approx \frac{\partial \underline{\mathbf{P}}}{\partial \Delta \underline{\mathbf{F}}} \Big|_{\underline{\mathbf{F}}^*} = \frac{\partial \underline{\boldsymbol{\tau}}}{\partial \Delta \underline{\mathbf{F}}} \Big|_{\underline{\mathbf{F}}^*} \underline{\mathbf{F}}^*{}^{-T} + \underline{\boldsymbol{\tau}} \frac{\partial \underline{\mathbf{F}}^{-T}}{\partial \Delta \underline{\mathbf{F}}} \Big|_{\underline{\mathbf{F}}^*} \quad (58)$$

or in index notation

$$\mathcal{A}_{ijkl} = \frac{\partial \tau_{ip}}{\partial \Delta F_{kl}} F_{jp}^{-1} - \tau_{ip} F_{jk}^{-1} F_{lp}^{-1} \quad (59)$$

By approximating the domain V_0 with a finite number of elements n_{el} denoted by V_0^e , the discrete form of the virtual work (50) is written

$$\sum_{e=0}^{n_{el}} \int_{V_0^e} \left([\mathbf{B}]^T \{\mathbf{P}\} - [\mathbf{N}^T] \{\mathbf{b}\} \right) dV - \sum_{e=0}^{n_{el}} \int_{\partial V_0^{tr,e}} [\mathbf{N}]^T \{\mathbf{t}\} dS = 0 \quad (60)$$

$[\mathbf{N}]$ and $[\mathbf{B}]$ denote the interpolation matrix and the discrete material gradient operator, respectively (see appendix 6). The element stiffness matrix is given by

$$[\mathbf{K}^e] = \int_{V_0^e} [\mathbf{B}]^T [\mathcal{A}] [\mathbf{B}] dV \quad (61)$$

The global stiffness matrix is obtained by assembling the element tangent stiffness

matrices as

$$[\mathbf{K}^g] = \mathbf{A} \sum_{e=1}^{n_{el}} ([\mathbf{K}^e]) \quad (62)$$

The linear set of equations to be solved for $\Delta \underline{\mathbf{u}}$ iteratively is given by

$$[\mathbf{K}]^g \Delta \underline{\mathbf{u}} = -\mathcal{R}(\underline{\mathbf{u}}) \quad (63)$$

where

$$\mathcal{R}(\underline{\mathbf{u}}) = f^{int}(\underline{\mathbf{u}}) - f^{ext} \quad (64)$$

The global internal and external forces are written

$$f^{int} = \mathbf{A} \sum_{e=1}^{n_{el}} \left(\int_{V_0^e} [\mathbf{B}]^T \{\mathbf{P}\} dV \right) \quad (65)$$

$$f^{ext} = \mathbf{A} \sum_{e=1}^{n_{el}} \left(\int_{V_0^e} [\mathbf{N}^T] \{\mathbf{b}\} dV + \int_{\partial V_0^{tr,e}} [\mathbf{N}]^T \{\mathbf{t}\} dS \right) \quad (66)$$

The consistent tangent moduli $\underline{\mathcal{A}}^c$ are calculated from the implicit incremental constitutive equations as

$$\frac{\partial \underline{\mathcal{T}}(\alpha_n, \underline{\mathbf{F}}_{n+1})}{\partial \Delta \underline{\mathbf{F}}_{n+1}} = \frac{\partial \underline{\mathcal{T}}(\alpha_n, \underline{\mathbf{F}}_{n+1})}{\partial \Delta \underline{\mathbf{F}}_{n+1}^e} \frac{\partial \Delta \underline{\mathbf{F}}_{n+1}^e}{\partial \Delta \underline{\mathbf{F}}_{n+1}} \quad (67)$$

The general iterative resolution algorithm of the incremental boundary value problem is summarized in Table 1.

3.3. Integration of constitutive equations

The set of time-integrated variables is given by

$$\mathcal{V}_{int} = \left\{ \underline{\mathbf{F}}^e \mid p_1, \boldsymbol{\alpha}_1; \cdots; p_n, \boldsymbol{\alpha}_n \right\} \quad (68)$$

p_i is the accumulated inelastic strain associated with the i -th mechanism, $\boldsymbol{\alpha}_i$ denote internal variables describing both isotropic (e.g. r_i) and kinematic hardening (e.g. $\boldsymbol{\alpha}_i$) specific to each mechanism. Semicolons in (68) represent the separation between different mechanisms. A distinction between $\boldsymbol{\alpha}_i$ and p_i was considered so that partial derivatives required by integration methods can be implemented efficiently. The model for each deformation mechanism will be defined by the following system of elementary equations via the `POTENTIAL` interface:

Table 1: Iterative resolution algorithm of the incremental boundary value problem

Result: Compute the displacement $\underline{\mathbf{u}}_{n+1}$ at t_{n+1}

(i) Set initial guess $\underline{\mathbf{u}}_{n+1}^{(0)}$, $k = 1$

while $k < N_{iter}^{max}$ **do**

(ii) $\underline{\mathbf{u}}_{n+1}^{(k)} = \underline{\mathbf{u}}_{n+1}^{(k-1)} + \Delta \underline{\mathbf{u}}^{(k)}$

(iii) $\underline{\mathbf{F}}_{n+1}^{(k)} = \underline{\mathbf{1}} + \nabla_X \underline{\mathbf{u}}_{n+1}^{(k)}$

(iv) Update stress and state variables using constitutive equations

(v) Compute consistent tangent moduli $\underline{\mathbf{A}}^c$

(vi) Calculate residuals $\mathcal{R}(\underline{\mathbf{u}}_{n+1}^{(k)}) = f^{int}(\underline{\mathbf{u}}_{n+1}^{(k)}) - f_{n+1}^{ext}$

if *convergence* **then**

| (viii) $\Delta \underline{\mathbf{u}}^{(k+1)} = -[\mathbf{K}^g]^{-1} \mathcal{R}$, $k \leftarrow k+1$

end

end

- Plasticity criteria $f_i(\underline{\mathbf{M}}, p_i, \underline{\boldsymbol{\alpha}}_i)$: Each criterion depends on the Mandel stress tensor, the accumulated plastic strain and variables that describe multi-kinematic hardening. Only the case where a criterion is associated with one and only one dissipation potential is discussed in the following. Alternative models involving multi-mechanisms and one single unified criterion can be found in [61]. The implementation of this kind of models is discussed thoroughly in [47].
- Flow rule: The plastic multiplier is defined in two ways. For time-independent plasticity, $\dot{\lambda}$ must fulfill the consistency condition Eq. (17). In the rate-dependent case, the multiplier is defined as the derivative of dissipation potential Ω_i w.r.t the yield function f_i Eq. (18). It follows that

$$\underline{\mathbf{L}}_i^p = \dot{\lambda}_i \frac{\partial f_i}{\partial \underline{\mathbf{M}}} = \dot{\lambda}_i \underline{\mathbf{N}}_i \quad (69)$$

with $\underline{\mathbf{N}}_i$ being the inelastic flow direction.

- Isotropic and kinematic hardening laws take the generic form

$$\dot{\underline{\boldsymbol{\alpha}}}_i = \dot{\lambda}_i \underline{\mathbf{m}}_i - \dot{\underline{\mathbf{q}}}_i \quad (70)$$

where \mathbf{m}_i is the hardening potential normal and $\dot{\mathbf{q}}_i$ represents the time derivative of the hardening variable evolution due to static recovery effects. Note that in case of associated plasticity, $\mathbf{m}_i = \frac{\partial f}{\partial \mathbf{A}_i}$, meaning that the hardening potential normal is simply given by the normal to the yield surface. For instance, $\mathbf{m}_i = \mathbf{N}_i - \frac{3D_i}{2C_i} \mathbf{X}_i$ for nonlinear kinematic hardening. The evolution of the nonlinear isotropic hardening variable r , from Eq. (14), writes $\dot{r} = \dot{\lambda}(1 - \frac{R}{Q})$ which imply that $m = 1 - \frac{R}{Q}$. The integrated variable r is related to R by $R = bQr$ (see Eq. (15)), with the material parameters b and Q . The latter model can be integrated analytically (cf. Eq. (104) in Section 5), which allows to reduce the number of time-integrated variables in the code.

Two integration methods for ordinary differential equations have been implemented for the present general formulation. The first one is explicit, namely second or fourth order Runge-Kutta methods with automatic time-stepping, the second one is implicit: θ -method resolved using the iterative Newton-Raphson scheme. Each inelastic deformation mechanism is accounted for within the class `POTENTIAL`. This class provides the increment of integrated variables for explicit integration and residuals for implicit integration. Each `POTENTIAL` object possesses various methods with regard to the model definition (isotropic and kinematic hardening, yield criteria, ...). The implementation supports an unlimited number of `POTENTIAL` objects with possible interactions. In case of interactions, another class is dedicated to add interaction terms appropriately. The expression of $\bar{\mathbf{L}}^p$ is calculated through summation of all potential contributions according to Eq. (27), in addition to the supplementary ad-hoc constitutive equation for the plastic spin.

`RUNGE_KUTTA`: . the integration of variables is based on the calculation of the rate of \mathcal{V}_{int} . For viscoplastic cases, the plastic multiplier is calculated using the flow rule. For time-independent plasticity, the increment of the plastic multiplier is derived from the consistency condition as

$$\begin{aligned}
2\mathbf{N} : \left[\mathbf{1} \otimes \mathbf{\Pi}^e + \frac{1}{2} \mathbf{C}^e \cdot \mathbf{C} \right] : \left(\mathbf{F}^{eT} \mathbf{D} \mathbf{F}^e - \mathbf{C}^e \sum_i^N \bar{\mathbf{L}}_i^p \right) \\
+ \frac{\partial f}{\partial \mathbf{A}_i} : \sum_i^N \frac{\partial \mathbf{A}_i}{\partial \boldsymbol{\alpha}_i} \dot{\boldsymbol{\alpha}}_i + \frac{\partial f}{\partial p_i} \dot{p}_i + \frac{\partial f}{\partial \text{EP}} : \dot{\text{EP}} = 0
\end{aligned} \tag{71}$$

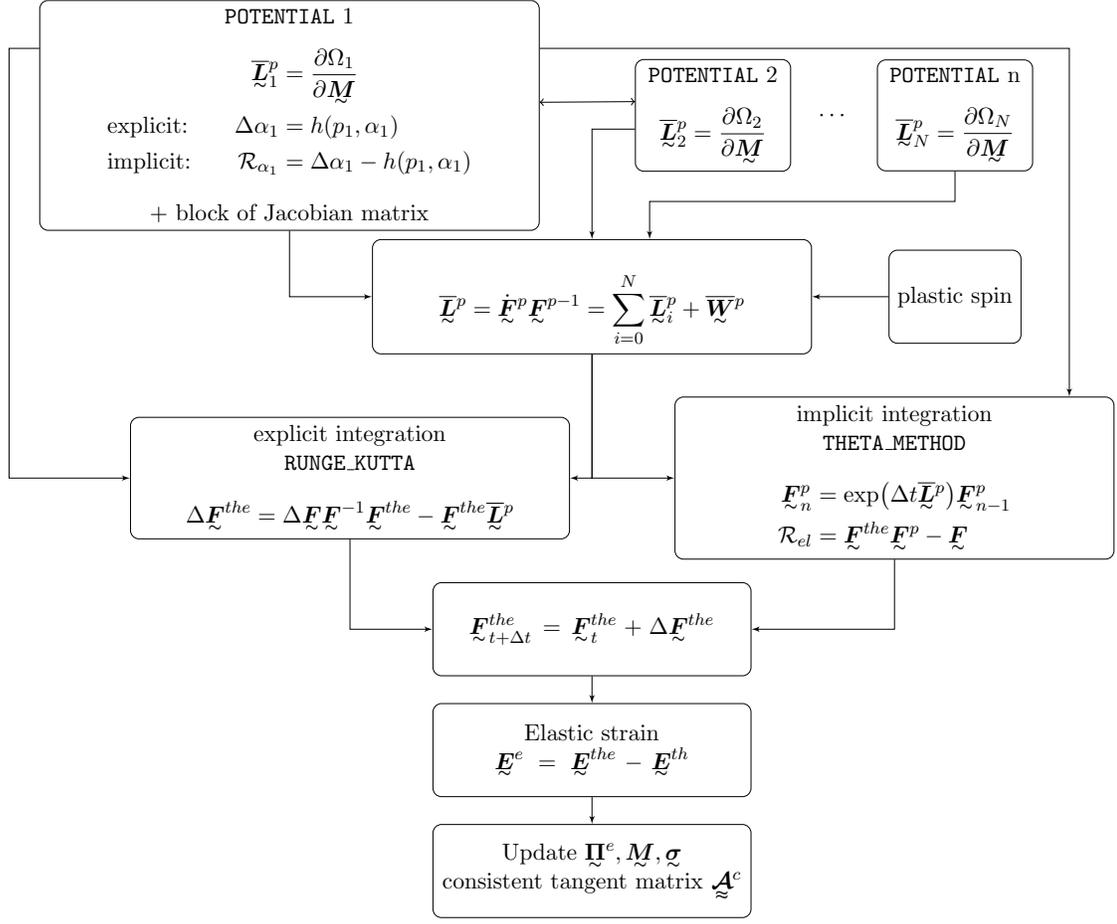

Figure 3: Diagram showing explicit and implicit integration methods. Each POTENTIAL provides the update of associated internal variables and the corresponding block of the Jacobian matrix.

THETA_METHOD: $\theta = 0$ corresponds to the explicit Euler method and $\theta = 1$ results in the so-called backward Euler method. The constitutive equations are expressed in the residual form as follows

$$\mathcal{R}_{el} = \mathbf{F}^e \mathbf{F}^p - \mathbf{F} \text{ or } \mathcal{R}_{el} = \Delta \mathbf{F}^e - \Delta \mathbf{F} \mathbf{F}^{-1} \mathbf{F}_{cor}^e + \mathbf{F}_{cor}^e \sum_{i=0}^N \Delta p_i \mathbf{N}_i \quad (72)$$

$$\mathcal{R}_{p_i} = f_i(\mathbf{M}, \mathbf{A}_i) \text{ or } \mathcal{R}_{p_i} = \Delta p_i - \Delta t \frac{\partial \Omega}{\partial f_i} \text{ (viscoplasticity)} \quad (73)$$

$$\mathcal{R}_{\alpha_i} = \Delta \alpha_i - \Delta p_i \mathbf{m}_i - \Delta t \dot{\mathbf{q}}_i \quad (74)$$

N being the total number of mechanisms. The residual in Eq. (72)-left involves the use of the exponential mapping which satisfies the plastic incompressibility [70, 71]. Its linearization requires the expression of the derivative of the exponential of a second order tensor w.r.t. a second order tensor. As $\bar{\mathbf{L}}^p$ is in general non symmetric, calculating these terms is a non-trivial task. In that case, the infinite series representation is used and truncated [31, 46]. Alternatively, in Eq. (72)b, the plastic incompressibility is not satisfied anymore. For this reason, the elastic part of the deformation gradient is corrected at each iteration as

$$\mathbf{F}_{cor}^e = \left(\frac{\det \mathbf{F}}{\det \mathbf{F}^e} \right)^{\frac{1}{3}} \mathbf{F}^e \quad (75)$$

The values of all associated forces and parameters evaluated at an intermediate time designated by θ are

$$\mathcal{V}_{int}^{t+\theta\Delta t} = \mathcal{V}_{int}^t + \theta\Delta\mathcal{V}_{int} \quad (76)$$

The set of equations (72,73,74) can be gathered in the following form

$$\mathcal{R}(\mathcal{V}_{int}^{t+\theta\Delta t}, \Delta\mathcal{V}_{int}) = 0 \quad (77)$$

Since Eq. (77) is highly non-linear, it is usually solved by means of a Newton method which requires the calculation of the Jacobian matrix $[J]$. The new estimate of $\Delta\mathcal{V}_{int}^{k+1}$ is then given by

$$\Delta\mathcal{V}_{int}^{k+1} = \Delta\mathcal{V}_{int}^k - [J]^{-1}\mathcal{R}^k \quad (78)$$

where

$$[J] = \left. \frac{\partial \mathcal{R}}{\partial \Delta\mathcal{V}_{int}} \right|_{k+1} \quad (79)$$

and \mathcal{R}^k denotes the local residual at the k -th iteration. The variation of \mathcal{R} resulting from the variation of ν_{int} and \mathbf{F} vanishes as well

$$\delta\mathcal{R} = \frac{\partial \mathcal{R}}{\partial \Delta\nu_{int}} \delta\Delta\nu_{int} + \frac{\partial \mathcal{R}}{\partial \Delta\mathbf{F}} \delta\Delta\mathbf{F} = 0 \quad (80)$$

which implies that, after convergence, the inverted Jacobian matrix relates the change of $\Delta\nu_{int}$ with respect to a change in $\Delta\mathbf{F}$ as

$$\delta\Delta\nu_{int} = - \left(\frac{\partial \mathcal{R}}{\partial \Delta\nu_{int}} \right)^{-1} \frac{\partial \mathcal{R}}{\partial \Delta\mathbf{F}} \delta\Delta\mathbf{F} \quad (81)$$

The expression of the Jacobian matrix is detailed in the appendix (6). By using Eq. (81), one can calculate the term $\frac{\partial \Delta \mathbf{F}^e}{\partial \Delta \mathbf{F}}$ in Eq. (67).

4. Applications to volume element simulations

The capabilities of the model formulation and its implementation are illustrated in this section in the case of complex homogeneous loading conditions. The tests are therefore performed at the material point level and require integration of the constitutive equations. Some original features of the models are highlighted.

4.1. Cyclic closed deformation path

Hypoelastic formulations are well known to result in some spurious predictions under complex loading conditions. For instance, when a closed strain cycle is applied, the resulting stress cycle is not necessarily closed. This issue was investigated theoretically [5, 6] and numerically [7] in the case of purely mechanical loadings. In this example, the response of finite strain formulations is investigated in the thermoelastic domain for two different loading cases. In both cases, we consider two hypoelastic constitutive models for the Cauchy stress based on the Jaumann and Green-Naghdi rates and a hyperelastic model given by Eq. (23).

Case 1: A cyclic and non-proportional mechanical loading is applied (see Fig. 4-a). Accordingly, the applied deformation gradient and the resulting Cauchy stress tensor have the following forms

$$\begin{pmatrix} F_{11}(t) & F_{12}(t) & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad \text{and} \quad \mathbf{\varrho} = \begin{pmatrix} \sigma_{11} & \sigma_{12} & 0 \\ \sigma_{12} & \sigma_{22} & 0 \\ 0 & 0 & \sigma_{33} \end{pmatrix} \quad (82)$$

where the functions $F_{11}(t)$ and $F_{12}(t)$ are prescribed.

Case 2: Is concerned with a non-proportional thermomechanical loading described in Fig. 4-b and corresponding to prescribed shear $F_{12}(t)$ and temperature variation $\Delta T(t)$. The deformation gradient is imposed as

$$\mathbf{F} = \begin{pmatrix} 1 & F_{12}(t) & 0 \\ 0 & F_{22}^* & 0 \\ 0 & 0 & F_{33}^* \end{pmatrix} \quad \text{and} \quad \mathbf{\varrho} = \begin{pmatrix} \sigma_{11} & \sigma_{12} & 0 \\ \sigma_{12} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad (83)$$

F_{22}^* and F_{33}^* are determined by the analysis in such a way that the conjugate Cauchy stress components vanish. The component σ_{11} does not vanish due to the applied

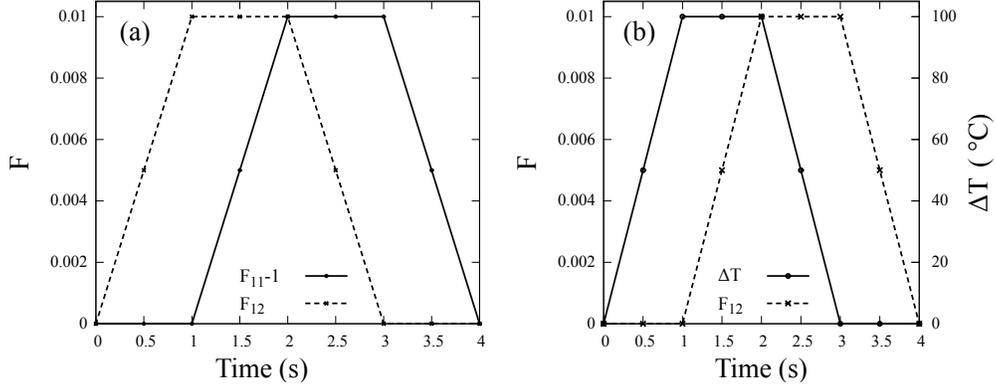

Figure 4: Illustration of loading conditions corresponding to (a) case 1, (b) case 2

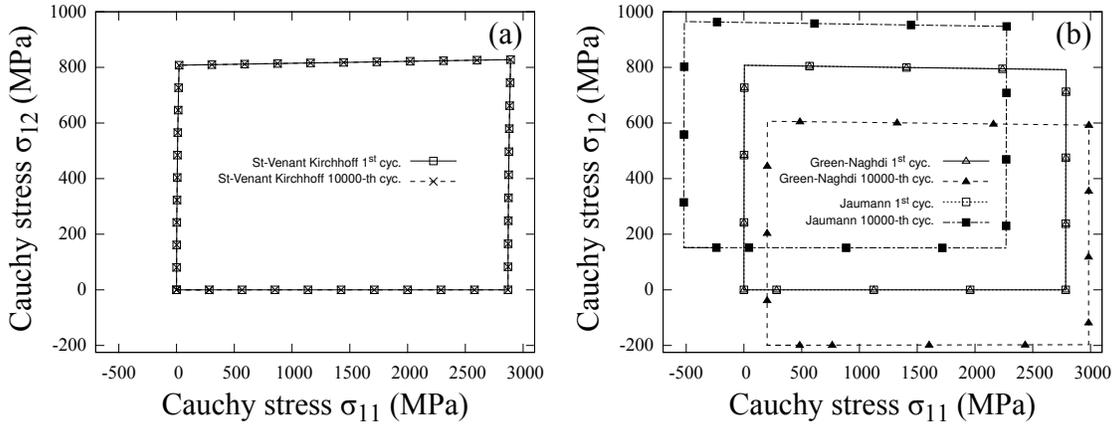

Figure 5: Case 1, the resulting stress during the first and the 10000th cycles for (a) hyperelastic material (b) hypoelastic materials. Young's modulus $E = 210000$ MPa, and Poisson ratio $\nu = 0.3$.

temperature and to the Poynting effect. The figures 5 and 6 depict an elastically non-consistent response of the two hypoelastic formulations, namely Jaumann and Green-Naghdi. When a closed strain cycle is applied, residual stresses remain at the end of each cycle. Consequently, due to the accumulation of residual stresses during the deformation process, the resulting stress drifts away over cycles. In contrast, for a hyperelastic model, no residual stresses are detected after each cycle, *i.e.* all stress components return back to zero. As suggested by [8], some hypoelastic models, e.g. based on the logarithmic rate, produce consistent results compared to hyperelastic models. Nevertheless, in the case of elastoplasticity, these rates are no longer integrable [10]. It has been shown that any hypoelastic law is integrable in the case of

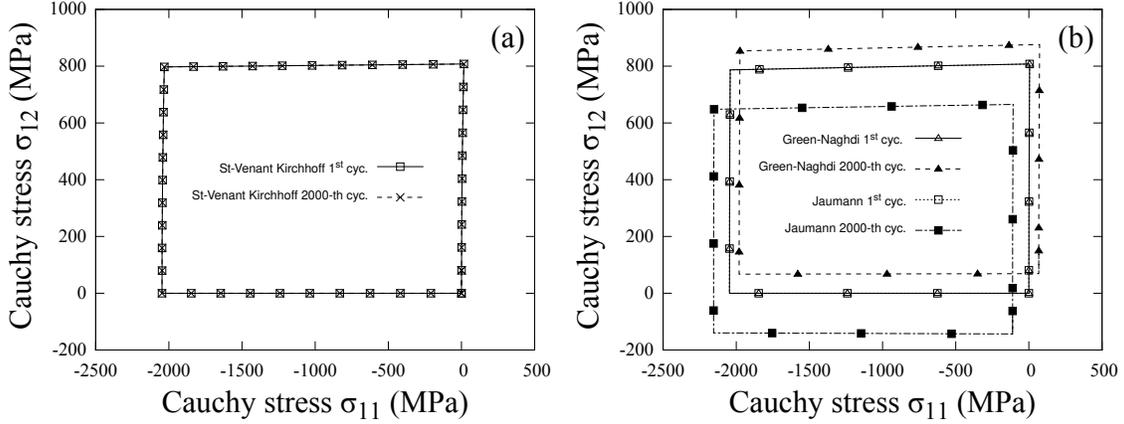

Figure 6: Case 2, the resulting stress during the first and the 2000th cycles for (a) hyperelastic material (b) hypoelastic materials. $E = 210000$ MPa, $\nu = 0.3$ and $\alpha_T = 10^{-4} K^{-1}$

proportional loading *i.e.* for deformation processes depending on a single parameter [72].

4.2. Simple glide with kinematic hardening

The deformation gradient for a simple glide test has the form

$$\tilde{\mathbf{F}} = \begin{pmatrix} 1 & \gamma(t) & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (84)$$

In this section, a comparison is drawn between the elastoplastic models previously presented by looking at the classical cases of monotonic and cyclic simple shear. The kinematic hardening contribution ψ^{kin} to the free energy is given in the Neo-Hookean form [31, 46]

$$\psi^{\text{kin}}(\tilde{\mathbf{E}}_s^p) = c \left(\text{tr}(\tilde{\mathbf{E}}_s^p) - \log(\det \tilde{\mathbf{F}}_s^p) \right) \quad (85)$$

In the case of linear kinematic hardening, significant differences are found between the various formulations as shown in Fig. 7 and Fig. 8. Fig. 7 depicts a spurious oscillatory response of both multiplicative and Jaumann formulations. In contrast, the model based on the Green-Naghdi rate predicts that σ_{12} increases monotonically. The model based on the multiplicative decomposition of the plastic part of the deformation gradient does not display oscillations as depicted in Fig. 8-a. These oscillations can be suppressed by increasing the value of the parameter D from Eq. (37). By doing so, kinematic hardening saturates rapidly which leads to almost the

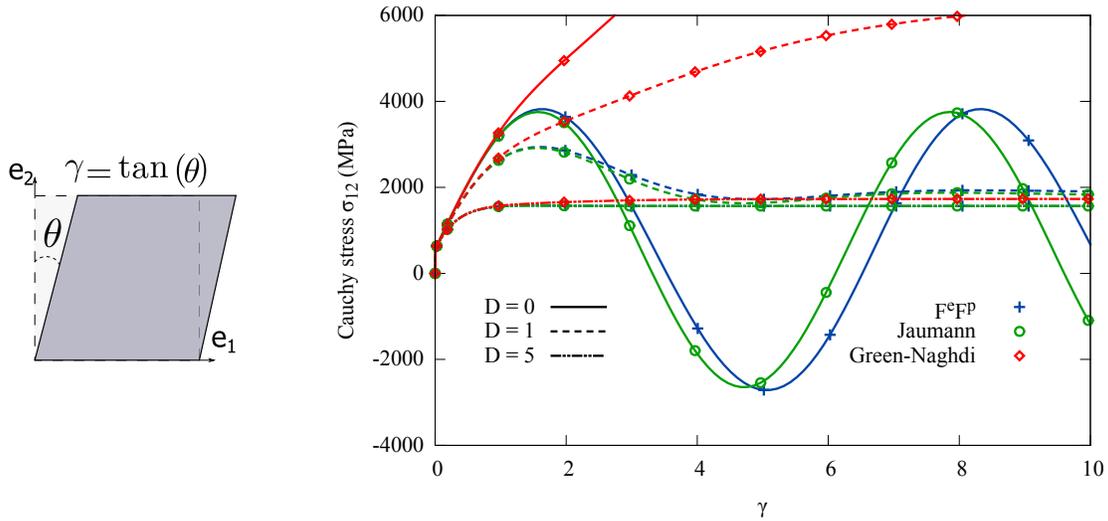

Figure 7: Monotonic simple glide test for different formulations of elastoplasticity with kinematic hardening: Stress oscillations in the case of Jaumann rate and the multiplicative decomposition if $D = 0$. These oscillations are suppressed as the parameter D increases. Values of material parameters: $C = 10000$ MPa, $R_0 = 1000$ MPa.

same predictions by different models. Accordingly, when the dynamic recovery term is sufficiently high (compared to the storage part), the saturation rate of the various models becomes similar.

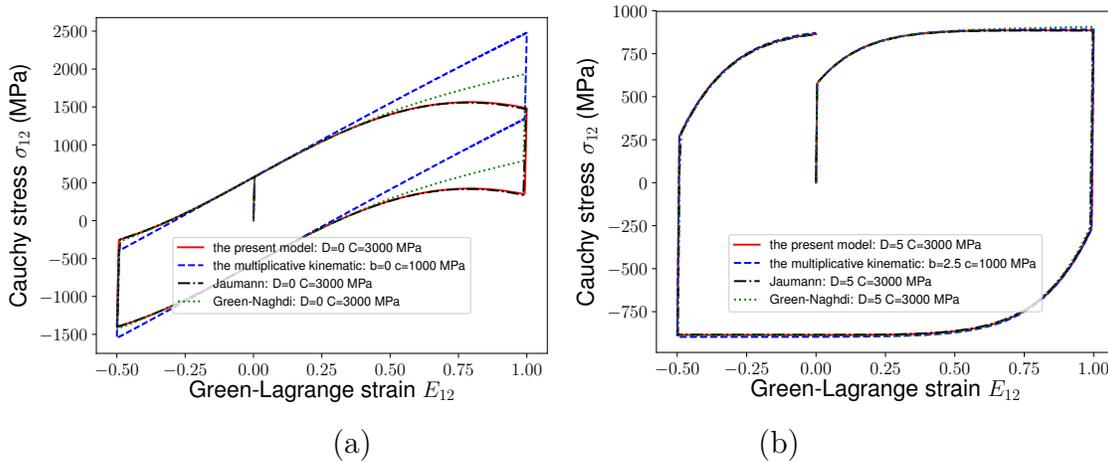

Figure 8: Cyclic simple glide loading: (a) linear ($D = 0$) (b) nonlinear kinematic hardening with dynamic recovery.

4.3. Static recovery of kinematic hardening

In this example, the effect of the static recovery of the kinematic hardening is illustrated. It corresponds to the last term in the evolution equation Eq. (37). This term introduces time-dependent material behavior even in the absence of viscosity. We consider a von Mises surface yield given by

$$f(\underline{\mathbf{M}}, R) = \left((\underline{\mathbf{M}} - \underline{\mathbf{X}})^{dev} : (\underline{\mathbf{M}} - \underline{\mathbf{X}})^{dev} \right)^{1/2} - R_0 \quad (86)$$

where $(\diamond)^{dev}$ denotes the deviatoric part. The back stress $\underline{\mathbf{X}} = \frac{2}{3}C\boldsymbol{\alpha}$ and the evolution of $\boldsymbol{\alpha}$ follows the constitutive equation (37). This model is applied to relaxation and creep tests.

4.3.1. Relaxation test under simple glide

A simple glide test is considered according to the following conditions

$$\underline{\mathbf{F}} = \begin{pmatrix} 1 & \gamma(t) & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad \gamma(t) = \begin{cases} \frac{t}{2} & 0 \leq t \leq 1 \\ \frac{1}{2} & 1 \leq t \leq 4 \end{cases} \quad (87)$$

which corresponds to monotonic glide followed by a constant shear value inducing stress relaxation in order to highlight the impact of the static recovery term. The material response is shown in Fig. 9 for three different sets of values of material parameters (m, M) . The following features can be observed

- $0 \leq t \leq 1$: During this time interval, the applied shear is monotonically increasing. After yielding, there is a competition between different terms in Eq. (37): storage part, dynamic and static recoveries. For given parameters C and D , a higher value of parameter M or a lower value of parameter m allow for slower recovery of the kinematic hardening leading to a higher value of σ_{12} (see Fig. 9).
- $1 \leq t \leq 4$: The imposed shear strain is constant *i.e.* $\dot{\underline{\mathbf{F}}} = 0$. Consequently, the variation of the accumulated plastic strain is low due to small elastic strain since $\underline{\mathbf{L}}^p = -\underline{\mathbf{F}}^{e-1}\dot{\underline{\mathbf{F}}}^e$ during a relaxation test. Therefore, the evolution of the kinematic hardening variable reduces to

$$\dot{\boldsymbol{\alpha}} \approx -\frac{3}{2} \left(\frac{\mathbf{J}(\underline{\mathbf{X}})}{M} \right)^m \frac{\underline{\mathbf{X}}}{\mathbf{J}(\underline{\mathbf{X}})} \quad (88)$$

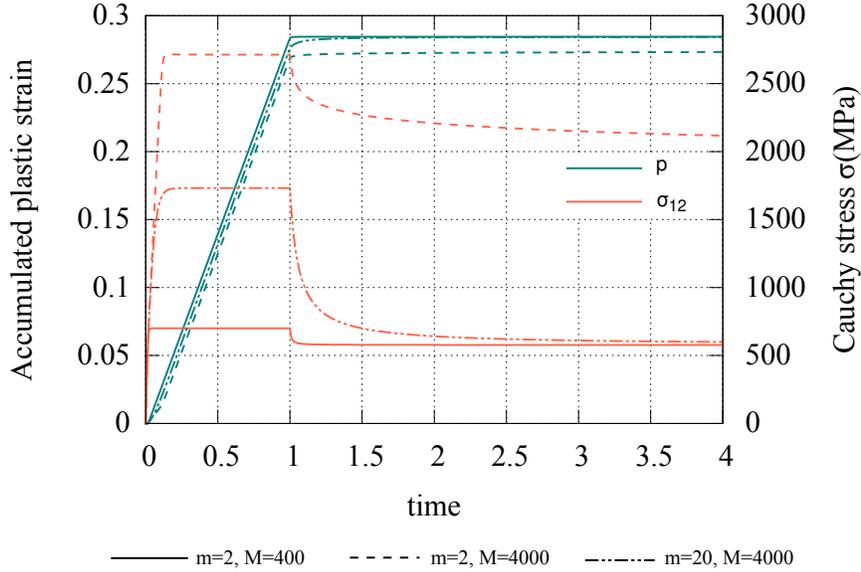

Figure 9: Relaxation test: Higher values of m and lower values of M result in a faster recovery of kinematic hardening. $C = 300000$ MPa, $D = 20$. Parameter M in MPa.

The recovery rate increases then with higher values of the power m (resp. lower values of M).

In metals, this effect occurs significantly at high temperature due to thermal activation. In fact, the crystalline structure of the metal is partially recovered by annihilation of dislocations and redistribution of point defects [29]. This relaxation of internal stresses generally results in a decrease of the mechanical resistance.

4.3.2. Creep test

In this example, the imposed deformation components are $F_{ij} = 0$ for $i \neq j$ and $\{ij\} \neq \{12\}$. F_{11} , F_{22} , F_{33} and F_{12} are set to be free. The imposed Cauchy stress component σ_{12} is given by

$$\sigma_{12} = \begin{cases} 1000t \text{ MPa}, & 0 \leq t \leq 1 \\ 1000 \text{ MPa}, & 1 \leq t \leq 4 \end{cases} \quad (89)$$

and the remaining components of Cauchy stress tensor will vanish. The material response is shown in Fig. 10. It is important to note that the used model does not include any viscosity, meaning that the yield condition is exactly fulfilled. The

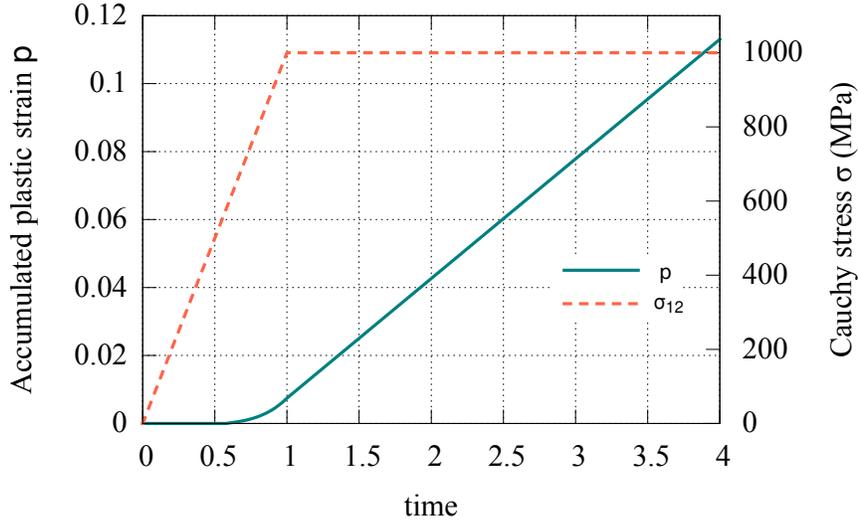

Figure 10: Plastic flow during a creep test.

creep deformation is induced solely by the static relaxation of the back-stress that has developed during the loading stage (see Eq. (37)):

- $0 \leq t \leq 1$: As the imposed stress increases, the accumulated plastic strain increases after yielding ($\sigma_{12} = \sqrt{3}R_0$).
- $1 \leq t \leq 4$: According to the consistency condition, the kinematic hardening does not evolve since the applied stress is constant. Therefore, the plastic multiplier is constant and the accumulated plastic multiplier increases linearly. Due the static recovery term, the model becomes time-dependent. In other words, if the static recovery term is omitted, then $\dot{\alpha} = 0 \Rightarrow \dot{p} = 0$.

4.4. Application to a von Mises-based multimechanism model

The concept of multimechanism modeling is applied in this section to the isotropic von Mises plasticity. A model is introduced involving two inelastic mechanisms and two plasticity criteria, called 2M2C in the terminology defined in the references [60, 61]. The yield function, flow rule and evolution equations adopted for this

example are as follows

$$f_p(\underline{\mathbf{M}}, \underline{\mathbf{X}}_p) = \left((\underline{\mathbf{M}} - \underline{\mathbf{X}}_p)^{dev} : (\underline{\mathbf{M}} - \underline{\mathbf{X}}_p)^{dev} \right)^{1/2} - R_{0p} \quad (90)$$

$$f_v(\underline{\mathbf{M}}, \underline{\mathbf{X}}_v) = \left((\underline{\mathbf{M}} - \underline{\mathbf{X}}_v)^{dev} : (\underline{\mathbf{M}} - \underline{\mathbf{X}}_v)^{dev} \right)^{1/2} - R_{0v} \quad (91)$$

$$\dot{v} = \left\langle \frac{f_v}{K} \right\rangle^n, \quad \dot{p} = \frac{\underline{\mathbf{N}}_p : \left(\underline{\mathbf{1}} \otimes \underline{\mathbf{\Pi}}^e + \frac{1}{2} \underline{\mathbf{C}}^e \cdot \underline{\mathbf{C}} \right) : \left(\underline{\mathbf{F}}^{eT} \underline{\mathbf{D}} \underline{\mathbf{F}}^e - \dot{v} \underline{\mathbf{C}}^e \underline{\mathbf{N}}_v \right)}{\underline{\mathbf{N}}_p : \left[\left(\underline{\mathbf{1}} \otimes \underline{\mathbf{\Pi}}^e + \frac{1}{2} \underline{\mathbf{C}}^e \cdot \underline{\mathbf{C}} \right) : \left(\underline{\mathbf{C}}^e \underline{\mathbf{N}}_p \right) \right] + \frac{1}{3} C_p \underline{\mathbf{N}}_p : \underline{\mathbf{m}}_p} \quad (92)$$

$$\dot{\underline{\boldsymbol{\alpha}}}_p = \dot{p} \left(\frac{\partial f_p}{\partial \underline{\mathbf{M}}} - D_p \underline{\boldsymbol{\alpha}}_p \right), \quad \dot{\underline{\boldsymbol{\alpha}}}_v = \dot{v} \left(\frac{\partial f_v}{\partial \underline{\mathbf{M}}} - D_v \underline{\boldsymbol{\alpha}}_v \right) \quad (93)$$

$$\begin{pmatrix} \underline{\mathbf{X}}_p \\ \underline{\mathbf{X}}_v \end{pmatrix} = \frac{2}{3} \begin{pmatrix} C_p & C_{pv} \\ C_{vp} & C_v \end{pmatrix} \begin{pmatrix} \underline{\boldsymbol{\alpha}}_p \\ \underline{\boldsymbol{\alpha}}_v \end{pmatrix} \quad (94)$$

The first plastic mechanism associated with the yield function f_p is rate-independent, whereas the second one is viscoplastic. The (visco)plastic multipliers are computed either by a power law or the consistency condition, according to Eq. (92). The material parameters used in the following examples are given in Table 2.

Consider now a simple tensile/compressive test under strain control, divided into five stages. The resulting stress state is uni-axial (σ_{11}). The response of the model for two distinct strain rates is given in Fig. 11. The following observations can be made:

- $F_{11} = 1.1 t$, for $0 \leq t \leq t_1$ (tension): The (v) mechanism is active first because the corresponding yield stress is taken as $R_{0v} = 0$. But after a while, the mechanism (p) is activated once the threshold R_p is reached. In fact, the activation of an inelastic mechanism will depend on the associated initial yield stress and also on the hardening properties of the other mechanism. Higher strain rates induce more plastic strain, while lower strain rates result in more viscoplastic strain.
- $F_{11} = 1.1$, for $t_1 \leq t \leq t_2$: During this stage the imposed strain is maintained at a constant value. The inelastic deformation remains quasi-constant accompanied by stress relaxation due to dynamic recovery of kinematic hardening.
- $F_{11} = 1.1 - 0.1(t - t_2)$, for $t_2 \leq t \leq t_3$ (unloading+compression): The plastic yielding in compression occurs at a rather large stress level due to the Bauschinger effect.

- $F_{11} = 0.9$, for $t_3 \leq t \leq t_4$: The imposed strain is constant. A quasi-constant inelastic deformation and stress relaxation due to kinematic hardening recovery are observed.
- $F_{11} = 0.9 + 0.1(t - t_4)$, for $t_4 < t < t_5$ (unloading phase). At $F_{11} = 1$, the residual stress does not vanish due to kinematic hardening.

E	ν	K	n	R_{0v}	C_v	D_v	R_{0p}	C_p	D_p

4.5. Plastic spin in anisotropic plasticity

The effect of plastic spin on the response of a Hill perfectly plastic material is illustrated in this example. Hill's yield criterion is expressed in terms of Mandel stress tensor in the form

$$f(\underline{\mathbf{M}}) = \left(F(M_{22} - M_{33})^2 + G(M_{33} - M_{11})^2 + H(M_{11} - M_{22})^2 + 2NM_{12}^2 + 2LM_{23}^2 + 2MM_{13}^2 \right)^{1/2} - R_0 \quad (95)$$

where F , G , H , N , M , L are material parameters characterizing the anisotropy of plasticity. This yield function reduces to von Mises if $F = G = H = 0.5$ and $H = N = M = 1.5$.

A simple glide test is considered with constant shear rate in the plane (1,2). When the hypoelastic-plastic model is used with the Jaumann derivative, the continuum under a constant shear strain rate $\dot{\gamma}$ rotates endlessly at the spin $\dot{\theta}^W = -\frac{\dot{\gamma}}{2}$. Consequently, the spin of directors is equal to $\dot{\theta}_{dir}^W = \dot{\theta}^W = -\frac{\dot{\gamma}}{2}$. The value of σ_{12} oscillates between $\frac{R_0}{\sqrt{2N}}$ at $F_{12} = \gamma = k\pi$ ($k \in \mathbb{N}$) and a peak (or valley) value $\frac{R_0}{\sqrt{F+G+4H}}$ at $\gamma = \frac{2k+1}{2}\pi$ ($k \in \mathbb{N}$). In the case of the Green-Naghdi formulation, the spin of directors is equal to $\dot{\theta}_{dir}^R = -\frac{2\dot{\gamma}}{4+\gamma^2}$. Therefore, the rotation angle converges to $\pi/2$ degrees as γ goes to infinity. This is illustrated by Fig. 13.

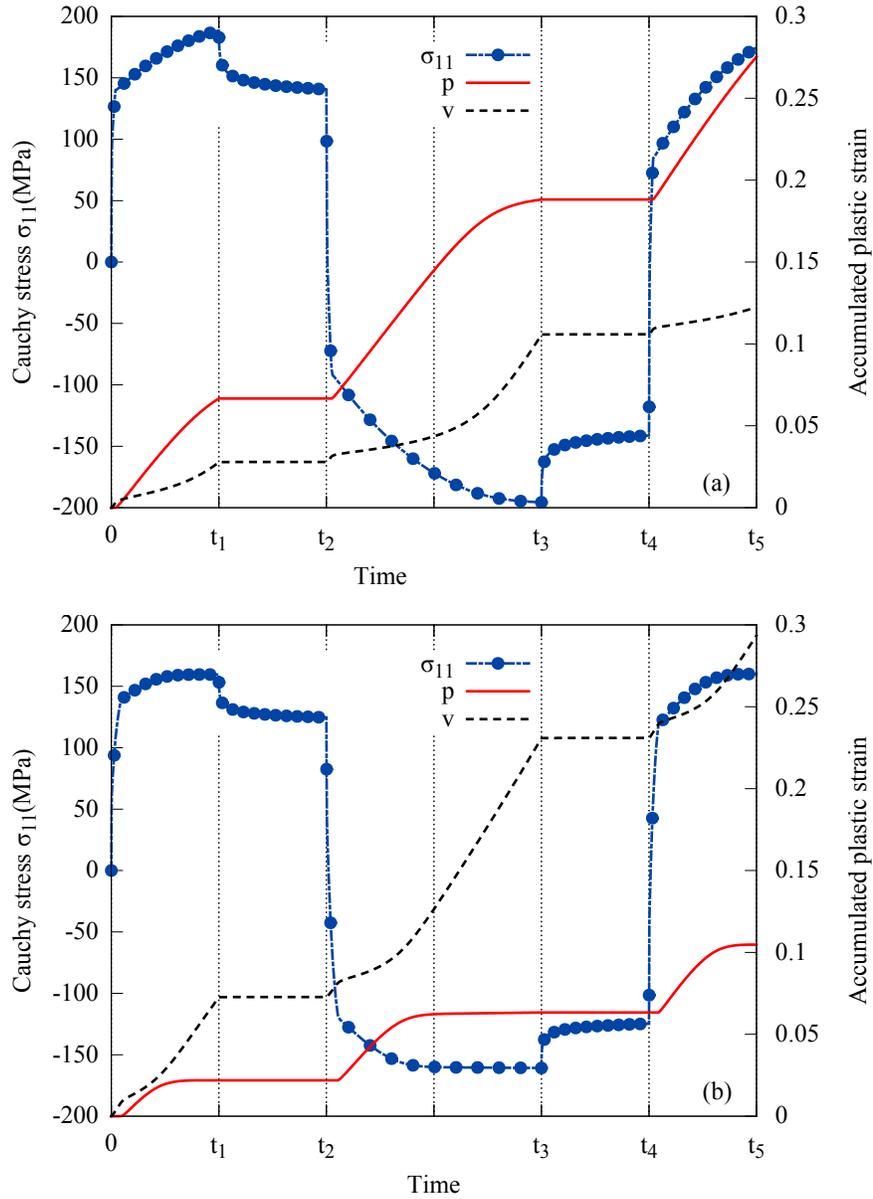

Figure 11: Tension/compression test for two deformation rates $\dot{F}_{11} = 0.1 \text{ s}^{-1}$ (a) and $\dot{F}_{11} = 0.001 \text{ s}^{-1}$ (b). Model with a time-independent and a viscoplastic mechanism.

The responses of the proposed model are shown in Fig. 14. If the plastic spin vanishes *i.e.* $\beta = 0 \text{ MPa}^{-1}$, for small elastic stretches, the proposed model without plastic spin and the model based on Jaumann derivative have the same response.

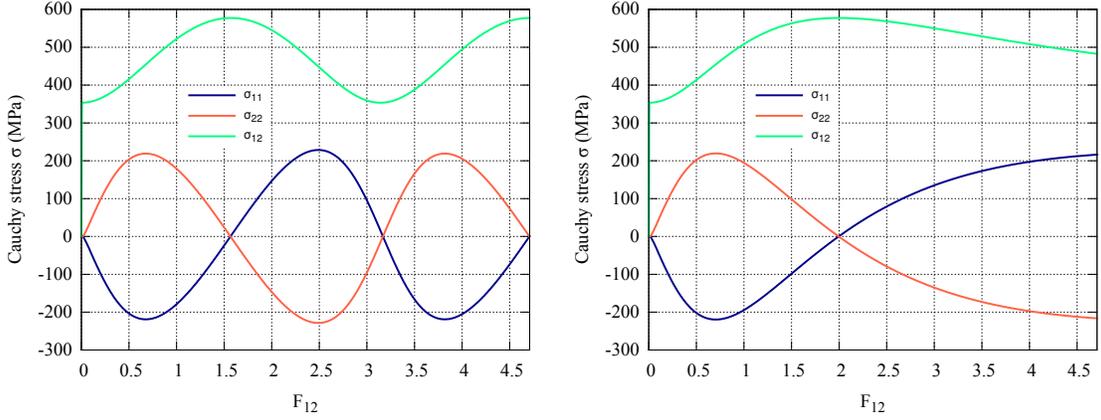

Figure 12: Hypoelastoplastic material response under simple glide loading. Jaumann (left) and Green-Naghdi (right) formulations. Coefficients of Hill’s yield criterion used in this simulation: $F = G = H = 0.5$, $L = M = 1.5$, $N = 4$, initial yield stress $R_0 = 1000$ MPa.

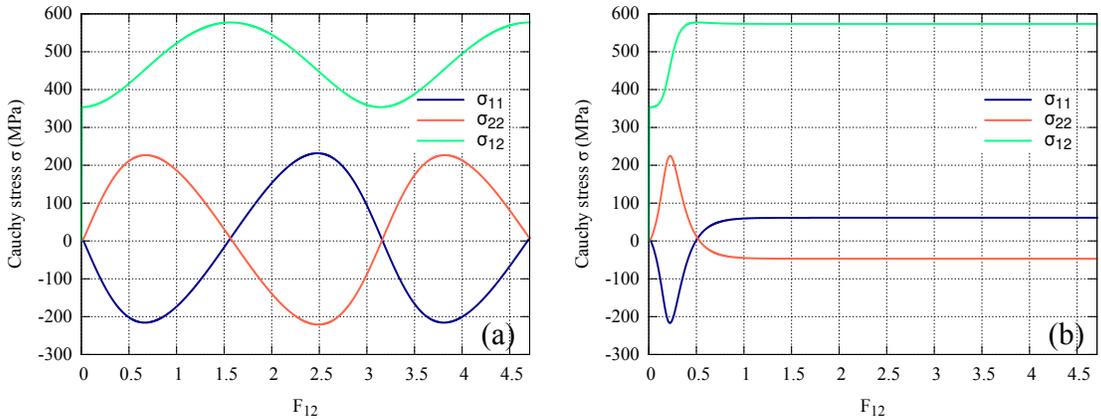

Figure 13: Effect of plastic spin on stress values in the case of simple glide loading. (a) Without plastic spin *i.e.* $\beta = 0$ MPa⁻¹ (b) with plastic spin $\beta = 0.01$ MPa⁻¹. Multiplicative plasticity model with yield stress $R_0 = 1000$ MPa, Hill yield criterion coefficients $F = G = H = 0.5$, $L = M = 1.5$, $N = 4$.

This means that the orthotropic axes rotate at the same rate as the continuum $\dot{\theta} = -\dot{\gamma}/2$. In contrast, as shown in Fig. 13, when $\beta \neq 0$ MPa⁻¹, the spin of the substructure is different from material spin. In fact, as the value of β increases, the spin induced by $\tilde{\mathbf{W}}^p$ balances out the material spin. Further, if β is sufficiently high, the rotation of directors saturates rapidly at an angle of $\approx \pi/4$. The rate of

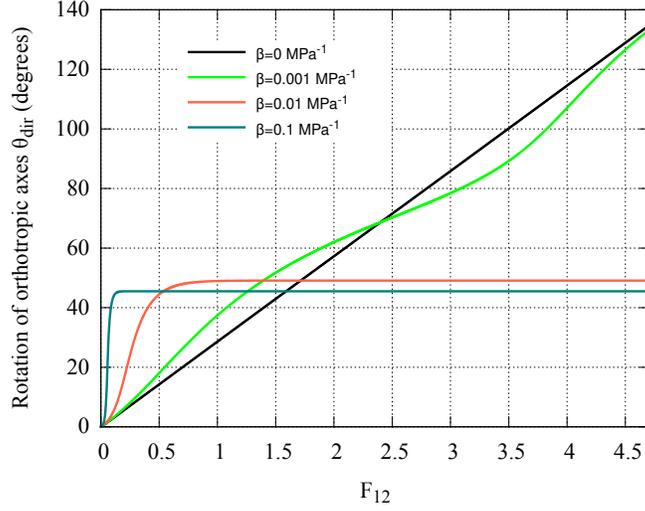

Figure 14: Directors' spin for various values of parameter β during a simple glide test for a Hill perfectly plastic material and multiplicative decomposition. When $\beta = 0 \text{ MPa}^{-1}$, the rotation rate of directors is constant and coincides with the material spin.

directors' spin is illustrated in Fig. 14 for several values of the plastic spin parameter β : constant spin for $\beta = 0$, rapid saturation for high values and oscillatory response for intermediate values.

4.6. Plastic spin: crystal plasticity

Crystal plasticity represents one of the few physical situations for which the plastic spin of crystal directors is precisely known. The spin of directors uniquely results from the slip of N^s systems on specific crystallographic planes and along specific slip directions. The dissipation potential is expressed in terms of the Schmid yield function f^s associated with each slip system s

$$f^s = \left| \underline{\underline{\mathbf{M}}} : \underline{\underline{\mathbf{N}}}^s - x^s \right| - \tau_c^s \quad \text{with} \quad \underline{\underline{\mathbf{N}}}^s = \underline{\underline{\mathbf{l}}}^s \otimes \underline{\underline{\mathbf{n}}}^s \quad (96)$$

where τ_c^s denotes the critical resolved shear stress (CRSS) for the s -th slip system, $\underline{\underline{\mathbf{l}}}^s$ and $\underline{\underline{\mathbf{n}}}^s$ are, respectively, the slip direction and the normal to the slip plane. The resolved Mandel shear stress $\tau^s = \underline{\underline{\mathbf{M}}} : \underline{\underline{\mathbf{N}}}^s$ is the driving force for activation of the s -th slip system. Kinematic hardening has been introduced by [73] in the crystal plasticity framework, in the form of a back stress variable x^s obeying the following evolution rule

$$\dot{\alpha}^s = \dot{\gamma}^s - D|\dot{\gamma}^s|\alpha^s, \quad x^s = C\alpha^s \quad (97)$$

where C, D are the kinematic hardening material parameters. For the sake of demonstration, a power law potential is considered

$$\Omega(\underline{\mathbf{M}}, \underline{\mathbf{N}}^s) = \sum_{s=0}^{N_s} \frac{K}{n+1} \left\langle \frac{|\underline{\mathbf{M}} : \underline{\mathbf{N}}^s - x^s| - \tau_c^s}{K} \right\rangle^{n+1} \quad (98)$$

where n and K are viscosity material parameters and $\langle \cdot \rangle$ denotes the Macauley brackets. Further, a non-linear hardening law is adopted for the CRSS τ_c^s given by

$$\tau_c^s = \tau_c^{\mathcal{F}(r)} + \sum_{r=0}^{N_s} H^{sr} (1 - \exp(-b^{\mathcal{F}(r)} \gamma_{cum}^r)) \quad (99)$$

$\mathcal{F}(r)$ identifies the slip system family to which the slip system r belongs (for example basal and prismatic system families in HCP crystals), N_s is the total number of slip systems and γ_{cum}^r denotes the accumulated plastic slip. The matrix H^{sr} accounts for interactions between slip systems. The evolution of the plastic slip variables γ^s follows as

$$\dot{\gamma}^s = \left\langle \frac{|\underline{\mathbf{M}} : \underline{\mathbf{N}}^s - x^s| - \tau_c^s}{K} \right\rangle^n \text{sign}(\underline{\mathbf{M}} : \underline{\mathbf{N}}^s - x^s) \quad (100)$$

According to the normality rule (27), the plastic deformation rate reads

$$\underline{\mathbf{L}}^p = \sum_{s=0}^{N_s} \dot{\gamma}^s \underline{\mathbf{N}}^s \quad (101)$$

and the plastic spin writes

$$\underline{\mathbf{W}}^p = \sum_{s=0}^{N_s} \dot{\gamma}^s \text{skw}(\underline{\mathbf{l}}^s \otimes \underline{\mathbf{n}}^s) \quad (102)$$

As an illustration, the simple glide kinematics (84) is imposed to a face centered cubic (FCC) single crystal. The single crystal model response is compared to two *fake* crystal models in order to highlight the importance of properly characterizing the plastic spin. In the *fake* models no plastic spin is introduced and Jaumann or Green–Naghdi hypoelastic laws are used instead of the actual plastic spin (102). The responses of the three models are shown in Fig. 15. The material is perfectly plastic, with an initial CRSS value $\tau_c^s = 100$ MPa. The simple glide loading direction 1 initially coincides with the crystal direction [100], whereas the direction 2 initially

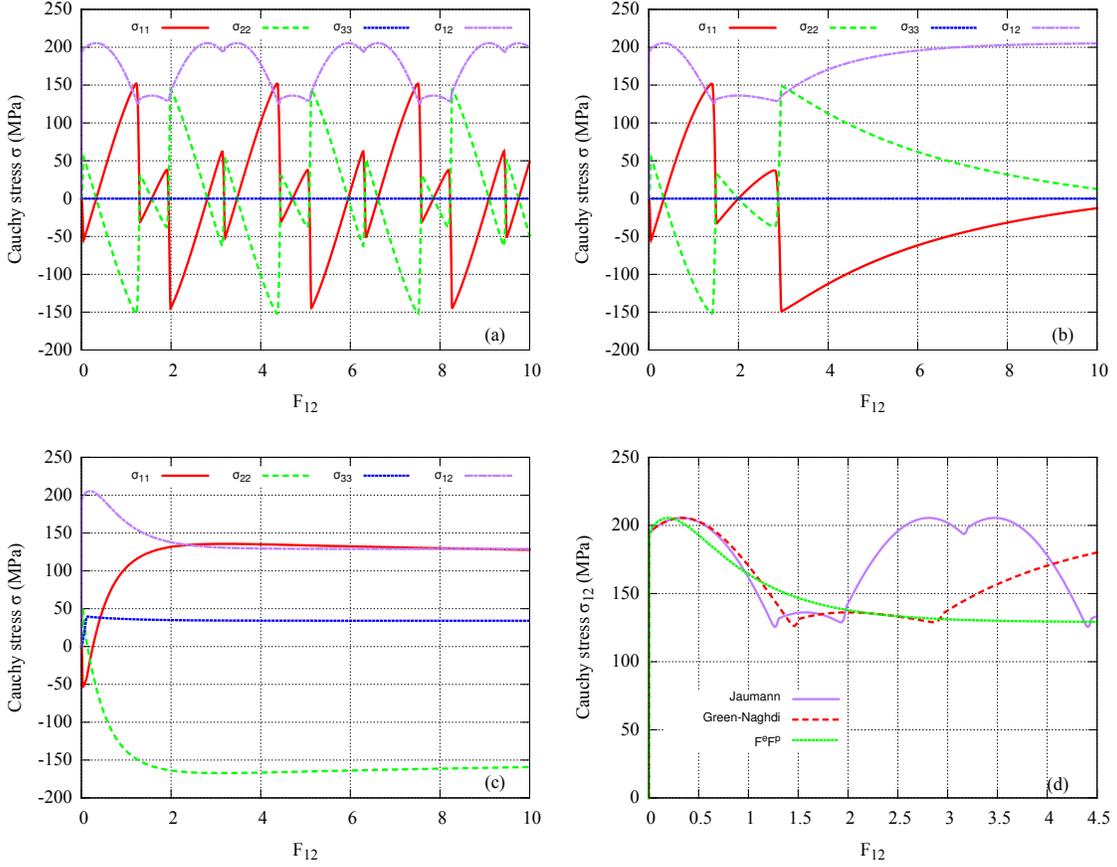

Figure 15: The effect of plastic spin in the case of a simple glide loading of a FCC single crystal for three different finite strain formulations: Jaumann (a) and Green-Naghdi(b) rates (with no plastic spin) and the multiplicative decomposition (c). (d) comparison of σ_{12} for all three formulations.

coincides with the crystal direction $[0\bar{1}1]$. The octahedral slip system family of the FCC crystal is employed and contains 12 slip systems. The reference solution based on the multiplicative decomposition and plastic spin predicts a saturation of stress levels after $F_{12} = 2$ shear. In contrast, the *fake* crystal responses exhibit oscillatory stress evolutions. It is noteworthy that the stress component σ_{33} vanishes for hypoelastic models. On the other hand, the approach based on the multiplicative decomposition includes a plastic spin derived from the dissipation potential. This model of plastic spin dictates the spin of directors independently of material rotation (see Fig. 16). In addition, the σ_{33} does not vanish according to the present model contrary to the hypoelastic formulations.

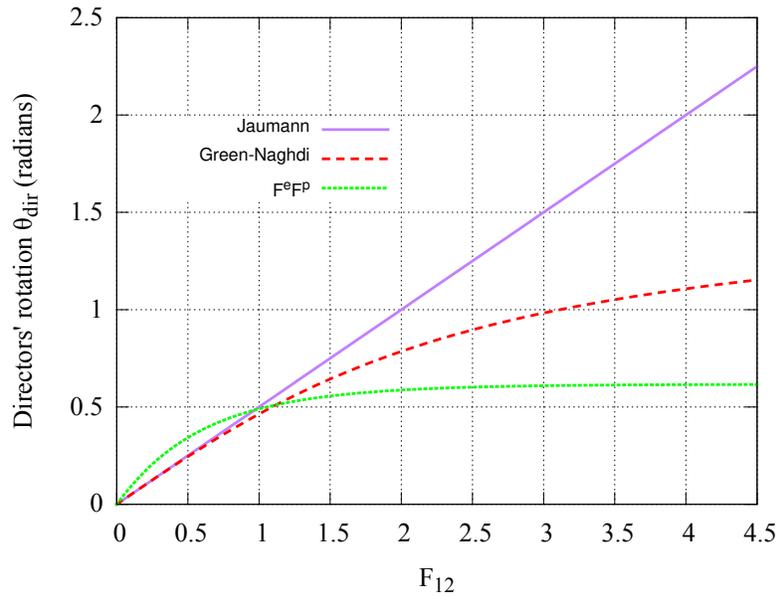

Figure 16: The spin of material directors in the case of a simple glide loading for three different finite strain formulations of crystal plasticity: Jaumann and Green-Naghdi rates and the multiplicative decomposition

Furthermore, the rotation rate tends to zero for the crystal orientation considered in the present example, which is not the case for Jaumann rate. The comparison with experimental results confirms that the rotation of anisotropic axes of a single crystal does not follow the material rotation [74, 75]. Clearly, the *fake* crystal plasticity models are physically inadequate. Note that oscillatory responses can be observed for special crystal orientations within the framework of multiplicative crystal plasticity, see [76].

4.7. Crystal plasticity with system interactions

The interaction matrix in Eq. (99) has the general form

$$\mathbf{H} = \begin{pmatrix} Q_1 \mathbf{H}_1 & Q_1 h_2^1 & \dots & Q_1 h_n^1 \\ \hline Q_2 h_2^1 & Q_2 \mathbf{H}_2 & \dots & Q_2 h_n^2 \\ \hline \vdots & \vdots & \ddots & \vdots \\ \hline Q_n h_n^1 & Q_n h_n^2 & \dots & Q_n \mathbf{H}_n \end{pmatrix} \quad (103)$$

where Q_i is the isotropic hardening parameter associated with each slip system family i , H_i matrices denote the self-hardening coefficients, and h_m^n denotes the latent hardening parameters (hardening of slip systems belonging to the family n caused by slip systems belonging to the family m). The table 3 shows typical material constants for a single crystal with octahedral and cubic slip system families. Such combination of octahedral and cube slip system families are encountered in single crystal Nickel-based superalloys [73].

K_1 (MPa ^{1/n₁})	n_1 (-)	$\tau_c^{(1)}$ (MPa)	Q_1 (MPa)	b_1 (-)	H_1 (-)	K_2 (MPa ^{1/n₂})	n_2 (-)	$\tau_c^{(2)}$ (MPa)	Q_2 (MPa)	b_2 (-)	H_2 (-)
0.1	20	100	50	50	1	0.1	20	100	100	100	1

Table 3: Material parameters for octahedral (1) and cubic (2) slip systems with isotropic hardening.

Fig. 17 shows the influence of latent hardening parameter h_2^1 on the activation of slip systems. In fact, if $h_2^1 = 0$, the cubic slip systems are activated as soon as $\sigma_{33} \approx \frac{3\sqrt{2}}{2}\tau_c^{(2)}$ (according to Schmid's law, neglecting the overstress due to viscoplasticity), and the octahedral slip systems are activated when $\sigma_{33} \approx \frac{3\sqrt{6}}{2}\tau_c^{(1)}$. If $h_2^1 > 0$, the octahedral slip systems will be activated later since the corresponding critical resolved shear increases due to accumulated cubic plastic slip according to Eq. (99). This is the manifestation of latent hardening between slip system families.

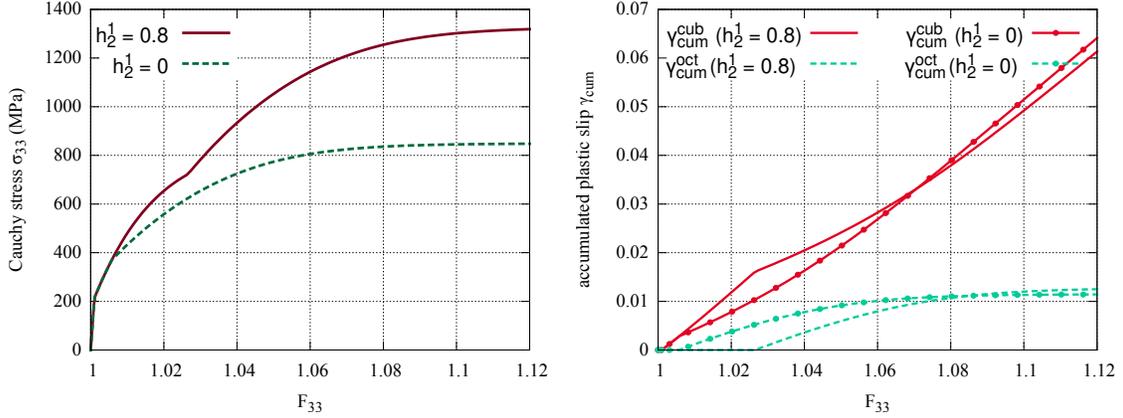

Figure 17: A single crystal including two slip system families (octahedral and cubic) in tension along $\langle 111 \rangle$. γ_{cum}^{cub} (resp. γ_{cum}^{oct}) denotes the accumulated cubic (resp. octahedral) plastic slip.

5. Structural applications

The proposed generic formulation and implementation are now illustrated in the case of structural components subjected to various loading conditions. The model predictions and computational efficiency are compared to those obtained by standard approaches involving hypo-elastoviscoplastic models.

5.1. Application 1: Deep drawing for anisotropic materials

The present approach is applied first to the three dimensional problem of cup deep drawing. This problem is common in literature and solved using various finite strain formulations, see [43, 22]. The geometry of the test is described in Fig. 18.

A time-independent elastoplastic model is considered with a Hill yield function as in Eq. (95). A nonlinear isotropic hardening rule is adopted in the form

$$R(p) = R_0 + Q(1 - \exp(-bp)) \quad (104)$$

Here the value of the initial yield stress is $R_0 = 253$ MPa, the isotropic hardening parameters are chosen as $b = 14$ and $Q = 215$ MPa. The parameters of Hill's yield function are set to $F = G = H = N = 0.5$ and $L = M = 1.5$. Herein, only a quarter of the cup is analyzed due to the orthotropic material symmetry. The mesh of the sheet contains 900 C3D8 hexahedral solid elements (linear interpolation with 8 Gauss points per element), with 3 elements in the thickness direction. The plate is initially circular. The tools are modeled as rigid surfaces and are completely fixed except the punch which is pushed in z -direction to a total displacement of $u_z = -40$ mm.

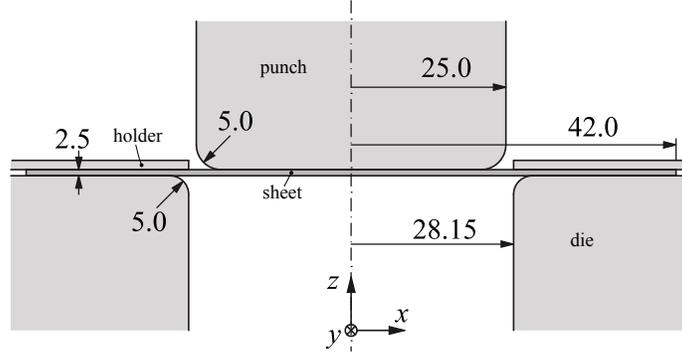

Figure 18: Schematic view of the cup drawing process. No friction is considered between sheet and tools. The die, punch and the holder are assumed to be linear elastic with a Young modulus of $E = 10^6$ MPa and a Poisson ratio $\nu = 0.3$. Lengths in mm.

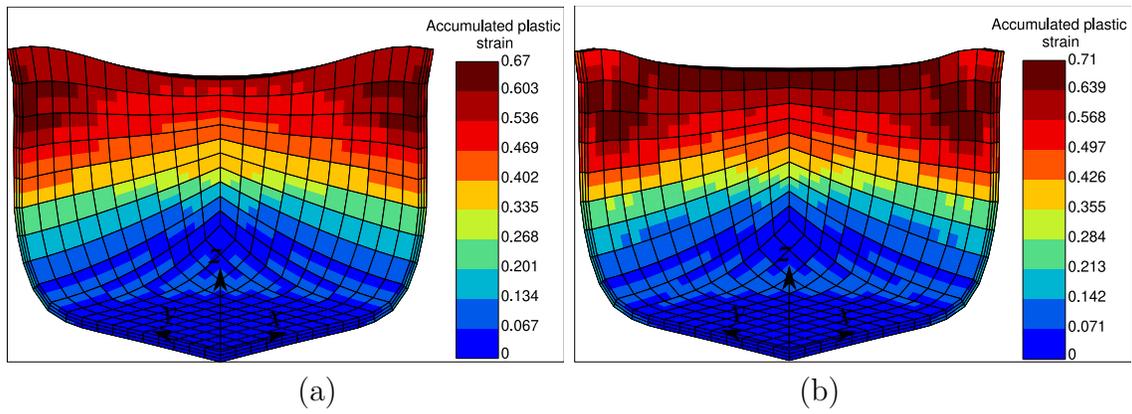

Figure 19: Accumulated plastic strain induced by cup drawing in an anisotropic elastoplastic plate: (a) Without plastic spin $\beta = 0$ MPa $^{-1}$, (b) with plastic spin $\beta = 0.01$ MPa $^{-1}$

Fig. 19 shows the distribution of the accumulated plastic strain and the deformed configuration. If the plastic spin vanishes, the maximal values of the accumulated plastic strain are located along the directions of the material symmetry x - and y -axes. When plastic spin is taken into account by means of parameter β from Eq. (45), the distribution of accumulated plastic strain tends to be more isotropic for $\beta = 0.01$ MPa $^{-1}$.

The earing profile after forming is depicted in Fig. 20 for two values of the parameter β . The edge of the sheet has a wavy shape. As the value of β increases, the edge shows less pronounced wave-shape. Similar results were reported in [43] for an isotropic elastic and a transverse isotropic Hill-type plastic model. The hypoelastic version of this model yields similar results to the present approach, including the wavy

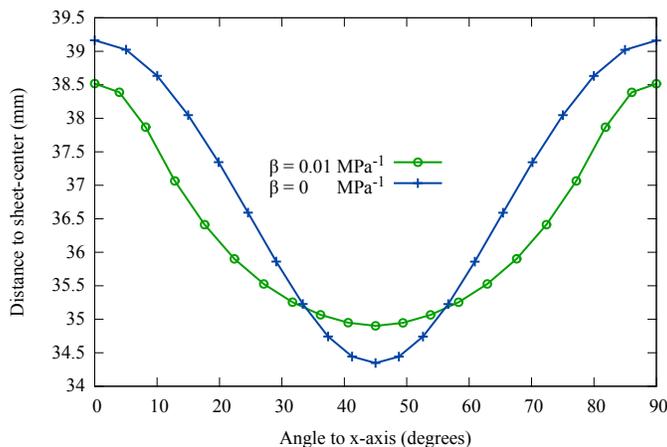

Figure 20: Distance of rim to the sheet center versus angle to x-axis. The curve shows the earing pattern for two values of the parameter β .

shape of the cup and the distribution of plastic strains. The present formulation, however, is advantageous since a supplementary plastic spin describing the evolution of anisotropy axes can be incorporated in the model.

5.2. Application 2: Turbine blade with single crystal plasticity

In the following, the behavior of a nickel-based superalloy single crystal turbine blade subjected to creep at high temperature is studied. During their operation, turbine blades are subjected to centrifugal forces induced by the rotation (~ 20000 RPM) of the turbine disc in addition to gas pressure. During one flight, the turbine blades are subjected to high and non-uniform temperatures (maximum temperature $\sim 1200^\circ\text{C}$), which will induce thermal strains. The thermomechanical loading is maintained for a longer time, compared to the nominal in-service conditions, at the maximum temperature ($\sim 640^\circ\text{C}$ at the root and $\sim 1200^\circ\text{C}$ at the tip). The mesh of the turbine blade geometry contains 1366 linear C3D8 hexahedral solid elements. We consider two initial orientations of the crystal. The first one is such that the crystal directions triplet ($[100] - [010] - [001]$) coincide with the orthogonal basis vectors triplet (x_1, x_2, x_3). For the second orientation, the crystal is tilt by 15° in the x_1 - x_3 plane. The objective is to assess the impact of crystal misorientation on the thermomechanical response of the blade.

The material model has 18 slip systems potentially active, 12 octahedral $\{110\}\langle 111\rangle$ and 6 cubic slip systems $\{110\}\langle 100\rangle$. The constitutive equations of the model including kinematic hardening law were given in Sec. 4.6. Typical values of the material parameters used in the simulation can be found in [77]. Cubic elasticity moduli, the

coefficient of isotropic thermal expansion, critical resolved shear stresses, viscoplastic flow parameters and nonlinear kinematic hardening parameters are identified as functions of temperature.

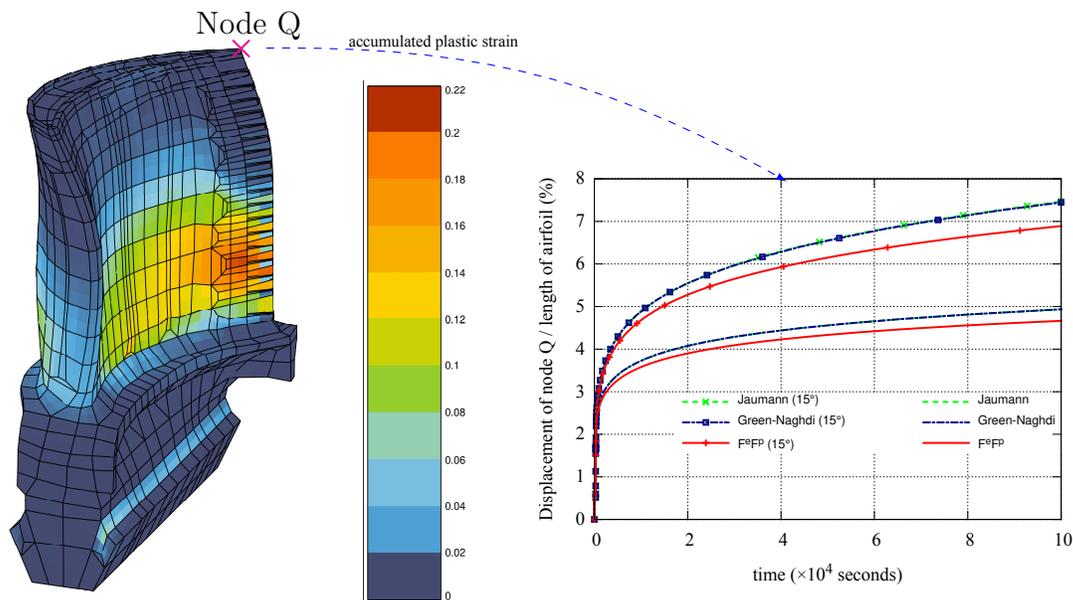

Figure 21: (a) The accumulated plastic strain in a turbine blade subjected to creep at high temperature. (b) Displacement of the node Q as a function of time: comparison of different finite deformation formulations.

Fig. 21 shows that both hypoelastic formulations yield similar creep results. The present model prediction slightly differs and the difference increases with time. The difference between various formulations becomes apparent when an initial rotation of 15° around y-axis is considered. Fig. 22 shows the relative rotation of material directors with respect to material rotation for the present model. For hypoelastic formulations, the spin of directors coincides with material rotation which is not the case for the model based on the multiplicative decomposition. The multiplicative crystal plasticity model assumes a relative rotation of crystal directors with respect to material lines, induced by the plastic spin (102). An initial misorientation of 15° leads to slightly larger relative rotation of crystal directors, as shown in Fig. 22. This result explains the fact that the difference in creep predicted by various formulations is much more pronounced for an initial misorientation of 15° compared to 0° . It must be underlined that the presented crystal plasticity formulations based on corotational frames are physically unsound but represent standard extensions of small strain crystal plasticity.

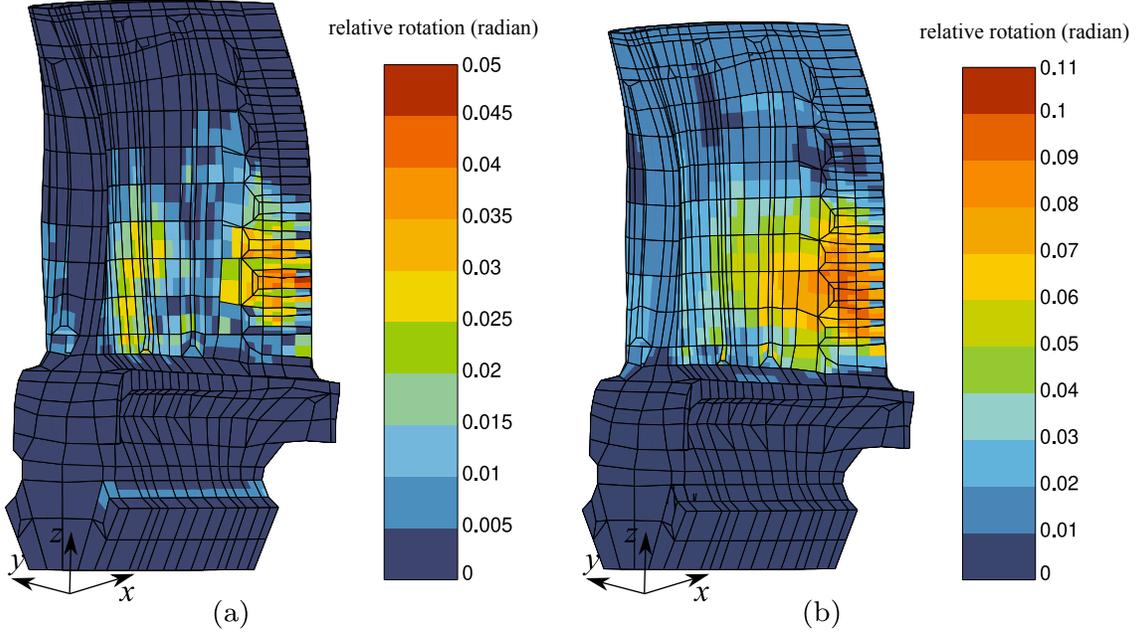

Figure 22: Relative rotation of crystal directors w.r.t. material lines for the multiplicative-based model in two cases (a) ideal $\langle 1001 \rangle$ orientation of the blade, (b) deviation of 15° around y-axis.

5.3. Computational efficiency of the approach

The present formulation is compared to two hypoelastic formulations, Jaumann (J) and Green-Naghdi (GN) rates, in terms of computational efficiency. We consider four examples of structural applications and different material models. In addition to the applications discussed previously, we carry out a tensile test on a notched specimen with 323703 nodes corresponding to 73920 C3D20R quadratic elements with reduced integration. A von Mises plasticity model is adopted with initial yield stress $R_0 = 300$ MPa. The parameter values for nonlinear isotropic and kinematic hardening are taken as $Q = 400$ MPa, $b = 2.5$, $C = 5700$ MPa and $D = 17$, as in [32]. The results predicted by different formulations (hypoelastic and multiplicative models) turn out to be almost identical in this isotropic case. Fig. 23 depicts the obtained accumulated plastic strain field. The objective of this example is to illustrate the performance of the approach for a problem with almost one million degrees of freedom.

Note that the integration of constitutive equations is carried out using a fully implicit integration method ($\theta = 1$). The time increment is set to the same value for all the formulations (if it does not converge, the time increment is divided by 2). Comparison results for various formulations are presented in Fig. 24. Computa-

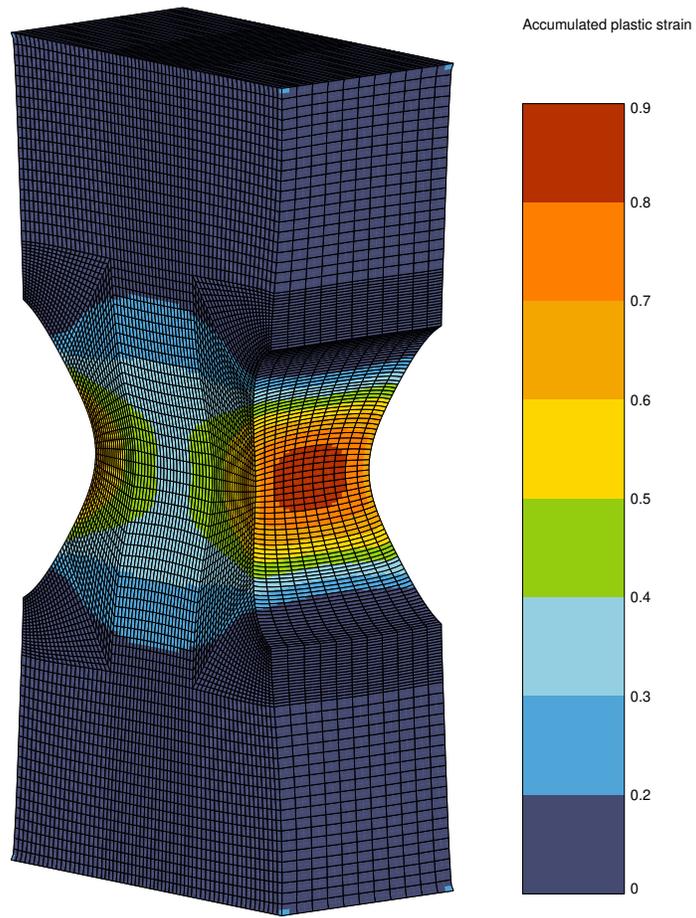

Figure 23: Accumulated plastic strain in a notched specimen subjected to tensile loading using the multiplicative decomposition based model.

tions were carried out on processors of type Intel(R) Xeon(R) CPU E5-2650 v4 @ 2.20GHz. It is found that the formulation based on the multiplicative decomposition leads to a slightly higher computational cost compared to hypoelastic formulations (+15%–20%). This is due to the fact that more operations are implied by the systematic use of non-symmetric tensors in the algorithm. Besides, the total number of iterations for convergence of global equilibrium, is slightly higher for the model based on the multiplicative decomposition. In spite of that, the computational cost is still reasonable compared to formulations common in commercial FEM software. The slight increase in computation time is counter-balanced by additional possibilities in the modeling of anisotropic inelasticity.

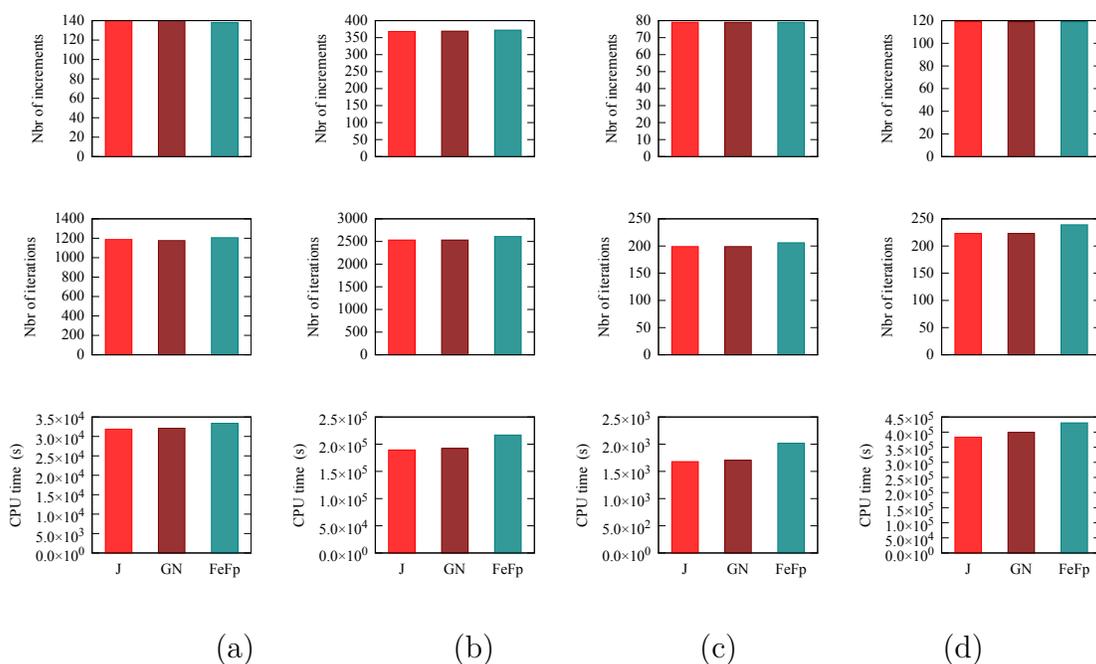

Figure 24: Comparison of the total number of increments, total number of iterations and CPU time for different formulations. Applications: (a) deep drawing with 900 C3D8 elements (1324 nodes), (b) deep drawing with 19500 C3D8 elements (26564 nodes), (c) turbine blade under creep with 1366 C3D8 elements (2498 nodes), (d) Notched specimen with 73920 C3D20R elements (323703 nodes). Simulations are run on 24 CPUs.

6. Conclusion

The present work demonstrates that elasto-viscoplastic models based on the multiplicative decomposition of the deformation gradient are now mature for a systematic

use in commercial finite element codes for structural computations. The proposed generic constitutive framework overcomes the shortcomings of standard formulations used in most available FE codes and based on hypoelastic laws and limited description of anisotropic behavior. It has been shown that the computing efficiency is comparable to the standard approach, although slightly less advantageous. The use of a thermodynamically consistent formulation of constitutive equations ensures increased reliability of model predictions.

The proposed extension of constitutive equations at finite strain relies upon the multiplicative decomposition of the deformation gradient and a hyperelastic relation between stress and elastic strain measures. The other characteristic feature is the expression of plasticity laws in terms of the Mandel stress tensor, which is generally non-symmetric. The approach accommodates contributions of many deformation mechanisms combining thermo-plasticity, viscosity and possibly damage, without resorting to arbitrary further multiplicative decompositions of elastic or plastic parts of the deformation gradient. Instead, the rates of multimechanism contributions are added in the viscoplastic flow rule. Anisotropy is incorporated via the consideration of directors and associated structural tensors and plastic spin concept which are often absent in existing standard formulations. It was illustrated in the case of Hill's criterion and crystal plasticity.

Two numerical integration methods of the nonlinear evolution equations are proposed. First, the elastic or the plastic part of the deformation gradient is integrated using an exponential map. In general, this method involves calculating the exponential of a non-symmetric second-order tensor and its derivative, which is not an easy task. An alternative integration method is considered, which consists of correcting the elastic part of the deformation gradient to enforce the plastic incompressibility. The present framework is illustrated through various models, including isotropic and anisotropic (visco)-plasticity with isotropic and kinematic hardening. Most formulations exist in the literature but a few are original: nonlinear non-symmetric kinematic hardening rule including dynamic and static recovery terms. In the case of linear kinematic hardening, models based on the Jaumann rate and the multiplicative decomposition exhibit stress oscillations extensively discussed in the literature. However, regarding nonlinear kinematic hardening including dynamic recovery term, the various models provide similar predictions for a proper choice of material parameters.

The capabilities of the present formulation are illustrated through elementary industrial applications. The effect of plastic spin on the evolution of anisotropy described by a triad of directors was evaluated in the case of cup drawing. This effect cannot be neglected, particularly for materials showing a high degree of anisotropy

under large plastic deformation. The comparison between hypo-elastoplastic models applied to crystal plasticity shows that the result heavily depends on the objective stress rate. The crystal plasticity model based on the multiplicative decomposition remains the reference model in that case and was successfully validated by experiments, especially the rotation of crystal directors with respect to loading axes.

Meanwhile, further research is necessary to develop yield criteria in terms of the generally non-symmetric Mandel stress tensor [45, 43]. The identification of the constitutive equations for the plastic spin requires more experimental investigations at large deformations. Furthermore, non-symmetric internal variables (e.g. kinematic hardening) are to be considered. Examples showing applications to compressible elastoviscoplastic materials could also be provided. Non associated flow rules for applications to granular media should also be envisaged.

It is hoped that the present results can increase the interest of the engineering computation community towards the systematic use of physically consistent nonlinear constitutive equations.

Appendix A: Hypoelastic-based formulations

The constitutive laws are formulated in terms of objective rates of stress measures, as e.g. of $\underline{\underline{\sigma}}$

$$\overset{\nabla}{\underline{\underline{\sigma}}} = \underline{\underline{\mathbb{C}}} : \underline{\underline{D}}^e = \underline{\underline{\mathbb{C}}} : (\underline{\underline{D}} - \underline{\underline{D}}^p) \quad (\text{A.1})$$

$\overset{\nabla}{\underline{\underline{\sigma}}}$ denotes an objective rate of Cauchy stress tensor given by

$$\overset{\nabla}{\underline{\underline{\sigma}}} = \dot{\underline{\underline{\sigma}}} + \underline{\underline{\sigma}}\underline{\underline{\Omega}} - \underline{\underline{\Omega}}\underline{\underline{\sigma}} \quad (\text{A.2})$$

$\underline{\underline{\Omega}}$ is a skew-symmetric second-order tensor. The most commonly used corotational objective stress rates are the Jaumann and Green–Naghdi rates. The spin tensors $\underline{\underline{\Omega}}$ corresponding to the Jaumann and Green–Naghdi rates are defined as

$$\underline{\underline{\Omega}}^J = \underline{\underline{W}} \quad \text{and} \quad \underline{\underline{\Omega}}^{\text{GN}} = \dot{\underline{\underline{R}}}\underline{\underline{R}}^T \quad (\text{A.3})$$

where $\underline{\underline{W}} = \text{skw}(\underline{\underline{L}})$ is the skew-symmetric part of the velocity gradient and $\underline{\underline{R}}$ is an orthogonal tensor such that $\underline{\underline{F}} = \underline{\underline{R}}\underline{\underline{U}}$ ($\underline{\underline{U}}$ is a symmetric second order tensor). The yield condition is given by

$$f(\underline{\underline{\sigma}}, A_I, T) = 0 \quad (\text{A.4})$$

The plastic part $\underline{\mathbf{D}}^p$ of the rate of deformation tensor is determined by the flow rule

$$\underline{\mathbf{D}}^p = \dot{\lambda} \frac{\partial f(\underline{\boldsymbol{\sigma}}, A_I, T)}{\partial \underline{\boldsymbol{\sigma}}} \quad (\text{A.5})$$

Appendix B: Finite element implementation

The nodal displacements are written in vector form as

$$\{\underline{\mathbf{u}}^e\} = \{u_1^1 \ u_2^1 \ u_3^1 \ \cdots \ u_1^p \ u_2^p \ u_3^p\}^T \quad (\text{A.6})$$

u_j^i denotes the j -th ($1 \leq j \leq 3$) component of the nodal displacement at node i . p is the total number of nodes. The shape functions can be written as

$$[\mathbf{N}] = \begin{bmatrix} N^1 & 0 & 0 & \cdots & N^p & 0 & 0 \\ 0 & N^1 & 0 & \cdots & 0 & N^p & 0 \\ 0 & 0 & N^1 & \cdots & 0 & 0 & N^p \end{bmatrix} \quad (\text{A.7})$$

and

$$\{\underline{\mathbf{u}}\} = [\mathbf{N}]\{\underline{\mathbf{u}}^e\} \quad (\text{A.8})$$

It follows that

$$\{\underline{\mathbf{F}}\} = \{F_{11} \ F_{22} \ F_{33} \ F_{12} \ F_{23} \ F_{31} \ F_{21} \ F_{32} \ F_{13}\}^T = [\mathbf{B}]\{\underline{\mathbf{u}}^e\} \quad (\text{A.9})$$

where

$$[\mathbf{B}] = \begin{bmatrix} \frac{\partial N^1}{\partial X_1} & 0 & 0 & \cdots & \frac{\partial N^p}{\partial X_1} & 0 & 0 \\ 0 & \frac{\partial N^1}{\partial X_2} & 0 & \cdots & 0 & \frac{\partial N^p}{\partial X_2} & 0 \\ 0 & 0 & \frac{\partial N^1}{\partial X_3} & \cdots & 0 & 0 & \frac{\partial N^p}{\partial X_3} \\ \frac{\partial N^1}{\partial X_2} & 0 & 0 & \cdots & \frac{\partial N^p}{\partial X_2} & 0 & 0 \\ 0 & \frac{\partial N^1}{\partial X_3} & 0 & \cdots & 0 & \frac{\partial N^p}{\partial X_3} & 0 \\ 0 & 0 & \frac{\partial N^1}{\partial X_1} & \cdots & 0 & 0 & \frac{\partial N^p}{\partial X_1} \\ 0 & \frac{\partial N^1}{\partial X_1} & 0 & \cdots & 0 & \frac{\partial N^p}{\partial X_1} & 0 \\ 0 & 0 & \frac{\partial N^1}{\partial X_2} & \cdots & 0 & 0 & \frac{\partial N^p}{\partial X_2} \\ \frac{\partial N^1}{\partial X_3} & 0 & 0 & \cdots & \frac{\partial N^p}{\partial X_3} & 0 & 0 \end{bmatrix} \quad (\text{A.10})$$

The linear set of equations to be solved for $\Delta \underline{\mathbf{u}}$ iteratively is given by

$$[\mathbf{K}]^g \Delta \underline{\mathbf{u}} = \int_{\Omega_0} [\mathbf{N}^T] \{\underline{\mathbf{b}}\} dV_0 + \int_{\partial \Omega_0^{tr}} [\mathbf{N}]^T \{\underline{\mathbf{t}}\} dS_0 - \int_{\Omega_0} [\mathbf{B}]^T \{\underline{\mathbf{P}}\} dV_0 \quad (\text{A.11})$$

where $[\mathbf{K}]^g$ is the global tangent matrix in Eq. (63) and Eq. (67) and $\{\tilde{\mathbf{P}}\}$ is the Boussinesq stress tensor. $\{\mathbf{b}\}$ and $\{\mathbf{t}\}$ denote the reference body force and surface traction fields, respectively.

Appendix C: Tangent matrices

The Jacobian matrix is required to integrate the constitutive equations at the Gauss point level. The block form of the Jacobian matrix writes

$$\begin{pmatrix} \frac{\partial \mathcal{R}_{el}}{\partial \Delta \tilde{\mathbf{F}}^e} & \frac{\partial \mathcal{R}_{el}}{\partial \Delta p_i} & \frac{\partial \mathcal{R}_{el}}{\partial \Delta \alpha_i} \\ \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \tilde{\mathbf{F}}^e} & \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta p_i} & \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \alpha_i} \\ \frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta \tilde{\mathbf{F}}^e} & \frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta p_i} & \frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta \alpha_i} \end{pmatrix} \quad (\text{A.12})$$

where the residuals are taken as

$$\mathcal{R}_{el} = \Delta \tilde{\mathbf{F}}^e - \Delta \tilde{\mathbf{F}} \tilde{\mathbf{F}}^{-1} \tilde{\mathbf{F}}^e + \tilde{\mathbf{F}}^e \sum_{i=0}^N \Delta p_i \tilde{\mathbf{N}}_i \quad (\text{A.13})$$

$$\mathcal{R}_{p_i} = f_i \quad \text{or} \quad \mathcal{R}_p = \Delta p_i - \Delta t \frac{\partial \Omega}{\partial f_i} \quad (\text{A.14})$$

$$\mathcal{R}_{\alpha_i} = \Delta \alpha_i - \Delta p_i \mathbf{m}_i + \Delta \mathbf{q}_i \quad (\text{A.15})$$

The terms related to the global part of the Jacobian (the first row and the first column) are given by

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta \tilde{\mathbf{F}}^e} = \mathbf{1} - (\Delta \tilde{\mathbf{F}} \tilde{\mathbf{F}}^{-1}) \otimes \mathbf{1} + \sum_{i=0}^N \Delta p_i \left(\mathbf{1} \otimes \tilde{\mathbf{N}}_i^T \right) + \theta \tilde{\mathbf{F}}^e \left[\sum_{i=0}^N \Delta p_i \frac{\partial \tilde{\mathbf{N}}_i}{\partial \tilde{\mathbf{M}}} \right] : \frac{\partial \tilde{\mathbf{M}}}{\partial \tilde{\mathbf{F}}^e} \quad (\text{A.16})$$

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta p_i} = \tilde{\mathbf{F}}^e \tilde{\mathbf{N}}_i + \Delta p_i \frac{\partial \tilde{\mathbf{N}}_i}{\partial \mathbf{A}_i} \frac{\partial \mathbf{A}_i}{\partial p_i} \quad (\text{A.17})$$

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta \alpha_i} = \theta \tilde{\mathbf{F}}^e \sum_{i=0}^N \Delta p_i \left(\frac{\partial \tilde{\mathbf{N}}_i}{\partial \mathbf{A}_i} \frac{\partial \mathbf{A}_i}{\partial \alpha_i} \right) \quad (\text{A.18})$$

$$\frac{\partial \mathcal{R}_p}{\partial \Delta \tilde{\mathbf{F}}^e} = \theta \frac{\partial f}{\partial \tilde{\mathbf{M}}} : \frac{\partial \tilde{\mathbf{M}}}{\partial \tilde{\mathbf{F}}^e} \quad \text{or} \quad \frac{\partial \mathcal{R}_p}{\partial \Delta \tilde{\mathbf{F}}^e} = -\theta \Delta t \frac{\partial p_i}{\partial f_i} \left(\frac{\partial f}{\partial \tilde{\mathbf{M}}} : \frac{\partial \tilde{\mathbf{M}}}{\partial \tilde{\mathbf{F}}^e} \right) \quad (\text{A.19})$$

$$\frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta \tilde{\mathbf{F}}^e} = -\theta \Delta p_i \frac{\partial \mathbf{m}_i}{\partial \tilde{\mathbf{M}}} : \frac{\partial \tilde{\mathbf{M}}}{\partial \tilde{\mathbf{F}}^e} \quad (\text{A.20})$$

where

$$\frac{\partial \underline{\underline{M}}}{\partial \underline{\underline{F}}^e} = \underline{\underline{1}} \bar{\otimes} (\underline{\underline{\Pi}}^e \underline{\underline{F}}^{eT}) + \underline{\underline{F}}^{eT} \underline{\underline{\otimes}} \underline{\underline{\Pi}}^e + \underline{\underline{F}}^{eT} \underline{\underline{F}}^e \frac{\partial \underline{\underline{\Pi}}^e}{\partial \underline{\underline{E}}^e} : \frac{\partial \underline{\underline{E}}^e}{\partial \underline{\underline{F}}^e} \quad (\text{A.21})$$

$$\frac{\partial \underline{\underline{E}}^e}{\partial \underline{\underline{F}}^e} = \frac{1}{2} \left(\underline{\underline{1}} \bar{\otimes} \underline{\underline{F}}^{eT} + \underline{\underline{F}}^{eT} \underline{\underline{\otimes}} \underline{\underline{1}} \right) \quad (\text{A.22})$$

Recall that $\theta \in [0,1]$ is a parameter of the integration method. Next, the block of the Jacobian related to the internal variable evolution equations writes

$$\frac{\partial \mathcal{R}_{p_i}}{\partial \Delta p_i} = \theta \frac{\partial f}{\partial p} \quad \text{or} \quad \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta p_i} = 1 - \theta \Delta t \frac{\partial \dot{p}_i}{\partial f_i} \frac{\partial f_i}{\partial p_i} \quad (\text{A.23})$$

$$\frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \alpha_i} = \frac{\partial f}{\partial \alpha_i} \frac{\partial \alpha_i}{\partial \Delta \alpha_i} \quad \text{or} \quad \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \alpha_i} = -\theta \Delta t \frac{\partial \dot{p}_i}{\partial f_i} \frac{\partial f}{\partial \mathbf{A}_i} \frac{\partial \mathbf{A}_i}{\partial \alpha_i} \quad (\text{A.24})$$

$$\frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta p_i} = -\mathbf{m}_i - \theta \Delta p_i \frac{\partial \mathbf{m}_i}{\partial p_i} \quad (\text{A.25})$$

$$\frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta \alpha_i} = \mathbf{1} - \theta \left(\Delta p_i \frac{\partial \mathbf{m}_i}{\partial \mathbf{A}_i} + \Delta t \frac{\partial \mathbf{q}_i}{\partial \mathbf{A}_i} \right) \frac{\partial \mathbf{A}_i}{\partial \alpha_i} - \theta \Delta p_i \frac{\partial \mathbf{m}_i}{\partial \alpha_i} \quad (\text{A.26})$$

The interaction terms are given by

$$\frac{\partial \mathcal{R}_{p_i}}{\partial \Delta p_j} = \theta \frac{\partial f_i}{\partial p_j} \quad \text{or} \quad \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta p_j} = -\theta \Delta t \frac{\partial \dot{p}_i}{\partial f_i} \frac{\partial f_i}{\partial p_j} \quad (\text{A.27})$$

$$\frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \alpha_i} = \theta \frac{\partial f}{\partial \mathbf{A}_i} \frac{\partial \mathbf{A}_i}{\partial \alpha_j} \quad \text{or} \quad \frac{\partial \mathcal{R}_{p_i}}{\partial \Delta \alpha_i} = -\theta \Delta t \frac{\partial \dot{p}_i}{\partial f_i} \frac{\partial f}{\partial \mathbf{A}_i} \frac{\partial \mathbf{A}_i}{\partial \alpha_j} \quad (\text{A.28})$$

$$\frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta p_i} = \mathbf{0} \quad (\text{A.29})$$

$$\frac{\partial \mathcal{R}_{\alpha_i}}{\partial \Delta \alpha_j} = \mathbf{1} - \theta \left(\Delta p_i \frac{\partial \mathbf{m}_i}{\partial \mathbf{A}_i} + \Delta t \frac{\partial \mathbf{q}_i}{\partial \mathbf{A}_i} \right) \frac{\partial \mathbf{A}_i}{\partial \alpha_j} \quad (\text{A.30})$$

The matrix $\frac{\partial \mathbf{A}_i}{\partial \alpha_j}$ accounts for interactions between the hardening variables.

The second method to integrate constitutive equations relies upon the following definition of the residual in Eq. (A.13)

$$\mathcal{R}_{el} = \underline{\underline{F}}^e \underline{\underline{F}}^p - \underline{\underline{F}} \quad (\text{A.31})$$

$\underline{\mathbf{F}}^p$ is the solution of the following differential equation

$$\dot{\underline{\mathbf{F}}}^p = \overline{\underline{\mathbf{L}}}^p \underline{\mathbf{F}}^p \quad (\text{A.32})$$

So $\underline{\mathbf{F}}^p$, at increment $n + 1$, can be estimated by using the exponential mapping [70] as

$$\underline{\mathbf{F}}_{n+1}^p = \exp(\Delta \overline{\underline{\mathbf{L}}}^p) \underline{\mathbf{F}}_n^p \quad (\text{A.33})$$

Accordingly, the plastic incompressibility, i.e. $\text{trace}(\overline{\underline{\mathbf{L}}}^p) = 0$ or $\det(\underline{\mathbf{F}}^p) = 1$, is satisfied since

$$\det(\exp \underline{\mathbf{A}}) = \exp(\text{tr} \underline{\mathbf{A}}) \quad (\text{A.34})$$

The first row of the Jacobian matrix in Eq. (A.12) is rewritten

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta \underline{\mathbf{F}}^e} = \underline{\mathbf{1}} \otimes \underline{\mathbf{F}}^{pT} + \theta \underline{\mathbf{F}}^e \left[\frac{\partial \exp(\Delta \overline{\underline{\mathbf{L}}}^p)}{\partial \Delta \overline{\underline{\mathbf{L}}}^p} : \left(\sum_{i=0}^N \Delta p_i \frac{\partial \underline{\mathbf{N}}_i}{\partial \underline{\mathbf{M}}} \right) : \frac{\partial \underline{\mathbf{M}}}{\partial \underline{\mathbf{F}}^e} \right] \underline{\mathbf{F}}_n^p \quad (\text{A.35})$$

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta p_i} = \underline{\mathbf{F}}^e \left(\frac{\partial \exp(\Delta \overline{\underline{\mathbf{L}}}^p)}{\partial \Delta \overline{\underline{\mathbf{L}}}^p} : \underline{\mathbf{N}}_i \right) \underline{\mathbf{F}}_n^p \quad (\text{A.36})$$

$$\frac{\partial \mathcal{R}_{el}}{\partial \Delta \underline{\boldsymbol{\alpha}}_i} = \underline{\mathbf{F}}^e \left[\frac{\partial \exp(\Delta \overline{\underline{\mathbf{L}}}^p)}{\partial \Delta \overline{\underline{\mathbf{L}}}^p} : \left(\sum_{i=0}^N \Delta p_i \frac{\partial \underline{\mathbf{N}}_i}{\partial \Delta \underline{\boldsymbol{\alpha}}_i} \right) \right] \underline{\mathbf{F}}_n^p \quad (\text{A.37})$$
