Research in context

Evidence before this study

Complications related to the use of short-term peripheral vascular catheters are common, leading to catheter failure in about half of cases before the end of treatment. Paradoxically, there are few recommendations on the modalities to prevent these complications. We searched on PUBMED for randomized-controlled and quasi experimental trials, systematic reviews and meta-analyses assessing skin preparation before peripheral venous catheter insertion and choice of medical devices. We included trials published from January 1, 1980 to December 31, 2019, in French or in English, using the following keywords (short term peripheral venous catheter) AND (chlorhexidine) OR (iodine) OR (antiseptic) OR (failure) OR (occlusion) OR (dislodgment) OR (infiltration) OR (phlebitis) OR (accidental removal). We screened title and abstracts to retrieve full-text articles for assessment of eligibility and checked reference lists of relevant trials and reviews for additional references. Concerning skin preparation, we identified only one randomised small study showing the superiority of 2% chlorhexidine-70% isopropyl alcohol over 70% isopropyl alcohol in reducing catheter colonisation, and no study comparing chlorhexidine to povidone iodine. Concerning the type of devices, we identified only one randomised controlled trial showing the benefit of closed catheters over standard catheters and two quasi experimental studies suggesting the benefit of using needleless connectors or disinfecting caps in reducing catheter-related infectious complications or catheter failure.

Added value of this study

We performed an investigator-initiated, open-label, single centre, randomised, two-by-two factorial trial in a French University hospital, in which 1000 patients due to receive a short-term peripheral venous catheter were assigned to one of four groups according to skin disinfection and type of devices. Skin disinfection was a 30-second single application of 2% chlorhexidine-70% isopropyl alcohol or of 5% povidone iodine-69% ethanol. Devices were closed integrated catheters and disinfecting caps with treatments administered through zero-flow needleless connectors preceded and followed by flushing with pre-filled saline syringes (innovation group) or open catheters with treatments administered through three-way stop cocks

(standard group). Patients assigned to chlorhexidine-alcohol group had fewer local infections (0/496 [0%] vs 6/493 [1.2%] patients) and fewer catheters colonised (4/431 [0.9%] vs 70/415 [16.9%] catheters among the catheters cultured) compared with those assigned to povidone iodine–alcohol group. Use of innovative solutions in combination reduced the risk of catheter failure (172/494 [34.8%] vs 235/495 [47.5%] catheters) compared with standard devices and extends the median [IQR] time between catheter insertion and catheter failure (50.4 [29.6-69.4] vs 30.0 [16.6-52.6] hours, $p=0.0017$). Skin reactions were uncommon (1.6%) and of minor severity, with no difference between the antiseptic groups.

Implications of all the available evidence

For skin preparation, 2% chlorhexidine-alcohol should be preferred to 5% povidone-iodine alcohol before the insertion of short-term peripheral venous catheters. Similarly, use of closed integrated catheters, zero-flow needleless connectors, prefilled flush syringes and disinfecting caps should be recommended to increase catheters indwell time without complication. Whether all compounds of the combination should be recommended remains to be established.

Summary

Background Two billion peripheral venous catheters are sold globally each year, but the optimal skin disinfection and types of devices are not well-established. We aimed to demonstrate the superiority of 2% chlorhexidine-alcohol over 5% povidone iodine-alcohol in preventing infectious complications, and of closed integrated catheters, zero-reflux needleless-connectors, disinfecting caps and single-use prefilled flush syringes used in combination (innovation group) over open catheters and three-way stop cocks for treatment administration (standard group) in preventing catheter failure.

Methods In this open-label, randomised-controlled trial with a two-by-two factorial design, we enrolled adults (age ≥ 18 years) visiting the emergency department at the Poitiers University hospital, France, and requiring one peripheral venous catheter before admission to the medical wards. Before catheter insertion, patients were randomly assigned (1:1:1:1) using a secure web-based random-number generator to one of four treatment groups based on skin preparation and type of devices. Primary outcomes were the incidence of infectious complications (local infection, catheter colonisation or bloodstream infections) and time between catheter insertion and catheter failure (occlusion, dislodgment, infiltration, phlebitis or infection). This study is registered with ClinicalTrials.gov, number NCT03757143.

Findings 1000 patients were recruited between Jan 7, 2019 and Sept 6, 2019, of which 500 were assigned to chlorhexidine-alcohol group and 500 to povidone iodine-alcohol group (250 with innovative solutions and 250 with standard devices in each antiseptic group). No significant interaction was found between the two study interventions. Local infections (0/496 [0%] vs 6/493 [1.2%] patients) and catheters colonisation (4/431 [0.9%] vs 70/415 [16.9%] catheters among the catheters cultured) occurred less frequently with chlorhexidine-alcohol than with povidone iodine-alcohol (adjusted subdistribution HR 0.08 [95% CI 0.02-0.18]). Median [IQR] time between catheter insertion and catheter failure (50.4 [29.6-69.4] vs 30.0 [16.6-52.6] hours, $p=0.0017$) was longer in the innovation group compared with the standard group. Minor skin reactions occurred in 1.8% and 1.4% in chlorhexidine-alcohol and povidone iodine-alcohol groups, respectively.

Interpretation For skin antisepsis, chlorhexidine–alcohol provides greater protection of peripheral venous catheter-related infectious complications than does povidone iodine–alcohol. Use of innovative solutions extends the catheters complication-free dwell time.

Funding Becton-Dickinson

INTRODUCTION

Short-term peripheral venous catheters (PVC) are the most commonly used invasive medical devices in hospitals; about two billion are sold annually world-wide.¹ Unfortunately, PVCs often fail before end of treatment due to mechanical, vascular or infectious complications.² These complications - occlusion, infiltration, phlebitis, dislodgment, and local or bloodstream infections - lead to interruption of treatment, which can be detrimental to patients. Catheter replacement causes pain and induces additional costs.³ In addition, bloodstream infections prolong hospitalisation and increase treatment costs and mortality.⁴ Prevention of these complications is therefore essential and is based on hygiene rules and use of biocompatible catheters. The choice of the most effective antiseptic solution for skin disinfection before catheter insertion is key. Although the use of alcoholic solutions is recommended by scientific societies,^{5,6} the superiority of 2% alcoholic chlorhexidine over 5% alcoholic povidone iodine in preventing infectious complications has been demonstrated only for short-term central venous and arterial catheters in critically ill patients.^{7,8} Similarly, innovative solutions such as closed integrated catheters, zero-reflux needleless-connectors, disinfecting caps and single-use prefilled flush syringes are being marketed to maintain catheter patency over a longer time lapse; but there is little scientific evidence to support their use in clinical practice⁹⁻¹² and no large-scale study has evaluated them when used in combination.

We hypothesised that skin preparation with 2% chlorhexidine-70% isopropanol (chlorhexidine-alcohol) is more effective than 5% povidone iodine-69% ethanol (povidone iodine-alcohol) in preventing PVC-related infectious complications. We also hypothesised that use of closed integrated catheters, zero-reflux needleless-connectors, disinfecting caps and single-use prefilled flush syringes in combination extends the time elapsed between catheter placement and catheter failure compared with the use of open catheters and three-way stop cocks for treatment administration.

METHODS

Study design

CLEAN 3 is an investigator-initiated, open-label, single-centre, randomised, two-by-two factorial, superiority trial conducted at Poitiers University Hospital, France. Patients were recruited at the emergency department, where the catheters were inserted, before being admitted to the medical wards. Patients were monitored daily for catheter-related complications for up to 48 hours after catheter removal, or earlier if discharged from hospital. The study protocol was approved by the French Southwest and Overseas Ethics Committee and the French Drug Safety Agency, and was published elsewhere.¹³ The study was carried out in accordance with the principles of the Declaration of Helsinki and the Clinical Trials Directive 2001/20/EC and 2005/28/EC of the European Parliament.

Participants

We enrolled adult patients (age ≥ 18 years) visiting our emergency department and requiring placement of a single PVC for 48 h or longer before hospital admission in medical wards. Exclusion criteria were¹³: known intolerance, hypersensitivity or contra-indication to chlorhexidine, povidone iodine, isopropanol or ethanol; suspicion of bloodstream infection; skin injury increasing the risk of catheter infection; presence of intravascular catheter in place within the last 2 days, or within the last 2 weeks and with local signs of catheter complication; suspicion of difficult catheter insertion; surgery required; prior participation in this study. We obtained written informed consent prior to study inclusion.

Randomisation and blinding

Randomisation was carried out by the emergency department physician through a secure web-based randomisation system. A statistician not involved in either screening patients or assessing outcomes provided a computer-generated numbered list. Patients were randomly assigned (1:1:1:1, in permuted blocks with varying block sizes from 4 to 12) to one of the four treatment groups based on skin preparation (chlorhexidine–alcohol or povidone iodine–alcohol) and devices used for the venous line (innovation group or standard group). Blinding of the participants and medical staff was not feasible due to the nature of the

interventions. However, the microbiologists who tested the catheters and blood samples and the statisticians (JP & DF) were blinded to the group assignment.

Catheters insertion

The PVCs were inserted by 39 nurses working in the emergency department. To participate in the study, nurses were required to have previously inserted at least 50 open PVCs. They also were required to follow French recommendations,⁵ similar to CDC recommendations,¹⁴ for catheter insertion and care. Hair was removed only if required with a clipper (no shaving) before catheter insertion. Hands of nurses were disinfected with hydro-alcoholic solution and wearing non-sterile gloves.

Skin preparation

Skin was disinfected with either 2% (weight/ volume [w/v]) chlorhexidine and 70% (v/v) isopropyl alcohol (ChloroPrep™, Becton Dickinson [BD], Le Pont de Claix, France) or 5% (w/v) povidone iodine and 69% (v/v) ethanol (Bétadine™ alcoolique, Mylan Medical SAS, Merignac, France). The assigned antiseptic solution was applied by moving back and forth using prefilled applicators (chlorhexidine–alcohol) or by circular movements using sterile gauzes soaked with the antiseptic (povidone iodine–alcohol) for at least 30 s, starting at the catheter insertion site and then extending to the entire work area. Assigned PVC was inserted once the work area was dry and taped with Tegaderm™ 1626W transparent film dressing (3M, St Paul, USA). No ultrasound guidance was allowed during the study.

Types of devices

In the innovation group, PVCs were the Nexiva™ single port catheter (BD). Intravenous fluids or drugs were administered through a zero-reflux needless-connector (MaxZero™ [BD]), after removal of the disinfecting cap covering the needle-free luer connector (PureHub™ [BD]). Before and after each drug administration, a “pulse” flushing technique with 5 mL of sterile saline solution in prefilled syringe [BD] was used to flush the catheter and its extension, followed by administering positive pressure to seal the tube (by pushing the flushing solution while simultaneously clamping the extension tubing). Pulse flushing consists in alternately pushing and pausing in flushing with saline solution, creating a small vortex within the catheter. Recapping

of the needle-free luer connector with a new disinfecting cap was systematic. Intravenous fluids were infused only if the patient needed them, not so as to avoid catheter occlusion, and usually discontinuously. In the standard group, PVCs were the Insyte™ Autoguard™ BC Winged (BD). Intravenous fluids and drugs were administered through a three-way stop cock (BD), after disinfecting the administration site with sterile gauzes soaked with an alcohol-based antiseptic. PVCs were continuously infused with saline or polyionic solution, by gravity, to prevent catheter occlusion, until catheter removal.

Catheters maintenance

Nurses' hands were decontaminated before any contact with the PVC or injection sites, using an alcohol-based hand rub. No restriction on the products administered through the PVCs was placed. Dressings were not changed except if soiled or loose. The same antiseptic procedure was used at each dressing change. Catheters were removed only for completion of treatment, phlebitis, infiltration, occlusion, dislodgment, or suspected infection, and usually not later than day 4. However, the decision to remove the catheter was made solely by the physicians in charge of the patients. Catheter tips were cultured with a simplified quantitative broth dilution technique.¹⁵

Nurses training and study monitoring

See Appendix, page 4

Definitions

We defined catheter colonisation as a quantitative catheter-tip culture eluate in broth showing at least one microorganism in a concentration of at least 1000 CFU per mL.

We defined local infection as organisms growing from purulent discharge with no evidence of associated bloodstream infection.

Definition of catheter-related bloodstream infection (CR-BSI) and all-cause bloodstream infection are provided in the Appendix, page 5.

We defined phlebitis as two or more of the following present simultaneously: patient-reported pain or tenderness (on questioning, followed by palpation by the research nurse) with severity of two or more on a ten-point scale; erythema extending at least 1 cm from the insertion site; swelling, extending at least 1 cm from the insertion site; purulent discharge; palpable venous cord beyond the intravenous catheter tip.

We defined infiltration as the infusion of non-blistering drug leaking through the normal vascular channel and resulting in the swelling of tissue peripheral to the puncture site.

We defined occlusion as the inability of the catheter to flush (not able to intravenously inject 1mL of normal saline within 30 s).

We defined dislodgment as any situation leading to a catheter being outside the vein.

Outcomes

The first primary outcome was the incidence of catheter-related infectious complications, and included local infection, catheter colonisation and CR-BSI. The second primary outcome was the time between catheter insertion and catheter failure. Catheter failure was defined as any premature removal of PVC before end of treatment, other than for routine replacement, and included phlebitis, infiltration, occlusion, dislodgment, local infection and CR-BSI (whichever occurred first). French guidelines recommend changing peripheral venous catheters every 4 days, a time frame that can be extended by decision of the attending physician. Additional prespecified outcomes were: incidence of local infection, catheter colonisation, CR-BSI, and of all-cause bloodstream infection, phlebitis, infiltration, catheter occlusion and catheter dislodgment; length of first hospital stay censored at day 28; and safety outcomes including daily skin status assessed using the International Contact Dermatitis Research Group scale; pain at catheter insertion using the 10-cm visual analogue scale (VAS, see Appendix, page 6); patient satisfaction at catheter removal using VAS; impact of venous line on patient's mobility at catheter removal using VAS. The International Contact Dermatitis Research Group scale includes four stages of increasing severity: faint erythema only; non-vesicular erythema, infiltration, possibly papules; vesicular erythema, infiltration, and papules; and

intense erythema and infiltration, coalescing vesicles, bullous reaction. The first two stages are considered minor reactions; the last two stages are considered severe reactions.

Each participant remained in the study until 48 h after catheter removal or until he/she decided to stop participating in the study.

Statistical analysis

Assuming a 12% infectious complication rate in the povidone iodine-alcohol group,¹⁶ 712 patients were required to detect a 50% reduction of PVC infectious complications with the use of chlorhexidine-alcohol,¹¹ with two-tailed alpha (type-I error) of 5% and a power of 80%. We enrolled 1000 patients to better rule out a potential interaction between the two strategies (+30%) and a maximum catheter culture loss of 10%. The analyses were performed by 2×2 factorial design on a modified intention to treat basis (all patients except those who withdrew consent).¹⁷ No interim analysis was planned.

Demographic data and catheter characteristics were described as number and percentage or median and interquartile range. For analysis of the primary outcomes, the interaction between two study interventions (antiseptic agent and type of device) was sought first using multivariable logistic regression models.

Treatments effects (antiseptics comparison or devices comparison) were then assessed with competing risks regression, taking into account catheters removed without having developed a complication (competing risk) and with adjustment for other intervention (device groups for antiseptics comparison or antiseptic groups for devices comparison). The proportional hazards assumption was assessed with Schoenfeld's residuals. To make inferences about the effect of treatments, adjusted subdistribution hazard ratios (aSHR) and 95% confidence intervals (95% CI) were determined, and average marginal effects were calculated as adjusted probability of events. Sensitivity analyses were performed to account for patients excluded from the analyses for catheter insertion failures and for consent withdrawals. Excluded catheters were considered having infectious complications in the chlorhexidine group or having failed in the innovation group, and free of complications in the povidone-iodine and standard groups.

Secondary outcomes were described as number and percentage or median and IQR and compared with logistic regression or multiple linear regression, according to the type of variable, to allow interactions terms as for primary outcomes; treatment effects are presented as adjusted relative risk or adjusted mean difference.

All of the tests are two-tailed with no adjustment for multiple testing. Analyses were done with SAS version 9.4 and R software. The analysis report is presented in accordance with the CONSORT Statement.¹⁸

Study registration

This study is registered with ClinicalTrials.gov, number NCT03757143 and is closed to new participants.

Role of the funding source

The University hospital of Poitiers, France, sponsored the study. Becton Dickinson, the manufacturer of the chlorhexidine–alcohol antiseptic solution and the innovative solutions used in this study, provided an unrestricted grant. Neither the sponsor nor BD had a role in trial initiation, study design, choice of antiseptic products, data collection, data analysis, data interpretation, writing of the report, or the decision to submit. The corresponding author had full access to all of the data in the study and had final responsibility for the decision to submit for publication.

RESULTS

Between Jan 7, 2019 and Sept 6, 2019, 1316 patients were eligible to participate in the study; we enrolled 1000 (figure 1). 250 patients (250 catheters) were randomly allocated to each study group. Five patients (1 in the chlorhexidine-alcohol/standard group and 4 in the povidone iodine-alcohol/standard group) withdrew consent and were excluded from the analyses. Baseline characteristics of the remaining 995 patients were similar for the four study groups (table 1 and table S1 Appendix, page 7). Failure to insert PVC was observed in 6 patients (3 in the chlorhexidine-alcohol/innovation group and 3 in the povidone iodine-alcohol/innovation group). In total, 989 PVCs were available to assess primary outcomes. Characteristics of

catheters were similar for the four study groups (table 2). We cultured 846 (86%) of the 989 catheters. 756 (76.4%) patients had their follow-up visit 24 hours after catheter removal and 677 (68.5%) at 48 hours. None of the patients who were not fully followed up revisited the emergency department for a catheter-related complication.

The OR of the interaction term between the two study interventions (antiseptic agent and type of device) and incidence of infectious complications or complications leading to catheter failure was 1.69 (95% CI 0.90-3.20). I.e., the results for comparison between the two antiseptics were not affected by the type of devices, nor were the results for comparison between standard and innovative devices affected by the type of antiseptic.

We identified six local infections and 74 colonised catheters. Local infection and catheter colonisation occurred in four cases in the same patient. Local infections (0/496 [0%] vs 6/493 [1.2%] patients; table 3 and table S2 Appendix, page 8) and catheters colonisation (4/431 [0.9%] vs 70/415 [16.9%] among the 846 catheters cultured; table 3 and table S2 Appendix, page 8) occurred less frequently with chlorhexidine-alcohol than with povidone iodine-alcohol (aSHR 0.08 [95% CI 0.02-0.18], figure 2), with similar effects on Gram-positive and Gram-negative organisms (table S3 Appendix, page 9). Adjusted probability of catheter-related infectious complications for the four study groups provided similar findings (table S4 Appendix, page 10). No CR-BSI was reported in either of the two antiseptic groups.

407 catheters (41.2%) failed before the end of treatment. Catheter failure (172/494 [34.8%] vs 235/495 [47.5%] catheters; absolute risk difference -12.7% [95% CI -18.7 to -6.6%]) occurred less frequently in the innovation group than in the standard group (aSHR 0.52 [95% CI 0.35-0.72], figure 3). Use of innovative solutions reduced catheter occlusion (4.0% vs 8.9%) and dislodgment (13.6% vs 19.0%), but not infiltration (14.4% vs 16.6%), phlebitis (2.4% vs 2.2%) and local infection (0.4% vs 0.8%) (table 3 and table S5 Appendix, page 11). Adjusted probability of catheter failure for the four study groups provided similar findings (table S4 Appendix, page 10). Median [IQR] time between catheter insertion and catheter failure (50.4 [29.6-69.4] vs 30.0 [16.6-52.6] hours, $p=0.0017$) was longer in patients assigned to the innovative group compared to those assigned to the standard group.

Incidence of all-causes bloodstream infections and length of stay in hospital were not affected by the choice of antiseptic agent or type of device (table 3). Impact of the venous line on mobility was rated as low by patients and their overall satisfaction upon catheter removal was very high, both of which were also unaffected by the choice of antiseptic agent or type of device (table 3).

No systemic or severe local adverse reactions to any antiseptic solution occurred. Minor skin reactions were uncommon (16 events, 1.6%), without any significant difference between chlorhexidine–alcohol and povidone iodine–alcohol (table 3). No adverse reactions related to the use of medical devices were reported.

Sensitivity analyses

When excluded patients of the chlorhexidine group (n=4) were considered to have catheter-related infectious complications and those of the povidone iodine group (n=7) were not, the risk of infectious complications (8/500 [1.6%] vs 72/500 [14.4%] catheters, absolute difference -12.8 % [95% CI -16.1% to -9.5%]) remained lower in patients assigned to the chlorhexidine group than in patients assigned to the povidone-iodine group. Similarly, when excluded patients of the innovation group (n=6) were considered to have catheter failure and those of the standard group (n=5) were not, the risk of catheter failure (178/500 [35.6%] vs 235/500 [47.0%] catheters, absolute difference -11.4% [95% CI -17.5% to -5.3%]) remained lower in patients assigned to the innovation group than in patients assigned to the standard group.

DISCUSSION

We report the first large-scale study comparing the efficacy of two antiseptics for the prevention of infectious complications related to the use of PVCs, and two types of venous lines for the prevention of complications leading to catheter failure. Use of 2% chlorhexidine-alcohol for skin antisepsis instead of 5% povidone iodine-alcohol reduced the risk of catheter colonisation and local infection. Use of innovative solutions including closed integrated catheters, needleless connectors, disinfecting caps and prefilled

syringes for flushing extended the catheters complication-free dwell time. Tolerance to antiseptics was excellent, with only rare minor skin reactions reported, without any difference between the two solutions. We chose a composite criterion combining catheter colonisation, local infection and CR-BSI to compare the efficacy of antiseptics in preventing infectious complications. Incidence of CR-BSI alone would likely have been a more clinically relevant outcome, but it is so rare, equal to 0.18% among 85063 PVCs from the available literature,¹⁹ that several thousand catheters would have been required to show a benefit. No CR-BSI was reported in our study despite the inclusion of nearly one thousand catheters. Catheter colonisation, which precedes catheter infection, is more frequent and has long been considered an acceptable substitute for CR-BSI,²⁰ although this has been questioned recently for central venous catheters.²¹ The inclusion of local infections, a more frequent event than CR-BSI, reinforces the clinical relevance of our composite criterion.

Very few studies have focused on the choice of the best antiseptic for skin preparation prior to PVC insertion. While the benefit of combining chlorhexidine with alcohol over alcohol alone has been suggested by one small-scale study,²² the best compound to combine with alcohol remained unknown before our study was started. French⁵ and English⁶ recommendations in favour of 2% chlorhexidine-alcohol were based on findings of the CLEAN study carried out on central venous and arterial catheters in critically ill patients.⁷ Our study confirms the superiority of chlorhexidine-alcohol over povidone iodine-alcohol in reducing both catheter colonisation and local infection, and warrants recommendation of chlorhexidine-alcohol as the preferred antiseptic for short-term PVC insertion and care. The superiority of chlorhexidine-alcohol has been associated with long-term antimicrobial suppressive activity of chlorhexidine and the inactivation of povidone iodine by blood and other protein-rich biomaterials present on skin^{23,24} even though the latter point has been challenged.²⁵

The high incidence and clinical and economic consequences of catheter failure warranted the addition of a second primary outcome. All in all, 41% of catheters in our study failed before the end of treatment, which is in agreement with the 43% of catheter failures reported in previous randomised controlled trials.² While some events (dislodgment, occlusion) have a universal definition, others (phlebitis, infiltration) have a non-

universal definition, rendering comparison between studies occasionally problematic . The number of catheter dislodgments observed in our study was two-times higher compared to previous studies²; this may be due to some extent to the inclusion of an older population at high risk of developing neurological disorders during hospitalisation.

Innovative solutions have been developed recently to decrease catheter complications and increase functional dwell time, but few studies have evaluated their benefit in clinical situations. One randomised trial compared 584 integrated PVCs (preassembled systems containing the catheter and extension tubing incorporated as one piece, and with a flatter hub profile resting against the skin surface) to 599 standard PVCs (separate components needing to be attached, with a rounded hub profile against the skin).⁹ The integrated group had fewer non-infectious complications (RR 0.64; 95% CI 0.47-0.88), leading to longer median functional dwell time and substantially reduced associated costs. In one quasi-experimental monocentre study, phlebitis rate (7% vs 60%, $p < 0.001$) was lower in 169 PVCs after introduction of needleless connectors than in 620 PVCs using regular caps.²⁶ Lack of randomisation and an unusually high rate of phlebitis in the baseline period make the findings questionable. Another quasi-experimental monocentre study showed a 43% reduction in bloodstream infections following introduction of disinfecting caps in a 630-bed hospital.¹⁰ Once again, the absence of randomisation and of significant statistical difference despite the long duration of the two study periods (21 months) precludes any conclusion. While flushing PVCs with saline solutions has the capacity to maintain catheter patency longer, use of manually filled syringes may be a barrier to regular flushing. In one quasi-experimental multicentre study involving 3853 PVCs, introduction of pre-filled flushing syringes was associated with a decrease in PVC failure rate (57.0% vs 43.4%; $p < 0.0001$).¹¹ Lack of randomisation and change in the catheter type used in a participating hospital between the two study periods also calls the findings into question.

Our randomized study is the first adequately designed to evaluate different innovative solutions that have shown potential benefit in reducing catheter failure. Compared to standard devices, utilisation of innovative solutions in combination reduced the relative risk of catheter failure by 27%, resulting in longer catheter dwell time without complications. The benefit of the combination became clear from the second

day of use (figure 3), suggesting that these devices should be restricted to patients requiring a vascular access for more than 24 hours. This advantage was significant on catheter occlusion and catheter dislodgment, but not on infiltration and phlebitis. These latter results could be explained by a lack of power of the study, but also by the fact that almost all dislodgments were accidental catheters removal by the patients. Of note, the number of catheters occlusion was lower in the innovation group despite the fact that only catheters in the standard group were routinely continuously infused.

Reasons for the superiority of the combination of innovative solutions are probably multifactorial.

Integrated PVC reduces pressures on the vein and the movement of the catheter body against the inner wall of the vein, which occurs when staffers manipulate the catheter, or when additional fluid tubing or direct injections are made through the dedicated port.²⁷ Decreasing pressure on the vein and catheter movements is key to reducing irritation of the tunica intima of the vessels, which in turn may reduce infiltration, occlusion or phlebitis. Flushing the catheter before and after drug administration contributes to maintaining the catheter patency by several ways: reduction of contact between incompatible drugs and/or fluids, limitation of the risk of thrombosis and phlebitis; and reduction of fibrin accumulation in the internal lumen of the catheter, reducing the risk of thrombosis and bacterial colonisation.¹¹ Use of pre-filled syringes has the advantage of increasing flushing compliance by making it easier to perform, saving nursing time and limiting the risk of bacterial contamination.

Adverse events to both antiseptic solutions were rare and similar in both frequency and severity in our study. Minor skin reactions occurred in 1.8% of patients assigned to chlorhexidine–alcohol and in 1.4% of patients assigned to povidone iodine-alcohol, a proportion 10-fold lower than those reported with the same antiseptics in critically ill patients.⁷ No severe skin reaction was reported in our study, while this complication was noted in 3% of patients assigned to chlorhexidine–alcohol and in 1% of patients assigned to povidone iodine-alcohol in critically ill patients.⁷ Greater severity of the disease and a threefold longer duration of exposure of the skin to antiseptics in critically ill patients may explain these differences. No adverse event related to use of the devices was reported. Six closed integrated catheter insertions failed. Limited acquisition of the insertion technique notwithstanding training of the teams before starting the

study could explain these observations, as suggested by the time of occurrence, all during the first half of the study.

Patient satisfaction was high overall, with no differences between study groups. These observations may be explained by the inclusion of patients at the beginning of hospitalisation, a period during which patients have little mobility due to their health condition, and by their difficulty in perceiving the benefit of the innovative approach in the absence of a concomitant standard approach.

Our study has several limitations. First, not all eligible patients were enrolled in the trial; indeed, emergency departments have strain periods not suitable for the inclusion of patients in studies. Second, blinding was not possible because the two antiseptics differed in colour and the medical devices were easily recognisable. However, the microbiologists and statisticians were blinded from the treatment group, and outcomes were based on strict definitions. Third, patients requiring surgery were excluded from the study in order to limit biases related to the higher risk of complications during patient transfers to the operating room. Four, results were not adjusted on nurses who inserted the catheters. However, only nurses with experience (≥ 50 PVC insertions) participated in the trial. Five, as assumed, no significant interaction was found between the two interventions. In spite of the relatively high number of catheters included, including the 30% increase in their estimated amount, such an interaction cannot be totally excluded. Six, despite the daily presence of research nurses in the wards, it was not possible to ensure full compliance with the protocol. Nevertheless, any mistake, such as the lack of flushing before or after each fluid or medication administration, would have rather disadvantaged the innovation group. Seven, since the innovation group was analysed as a whole, it is impossible to know whether all components of the combination are useful or not. We have chosen to compare the approach currently recommended in France to a set of innovations for which a synergistic benefit may be anticipated. Finally, it is not clear from the study whether the use of innovative solutions is cost-effective. Such a study should be carried out to compare the additional costs of innovative solutions with those related to the treatment of catheter complications and catheter replacement.

The strengths of our study include the participation of nearly all medical wards of our hospital, the study design including randomisation, the high number of catheters included, the training of all health-care personnel in the use of medical devices before initiating inclusion, and the availability of clinical research nurses to ensure compliance with the protocol 7 days a week. The majority of medical patients requiring admission in the wards were included. Patients requiring catheter placement in extreme emergency were excluded given the risk of non-compliance with recommended hygiene procedures. Therefore, we believe that our results can be extrapolated to all adult patients admitted to a medical ward and requiring PVC placement and, by extrapolation, to those admitted to a surgical ward.

In conclusion, use of 2% alcoholic chlorhexidine should become the first-line antiseptic for skin disinfection prior to insertion of a short-term peripheral venous catheter. Use of closed integrated catheters, zero-flow needleless connector, disinfecting caps and pre-filled flush syringes should be the rule when expected catheter dwell time exceeds 24 hours. Further studies are needed to identify the most cost-effective components of the combination.

Contributors

JG, BG, RO and OM led the trial. All the investigators mentioned as coauthors collected the data. JP and DF did the statistical analysis and were blinded for group assignment. OM, JG and DF wrote the article.

Declaration of interests

OM received personal fees, funding for congress and funding from Becton Dickinson. MB received personal fees from Becton Dickinson. All other investigators declare no competing interests.

Acknowledgments

We thank all the nurses in charge of the patients during the study for their support.

Data sharing

See Appendix, page 12
