ABSTRACT. We address the estimation of the source(s) location in the eikonal equation on a Riemann surface, as well as the determination of the metric when it depends on a few parameters. The available observations are the arrival times or are obtained indirectly from the arrival times by an observation operator, this frame is intended to describe electro-cardiographic imaging. The sensitivity of the arrival times is computed from Log_x the log map wrt to the source x on the surface. The Log_x map is approximated by solving an elliptic vectorial equation, using the Vector Heat Method. The L^2 -error function between the model predictions and the observations is minimized using Gauss-Newton optimization on the Riemann surface. This allows to obtain fast convergence. We present numerical results, where coefficients describing the metric are also recovered like anisotropy and global orientation.

3 **1. Introduction.**

4 **1.1. Context.** The study presented in this article aims to reconstruct from par-
5 tial measurements the sources locations and the metric associated to an eikonal
6 equation on a manifold. The measurements can be performed either directly on
7 the same manifold, or indirectly, e.g. on another surface surrounding the latter.
8 This problem is closely related to a practical issue in electrocardiology, which is the
9 inverse problem of electrocardiographic imaging (ECGI).

10 ECGI is a non-invasive imaging modality used to reconstruct the electrical activ-
11 ity of the heart. It combines electrical potential measurements on the torso surface
12 with a geometric description of the heart and torso. Electric measurements are per-
13 formed on the torso from a dense array of electrodes (typically 250 electrodes) that
14 measure the potential at a high time rate (typically 2 kHz). The geometric descrip-
15 tion of the torso and heart is obtained through Computerized Tomography (CT)
16 or Magnetic Resonance Imaging (MRI) and thus is personalized for each patient.

17 ECGI aims at bridging the gap between the classical non-invasive 12-leads ECG
 18 that lacks in sensitivity and specificity and the invasive intra-cardiac measurements
 19 with catheters.

20 The determination of electrical activity of the heart can in principle be obtained
 21 by solving at each time instant a Cauchy problem for the Laplace equation in the
 22 torso volume to reconstruct epicardial potential maps from body surface potential
 23 maps. However this problem is extremely ill-posed and an adequate regularization
 24 strategy has to be used to deal with this ill-posedness, for example Tikhonov regu-
 25 larization, or by incorporating anatomical knowledge or other a-priori information.

26 Another strategy consists in using the global information available during the
 27 complete measurement time interval, instead of processing each time-step indepen-
 28 dently. Taking into account the fact that electric potential in the heart are obtained
 29 by the propagation of an electric wave is an alternative way of regularizing the in-
 30 verse problem, by considering information from other time steps. The present work
 31 is an attempt in this direction. The electrical conduction in the heart is described
 32 by the bidomain model [6] which considers the interaction between intracellular and
 33 extracellular media. We consider here the anisotropic eikonal equation, which is a
 34 simplified model of propagation of the electrical activation front in its asymptotic
 35 regime [11], but yet accurate enough to produce realistic electrograms [25, 20, 21].

The solution T of the eikonal equation is the depolarization time of the heart
 surface, i.e. $T(x)$ is the arrival time of the activation front at the point x . The
 equation reads

$$\begin{cases} \|\nabla T\|_{D(x)}^2 &= 1, \\ T(x_i^0) &= \tau_i, i = 1 \dots s, \end{cases}$$

36 where

37 - the tensor quantity $D(x)$ describes the anisotropic conduction. It accounts for
 38 the local fiber orientation that induces an anisotropy in conduction velocity of the
 39 cardiac tissue.

40 - the boundary conditions depict the initialization of the electric front at earliest
 41 activation sites, that we will call throughout this paper the sources. In other words
 42 a front is initiated at the source x_i^0 at time τ_i . Physiologically, the source x_i^0
 43 is activated by the network of Purkinje fibers.

44 We consider in the present work only the surface of the heart (epicardial po-
 45 tential) and the domain is viewed as a 2-dimensional manifold equipped with the
 46 metric induced by $D(x)$. The formulation of the eikonal equation in this context
 47 requires more material and is provided in equation (1).

48 At this point, let us remark that the aforementioned electrical reconstructions
 49 on the heart surface are used to build activation maps that are used by cardiolo-
 50 gists in order to help to diagnose and treat cardiac conditions. In these activation
 51 maps some features are particularly interesting to be detected: the earliest sites of
 52 electrical activation (and their activation times), and the presence of zones where
 53 the front propagation speed is slower. Thus one additional advantage of using an
 54 eikonal equation is that these features are naturally parameters of the model.

55 In this paper, we formulate rather the eikonal equation in the framework of
 56 a Riemannian manifold, because this framework is convenient to describe partial
 57 differential equations on a surface with local properties. In this case the conductivity
 58 is directly taken into account in the metric of the manifold. The inverse problem to
 59 solve amounts to identify the sources, their activation times and possibly parameters

60 of the metric, from direct (on the heart surface) or indirect (on another surface)
 61 electrical measurements. In practice, we use a variational approach and minimize a
 62 quadratic cost function measuring the mismatch between the observations and the
 63 predictions of the model. To this purpose we compute the sensitivity of the arrival
 64 times of the eikonal equation with respect to the source locations, and with respect
 65 to the metric. The sensitivity with respect to the source locations is obtained
 66 by computing Log_x , which is the logarithmic map with respect to the source x
 67 on the surface of the manifold. The Log_x map is approximated by solving an
 68 elliptic vectorial equation, namely the Vector Heat Method [26]. The sensitivity
 69 with respect to the metric is obtained by an algorithmic differentiation based on
 70 the computation of the distance map with the Heat method. Using the Heat method
 71 and the Vector Heat Method avoids to compute geodesics on the manifold one by
 72 one, which would require a much higher computational cost.

73 **1.2. Related work.** Let us briefly present some recent works that adress similar
 74 problems. In [23], the electrical activity of the endocardium is modelled by an
 75 isotropic eikonal equation. The objective is to reconstruct the Purkinje network,
 76 that provides the earliest activation sites (together with their activation times).
 77 The available data are endocardial measures of the arrival times at N sampling
 78 points (N of the order of a few 100s). In this work an iterative method adapts
 79 the tree-like structure of the Purkinje network in order to increase the number
 80 of sampling points where the predictions are close from the measurements. The
 81 work [16] considers a bidomain model, which is more accurate than the eikonal
 82 approximation. The geometry is a square with horizontal fiber directions, and the
 83 sources locations are known. A numerical investigation is performed in order to
 84 evaluate the identifiability of the stimulus location and duration, with different
 85 measurement models: the extracellular potential is measured either in the domain,
 86 or at the boundary or at part of the boundary. The findings are that a local
 87 convergence is observed in all cases, using L-BFGS algorithm.

88 The work [19] addresses source localization, and uses the viscous eikonal equation,
 89 where a term $-\epsilon\Delta T$ is added. It is thus a nonlinear elliptic equation. The sources
 90 are described by small subdomains ω_i where a homogeneous Dirichlet condition
 91 is imposed, therefore it amounts to assume that all the sources are initiated at
 92 time $\tau_i = 0$. In this framework, a shape derivative of the cost function (quadratic
 93 mismatch between observed and predicted arrival times measured on part of the
 94 boundary) is calculated. It requires the solution of an adjoint problem and provides
 95 a vector field h that is used to advect the sources in a direction that decreases the
 96 objective function.

97 The work [24] addresses real ECG data processing. The activation time is as-
 98 sumed to satisfy an anisotropic eikonal equation, where the conductivity's principal
 99 direction is obtained by a rule-based method excepted at the scars which are iden-
 100 tified from MRI images. A derivative-free algorithm is used to iteratively estimate
 101 the sources activations times and some electrical parameters, and then sources with
 102 small region of influence are removed. Results on a cohort of 11 patients are pre-
 103 sented.

104 The reference that uses the closest approach from ours is [14], where the model
 105 is the anisotropic eikonal equation. The quadratic cost function is minimized using
 106 an over-relaxed gradient descent, and the location and timing of the sources are
 107 estimated. The Log_x map is computed by extracting each geodesic and the heavy

108 computational load requires the use of a Graphic Processing Unit. The complemen-
 109 tary contribution [15] by the same group proposes to estimate the conduction tensor
 110 assuming the source is known. The reconstruction is based on the minimization of
 111 a cost-function with a Total-Variation-like regularization that tends to align the
 112 fibers.

113 **1.3. Main contributions and organization.** The present paper intends to pro-
 114 pose and validate an efficient computational method to solve the inverse problem
 115 of location of sources and identification of metric parameters. It is organized as fol-
 116 lows: in section 2 we present the continuous problem formulated in the framework
 117 of Riemannian manifolds. In section 3 we compute the sensitivity of the arrival
 118 times of the eikonal equation with respect to the source locations and to the met-
 119 ric. In section 4 we present our methodology to solve the inverse problem with a
 120 least squares minimization using a manifold Gauss-Newton method. In section 5
 121 we provide details about the numerical methods used to compute in practice the
 122 sensitivities with respect to the source locations and to the metric and finally in
 123 section 6 we present the validation of the method on several test cases.

124 2. The continuous problem.

2.1. **Notation.** Let \mathcal{M} be a 2-dimensional Riemannian manifold. The tangent
 space to \mathcal{M} at the point x is denoted $T_x\mathcal{M}$. The inner product $\langle \cdot | \cdot \rangle_x$ on the space
 $T_x\mathcal{M}$ induces a linear mapping

$$\mathbf{A}(x) : T_x\mathcal{M} \rightarrow T_x^*\mathcal{M},$$

such that for any two vectors $v, w \in T_x\mathcal{M}$, the following identity is true:

$$\langle v | w \rangle_x = \langle \mathbf{A}(x)v | w \rangle_{T_x^*\mathcal{M}, T_x\mathcal{M}}.$$

125 The associated norm is denoted $\|v\|_x$. $\mathbf{A}(x)$ is a positive definite matrix, whose
 126 coefficients define a metric on \mathcal{M} .

On the cotangent space $T_x^*\mathcal{M}$ the inner product is defined, for any two covectors
 $p, q \in T_x^*\mathcal{M}$, by:

$$\langle p | q \rangle_{T_x^*\mathcal{M}} = \langle p | \mathbf{A}(x)^{-1}q \rangle_{T_x^*\mathcal{M}, T_x\mathcal{M}}.$$

127 The associated norm is denoted $\|p\|_{T_x^*\mathcal{M}}$.

128 **2.2. Forward model for one source.** Let $x \in \mathcal{M}$. The arrival time of a front
 129 issued from the point x at time $t = 0$ is the unique viscosity solution u [8] of the
 130 eikonal equation

$$\|\nabla u(y)\|_{T_y\mathcal{M}}^2 = (\mathbf{A}(y)\nabla u(y) | \nabla u(y))_{T_y^*\mathcal{M}, T_y\mathcal{M}} = 1, \quad u(x) = 0. \quad (1)$$

Here $\nabla u(y) \in T_y\mathcal{M}$ denotes the gradient of u on the Riemannian manifold,
 defined as

$$\forall h \in T_y\mathcal{M}, du(y).h = \langle \nabla u(y) | h \rangle_y.$$

131 Equivalently, the value $u(y)$ is the length of the shortest path $\gamma_{x \rightarrow y}$ joining x and
 132 y :

$$u(y) = \int_t \|\gamma'_{x \rightarrow y}(t)\|_{\gamma_{x \rightarrow y}(t)} dt. \quad (2)$$

The path $\gamma_{x \rightarrow y}$ is the geodesic joining x and y . It achieves the minimum in the
 following functional:

$$\int_t \|\gamma'(t)\|_{\gamma(t)} dt,$$

133 among all curves parametrized by $t \in [0, 1]$.

In order to emphasize that u is the solution of the eikonal equation issued from the point x , we will also write $u = \phi_x$, or use the alternative notation $\phi(x \rightarrow y) = u(y) = \phi_x(y)$. It is well known [8, 3] that u is differentiable everywhere, excepted at the point x and at the cut-locus which is the set of points that can be attained by different shortest geodesics with the same length issued from x . The measure of the cut-locus is zero. Moreover the differential of u can be estimated using a variation of the geodesic from x to y [22]. It is given by

$$du(y).h = \frac{\langle \gamma'_{x \rightarrow y}(1) | h \rangle_y}{\|\gamma'_{x \rightarrow y}(1)\|_y}.$$

But it follows from the formulation in terms of geodesics (2) that x and y play symmetric roles, and therefore if $y \neq x$ is fixed and is not in the cut locus, then $\phi(x \rightarrow y)$ is differentiable w.r.t x and

$$D_x \phi(x \rightarrow y).h = -\frac{\langle \gamma'_{x \rightarrow y}(0) | h \rangle_x}{\|\gamma'_{x \rightarrow y}(0)\|_x},$$

134 where γ is the geodesic joining x and y . This formula can be also found in [14].

This result can be formulated using the Exponential map, and its inverse the Log map, that are defined as follows. For $v \in T_x \mathcal{M}$ there is a unique geodesic γ issued from x with tangent vector $\gamma'(0) = v$, at least for v in a neighborhood of 0. Then by definition

$$\text{Exp}_x v := \gamma(1),$$

in other words $\text{Exp}_x v$ is obtained by following along the geodesic with initial direction v . Conversely, for $y \in \mathcal{M}$ if there is a unique shortest geodesic γ from x to y then by definition

$$\text{Log}_x(y) = \gamma'(0).$$

It follows that for $v \in T_x \mathcal{M}$ and for $y = \text{Exp}_x v$:

$$D_x \phi(x \rightarrow y).h = -\frac{\langle v | h \rangle_x}{\|v\|_x},$$

which reads also, for $y \in \mathcal{M}$:

$$D_x \phi(x \rightarrow y).h = -\frac{\langle \text{Log}_x(y) | h \rangle_x}{\|v\|_x}.$$

When the front starts from the point x at some instant τ called the activation time of x , then the arrival time $F(y)$ at any point y is simply shifted by the activation time:

$$F(y) = \tau + \phi(x \rightarrow y).$$

135 **2.3. Observation operator.** The observations are obtained from the arrival times
 136 map $F = \tau + \phi(x \rightarrow \cdot)$. It is continuous on \mathcal{M} , even differentiable almost everywhere.
 137 We will use the fact that $F \in L^2(\mathcal{M})$.

In a general inverse problem framework the observation operator is given by

$$G : L^2(\mathcal{M}) \rightarrow Y,$$

138 where Y is a Hilbert space equipped with a norm $\|\cdot\|_Y$. Our theoretical derivations
 139 will use a general differentiable observation operator G , but in practical cases of
 140 interest we will use either of

141 • $Y = L^2(\omega)$, where $\omega \subset \mathcal{M}$ and G consists in observing u on the subdomain ω ,

142 • when thinking of electrocardiography, $Y = L^2(\omega \times [0, T])$, where ω represents
 143 the union of the electrodes, and G consists of determining the signal at the electrodes
 144 during the time interval $[0, T]$. The modelling of this map requires the potential of
 145 action and the conductivity map between the surface of the heart \mathcal{M} and the torso
 146 where the electrodes are located.

As a summary the observations depending on the source location x and the activation time τ are obtained as follows:

$$\begin{array}{ccccc} \mathcal{M} \times \mathbf{R} & \longrightarrow & L^2(\mathcal{M}) & \longrightarrow & Y \\ (x, \tau) & \longmapsto & F(x, \tau) := \tau + \phi(x \rightarrow \cdot) & \longmapsto & G \circ F(x, \tau). \end{array}$$

147 3. Tangent model.

3.1. Sensitivity w.r.t the source location. In order to compute the sensitivity of the source-to-observations operator, we use the chain rule. The derivative of G depends on the specific choice of G and will be detailed for each example presented in section 6. We focus here on the sensitivity of $F : x \mapsto \phi(x \rightarrow \cdot)$ and suppose for the moment that the activation time is $\tau = 0$. We have proved that if $y \neq x$ does not belong to the cut locus, then

$$D_x \phi_x(y).h = -\langle \text{Log}_x(y) | h \rangle_x.$$

148 This is a pointwise differentiability result, for a fixed point y . It remains to prove
 149 the following global differentiability result:

Theorem 3.1. *Let \mathcal{M} be a complete Riemannian manifold, and $x^\dagger \in \mathcal{M}$. Let K be a compact included in the complementary of the cut locus wrt x^\dagger . Then the mapping*

$$\begin{array}{ccc} \mathcal{M} & \rightarrow & L^2(K) \\ x & \mapsto & \phi_x = \phi(x \rightarrow \cdot) \end{array}$$

150 *is differentiable at the point x^\dagger , and*

$$D_x \phi_x = -\mathbf{A}(x^\dagger) \text{Log}_{x^\dagger}. \quad (3)$$

151 The proof is based on the use of the Exp_x map as a chart for K and is postponed
 152 to the Appendix.

153 **3.2. Case of s sources.** In practice, there may be a (small) number s of sources
 154 to identify, as well as the activation time of each source, that is the initial condi-
 155 tion. Let us denote these sources x_1, \dots, x_s and the activation times τ_1, \dots, τ_s . The
 156 equation to be solved is then

$$\|\nabla F(y)\|_{L^2_y \mathcal{M}}^2 = 1, \quad F(x_i) = \tau_i, i = 1 \dots s. \quad (4)$$

There is a compatibility condition between the different activation times [2, 5], namely for any pair of sources the distance between these sources must be larger than the difference of their respective activation times. Under this condition, the manifold \mathcal{M} can be partitioned into Voronoi regions relative to each of the sources, up to a set of measure zero called the cut locus. The Voronoi region V_i of a source x_i is the set of points that are closer from x_i than from any other source, once the difference in activation times is taken into account. More precisely

$$V_i = \{y \in \mathcal{M} \mid \tau_i + \phi(x_i \rightarrow y) < \tau_j + \phi(x_j \rightarrow y) \text{ for } j \neq i\}.$$

The solution F of (4) can also be defined by

$$F(y) = \min_{1 \leq j \leq s} \tau_j + \phi(x_j \rightarrow y).$$

157 The Voronoi region V_i is the set of points y where i achieves strictly the min in the
158 equation above.

159 The modification of the activation time τ_i of the source x_i has the effect of
160 changing the value of F in V_i by adding a constant to F , and also changing the
161 Voronoi region (it grows if τ_i decreases and shrinks if τ_i increases). However the
162 modification of the Voronoi region has an impact that is of second order on the
163 value of F . More precisely, a variation of τ_i of value ϵ induces a displacement of
164 the boundary of the Voronoi region smaller than ϵ , and the value of F in the region
165 in-between (with area $O(\epsilon)$) is modified by a value smaller than ϵ . On the other
166 hand, in V_i (area $O(1)$) the value of F is modified by a value equal to ϵ . Therefore
167 we will neglect the variation of V_i in our numerical computation of the first order
168 derivative.

169 Similarly, the effect of the displacement of the source x_i affects the value of F
170 in V_i as well as the boundary of V_i . We neglect the second effect in our numerical
171 simulations.

172 **3.3. Sensitivity w.r.t the metric.** We are also interested in the case where the
173 metric $\mathbf{A}(x)$ is variable. It is hopeless to recover the value of the metric at each
174 point of \mathcal{M} , therefore we will assume that the metric depends on a finite number p
175 of parameters $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_p)$. The metric at the point x will be denoted $\mathbf{A}_{\boldsymbol{\alpha}}(x)$.

The arrival time u solution of (1) depends also on $\boldsymbol{\alpha}$ and we emphasize this
dependence by denoting

$$\phi^{\boldsymbol{\alpha}}(x \rightarrow y)$$

176 the solution with the metric $\mathbf{A}_{\boldsymbol{\alpha}}(x)$.

When the parameters $\boldsymbol{\alpha}$ that define the metric are perturbed in some direction
 $\boldsymbol{\beta}$, let us study if the quantity

$$D_{\boldsymbol{\alpha}}\phi^{\boldsymbol{\alpha}}(x \rightarrow y) \cdot \boldsymbol{\beta}$$

can be defined. We have

$$\phi^{\boldsymbol{\alpha}}(x \rightarrow y) = \int_{t=0}^1 \|\gamma^{\boldsymbol{\alpha}'(t)}\|_{\gamma^{\boldsymbol{\alpha}}(t)} dt,$$

where $\gamma^{\boldsymbol{\alpha}}$ is the geodesic from x to y for the metric $\mathbf{A}_{\boldsymbol{\alpha}}$. In other words

$$\phi^{\boldsymbol{\alpha}}(x \rightarrow y) = \int_{t=0}^1 \langle \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle^{1/2} dt.$$

When $\boldsymbol{\alpha}$ is perturbed in some direction $\boldsymbol{\beta}$, the geodesic $\gamma_{\boldsymbol{\alpha}}$ is perturbed in some
direction δ that depends linearly on $\boldsymbol{\beta}$. We have

$$D_{\boldsymbol{\alpha}}\phi^{\boldsymbol{\alpha}}(x \rightarrow y) \cdot \boldsymbol{\beta} = \int_t \frac{\langle \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \delta'(t) \rangle}{\langle \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle^{1/2}} + \frac{\langle D_{\boldsymbol{\beta}} \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle}{2 \langle \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle^{1/2}} dt.$$

The contribution of the first term vanishes since it is the first variation of the length
of the geodesic $\gamma^{\boldsymbol{\alpha}}$ in the direction δ . It remains

$$D_{\boldsymbol{\alpha}}\phi^{\boldsymbol{\alpha}}(x \rightarrow y) \cdot \boldsymbol{\beta} = \int_t \frac{\langle D_{\boldsymbol{\beta}} \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle}{2 \langle \mathbf{A}_{\boldsymbol{\alpha}}(\gamma^{\boldsymbol{\alpha}}(t)) \gamma^{\boldsymbol{\alpha}'(t)} | \gamma^{\boldsymbol{\alpha}'(t)} \rangle^{1/2}} dt,$$

177 which proves that $\phi^{\boldsymbol{\alpha}}(x \rightarrow y)$ is differentiable wrt $\boldsymbol{\alpha}$, and the derivative is given
178 by an integral along the geodesic. In our numerical solution, we implemented an
179 algorithmic differentiation of the Heat Method, see Algorithm 3 below. This allows
180 to bypass the tedious computation of "all" the geodesics.

181 **4. Parameters estimation.** We propose an iterative algorithm to estimate the
 182 source location, the activation time and the parameters of the metric. We first
 183 detail the approach used for the source location and activation time, since this part
 184 involves optimization on a manifold.

185 **4.1. Location of the source and activation time.** When the metric is fixed,
 186 and the source and the activation time are to be retrieved, we proceed using a
 187 variational approach. The aim is to minimize the misfit between the observations
 188 and the predictions of the model in a L^2 sense. More precisely consider the cost
 189 function defined for $(x, \tau) \in \mathcal{M} \times \mathbf{R}$ by

$$J(x, \tau) = \frac{1}{2} \|G(\tau + \phi_x) - g^{\text{OBS}}\|_Y^2. \quad (5)$$

In this writing, x is the location of the source, and g^{OBS} is the vector describing the observations, that can be viewed as

$$g^{\text{OBS}} = G(\tau^* + \phi_{x^*}) + \eta,$$

190 where x^* is the true location of the source, τ^* is the true activation time and η is
 191 a noise that affects the measurements.

192 We solve the least square minimization of J by following the approach of Gauss
 193 Newton optimization on a manifold sketched in [1]. It is an iterative method where
 194 the k -th iterate is denoted (x^k, τ^k) . We determine the direction $(v, \eta) \in T_x \mathcal{M}$ that
 195 minimizes the linearized model

$$\ell(v, \eta) = \frac{1}{2} \|G(\phi_{x^k}) + D_x(G(\tau^k + \phi_{x^k})).v + D_\tau(G(\tau^k + \phi_{x^k})).\eta - g^{\text{OBS}}\|_Y^2. \quad (6)$$

196 We estimate the linear term using the chain rule:

$$D_x(G(\tau^k + \phi_{x^k})).v + D_\tau(G(\tau^k + \phi_{x^k})).\eta = DG(D\phi_{x^k}.v) + \eta DG. \mathbf{1}. \quad (7)$$

197 The first quantity can be explicitly computed when v is given, since we have seen
 198 that $D\phi_x(y).v = \langle \text{Log}_x(y) | v \rangle_{T_x \mathcal{M}}$. In practice, we determine $D_x(G(\tau + \phi_x)).v$ for
 199 two values of the vector v that form a basis of $T_x \mathcal{M}$, this gives $D_x(G(\tau + \phi_x))$. The
 200 second quantity is $DG. \mathbf{1}$ which is known analytically for practical cases of G . Once
 201 the linear maps $T_x \mathcal{M} \rightarrow Y$ and $\mathbf{R} \rightarrow Y$ are known, the minimization of the linear
 202 model (6) is a least-squares problem in dimension 3. We denote (v^*, η^*) its solution.

Following [1] the next iterate in the minimization algorithm is

$$x^{k+1} := \text{Exp}_{x^k}(v^*), \quad \tau^{k+1} := \tau^k + \eta^*.$$

203 **4.2. Localization of several sources and their activation time.** In the case
 204 of a number s of sources, the modification of the location or the activation time of
 205 one source affects only its Voronoi region. The linear model (6) is replaced by an
 206 analogous expression, where the i -th source affects only V_i .

4.3. Joint estimation of the metric and source location. Suppose that in addition to the location of the source and the activation time, one also wishes to estimate the metric. We assume here again that the metric depends on a small number p of parameters: $\alpha = (\alpha_1, \dots, \alpha_p)$. The cost function to be minimized is now:

$$J(\alpha, x, \tau) = \frac{1}{2} \|G(\tau + \phi_x^\alpha) - g^{\text{OBS}}\|_Y^2.$$

207 The linearized model around (α, x, τ) in the direction (β, v, η) is given by

$$\ell(\beta, v, \eta) = \frac{1}{2} \|G(\tau + \phi_x^\alpha) + D_\alpha(G(\tau + \phi_x^\alpha)) \cdot \beta + D_x(G(\tau + \phi_x^\alpha)) \cdot v + D_\tau(G(\tau + \phi_x^\alpha)) \cdot \eta - g^{\text{OBS}}\|_Y^2. \quad (8)$$

The minimization of this least squares problem of dimension $p + 3$ leads to the next iterate. It is straightforward to compute when the linear parts are known. We have already given the linear part corresponding to the variables v and η . For the variable β the chain rule yields

$$D_\alpha(G(\tau + \phi_x^\alpha)) \cdot \beta = DG(D_\alpha \phi_x^\alpha \cdot \beta).$$

208 5. Practical Implementation.

209 **5.1. Discretization of the surface.** The manifold \mathcal{M} is discretized as a triangulated surface \mathcal{M}_h , composed of a set of vertices $\{i\}$ and a set of edges $\{ij\}$. The metric \mathbf{A} is given in practice by the lengths of the edges of the triangulation. In order to solve the eikonal equation using Fast-Marching methods the triangulation needs to satisfy an acuteness condition, meaning that all the triangles must be acute [17]. We use in the present work the Heat Method to solve the eikonal equation see subsection 5.2, which requires a slightly different geometric condition, namely the triangulation must be Delaunay w.r.t. the considered metric [4, 26].

217 In order to encode the tangent space $T_x \mathcal{M}$ to some vertex x we choose a reference direction along an edge issued from x . The sum of the angles issued from x is normalized to 2π , see [18]. A tangent vector at x is then encoded as a complex number attached to x . The mass matrix as well as the stiffness matrices of the Laplace-Beltrami and the connection Laplacian operators are assembled following [26].

223 **5.2. Direct problem.** We discretize the space of possible locations for the source x , by imposing that the point x is a vertex of the mesh. The distance map ϕ_x is solved using the Heat Method [9], which requires to assemble the matrix of the Laplace-Beltrami operator on the triangulated surface \mathcal{M}_h . The Heat Method relies on a well-known relationship between geodesic distance and heat kernel on a Riemannian manifold [27]. In practice, with the Heat Method, first the heat kernel is solved, then its gradient is normalized to recover the gradient of the distance field, then the distance field itself is reconstructed from this gradient. This procedure circumvents the high accuracy requirements if the distance field was directly reconstructed from the heat kernel.

Algorithm 1 Heat-Method to compute ϕ_x , see [9]

Input: Triangulated surface \mathcal{M}_h , metric \mathbf{A} , source point x .

Output: ϕ_x the distance map to x .

Assemble the discrete Laplace-Beltrami operator Δ .

Fix some small time $\tau > 0$ and set $u_0 := \delta_x$ (Dirac mass).

Solve for u the implicit Euler equation $(Id - \tau \Delta)u = u_0$.

Evaluate the vector field $X = -\nabla u / |\nabla u|$.

Solve the Poisson equation $\Delta \phi = \nabla \cdot X$.

Note that the change of variable $u = \exp(v/\sqrt{\tau})$ leads to v satisfying

$$-\sqrt{\tau} \Delta v + |\nabla v|^2 - 1 = 0$$

233 outside the source point. This is exactly the vanishing viscosity solution of the
 234 eikonal equation with parameter $\sqrt{\tau}$. The steps in algorithm 1 that construct ϕ
 235 from u amount to straighten up the (smooth) vanishing viscosity solution by weakly
 236 imposing a gradient of norm 1.

237 In practice an heuristic is proposed in [9] that uses for u the average between
 238 the solutions with homogeneous Dirichlet and Neumann boundary condition. This
 239 note does not apply to the examples presented in Section 6 where \mathcal{M} is a sphere or
 240 a closed surface hence has no boundary.

241 **5.3. Numerical derivative w.r.t. the source location.** Following equations
 242 (7) and (3), it suffices to compute the discrete Log_x map on \mathcal{M}_h to obtain the
 243 sensitivity w.r.t. x . In order to compute the Log_x map, we use the Vector Heat
 244 Method [26] which requires the connection Laplacian. We provide here a brief
 245 description and a sketch of the algorithm. For a more complete description we refer
 246 the reader to [26]. The Vector Heat Method relies on the result that the vector
 247 heat kernel on Riemannian manifolds behaves like parallel transport along shortest
 248 paths.

249 The connection Laplacian is a second derivative on vector fields, and is discretized
 250 as a complex matrix on the 2-dimensional surface \mathcal{M}_h . The Vector Heat Method
 251 has the advantage of providing $\text{Log}_x(y)$ for every mesh point y in one solve, and
 252 avoids the costly computation of geodesics issued from each point y . This requires
 253 the assembly of the (complex valued) stiffness matrix of the connection Laplacian.

Algorithm 2 Vector Heat-Method to compute Log_x , see [26]

Input: Triangulated surface \mathcal{M}_h , metric \mathbf{A} , source point x , reference unit vector
 $e_1 \in T_x \mathcal{M}_h$.

Output: Log_x the log map with origin x .

Assemble the discrete connection Laplacian Δ^∇ .

Fix some small time $\tau > 0$ and set $Y_0 := \delta_x e_1$ (Dirac mass).

Integrate $\partial_t Y_t = \Delta^\nabla Y_t$ between 0 and τ with $Y(t=0) = Y_0$.

The horizontal vector field is then $H = Y_\tau / |Y_\tau|$.

Define R_0 the discretized radial vector field issued from x .

The radial vector field R is obtained by transporting R_0 .

The coordinates (r, φ) of each vertex y are obtained using R, H and the distance
 map ϕ_x .

Set $\text{Log}_x(y) = r(\cos \varphi e_1 + \sin \varphi e_1^\perp)$.

254 **5.4. Algorithmic differentiation w.r.t. the metric.** When the metric is also
 255 to be recovered, in the case when it depends on the parameters $\alpha = (\alpha_1, \dots, \alpha_p)$,
 256 the description of the problem must include the derivative of each edge length w.r.t.
 257 each parameter α_k . In this case we compute the derivative of the arrival time ϕ_x
 258 w.r.t. to α_k using algorithmic differentiation as follows.

259 The numerical approximation of the arrival time ϕ_x is computed using Algorithm
 260 1. We use algorithmic differentiation (chain rule) to estimate the derivative of ϕ_x
 261 w.r.t. the metric. Let us denote $\mathbf{A}_k = \partial_{\alpha_k} \mathbf{A}$, and we assume that \mathbf{A}_k is given
 262 on the computational mesh, as the derivative of the length of each edge. This is
 263 the case in our examples where the metric depends on a few parameters through
 264 explicit analytic formulas.

FIGURE 1. Some triangle ABC of the mesh and the associated angles.

The key is to estimate the derivative of the Laplace-Beltrami operator Δ . Let us have more insight on the assembly of Δ as a finite element matrix. For each triangle in the mesh \mathcal{M}_h the contribution to the stiffness matrix is

$$-\frac{1}{2} \begin{pmatrix} b+c & -c & -b \\ -c & c+a & -a \\ -b & -a & a+b \end{pmatrix}$$

where a, b, c are cotangents of the angles of the considered triangle, see Figure 1. The values of the cotangents are related to the lengths of the edges l_{AB}, l_{AC}, l_{BC} using the cosine formula:

$$a = \cot \alpha = \frac{\cos \alpha}{\sin \alpha} = \frac{\cos \alpha}{\sqrt{1 - \cos^2 \alpha}}, \quad \cos \alpha = \frac{l_{AB}^2 + l_{AC}^2 - l_{BC}^2}{2l_{AB}l_{AC}}.$$

From the knowledge of $\partial_{\alpha_k} \mathbf{A}$ one can estimate the derivative of the edge lengths $\partial_{\alpha_k} l_{AB}, \partial_{\alpha_k} l_{AC}, \partial_{\alpha_k} l_{BC}$. Using the above formulas and the chain rule yields ∂_{α_k} . This allows to assemble the derivative of the stiffness matrix $\partial_{\alpha_k} \Delta$, with a contribution in each triangle of the form

$$-\frac{1}{2} \begin{pmatrix} \partial_{\alpha_k} b + \partial_{\alpha_k} c & -\partial_{\alpha_k} c & -\partial_{\alpha_k} b \\ -\partial_{\alpha_k} c & \partial_{\alpha_k} c + \partial_{\alpha_k} a & -\partial_{\alpha_k} a \\ -\partial_{\alpha_k} b & -\partial_{\alpha_k} a & \partial_{\alpha_k} a + \partial_{\alpha_k} b \end{pmatrix}$$

265 The derivative $\partial_{\alpha_k} \phi_x$ of ϕ_x is obtained with the following algorithm that is obtained by differentiating Algorithm 1:

Algorithm 3 Differentiation of the Heat-Method to compute $\phi' = \partial_{\alpha_k} \phi_x$

Input: Triangulated surface \mathcal{M}_h , metric \mathbf{A} , derivative $\partial_{\alpha_k} \mathbf{A}$ of the metric, source point x .

Output: $\phi' = \partial_{\alpha_k} \phi_x$ the derivative of the distance map to x .

Assemble the derivative of Laplace-Beltrami operator $\Delta' = \partial_{\alpha_k} \Delta$.

Fix some small time $\tau > 0$ and set $u_0 := \delta_x$ (Dirac mass).

Solve for u the implicit Euler equation $(Id - \tau \Delta)u = u_0$.

Solve for u' the equation $(Id - \tau \Delta)u' = \tau \Delta' u$.

Evaluate the vector field $X' = -\frac{|\nabla u| \nabla u' - (\nabla u \cdot \nabla u') \nabla u}{|\nabla u|^2}$.

Solve the Poisson equation $\Delta \phi' = \nabla \cdot X'$.

267 **6. Numerical results.** The test cases 1, 2 and 3 are obtained by direct simulation
 268 on a sphere. The anisotropic Riemannian metric is defined using the following 3
 269 parameters: $(\alpha, \kappa, d_{\parallel})$ where α is the angle between the principal axis and the
 270 meridians on the sphere, κ is the transverse slowness and d_{\parallel} is the longitudinal
 271 slowness.

272 The simulations were run on a mesh comprising approx. 6000 nodes and 12000
 273 triangles. This mesh was generated using Gmsh [13], and then the Delaunay flip
 274 algorithm [10, 4] was applied to obtain a Delaunay triangulation w.r.t. the metric.
 275 In order to generate the observations, the anisotropic eikonal equation is solved using
 276 AGSI [5]. It is deliberate to use a different method to generate the observations
 277 and to solve the inverse problem, this avoids so-called inverse crime [7].

278 All simulations were implemented with Python 3.7 and run on a laptop equipped
 279 with a 2.5 GHz Intel Core i7 processor.

280 **6.1. Test case 1: localization of a single source.** For this test case the Rie-
 281 mannian metric is defined by the following parameters: $(\alpha = \pi/3, \kappa = 1.8, d_{\parallel} = 1)$.
 282 There is one true point source x^* . The observation operator consists in observing
 283 the arrival times on a subset of the mesh vertices composed of 50% randomly se-
 284 lected vertices. The observations are corrupted by an additive Gaussian noise with
 285 standard deviation equal to a fraction of the largest arrival time $\|\phi_x\|_{\infty}$, either 1%
 286 (case 1a) or 10% (case 1b).

FIGURE 2. Left: location of the successive iterates x^k (red) and the true source point x^* (blue), the 3rd iterate x^3 coincides with x^* . Center: evolution of the cost function J for cases 1a and 1b. Right: evolution of the distance to the solution $\|x^k - x^*\|$ in both cases, note that the iterates are the same for cases 1a and 1b.

287 The initial position of the source is randomly chosen. We present in Figure 2 the
 288 location of the successive iterates, the evolution of the cost function J defined in (5),
 289 and the distance of the current iterate to the true location for cases 1a and 1b. We
 290 present in Table 1 the estimated activation times. The error is of the order of 0.03,
 291 to be compared to the maximum observed arrival time that is about 4.12. Note that
 292 in both cases the exact location is retrieved in 3 iterations, and the computational
 293 time is approx. 60s.

294 **6.2. Test case 2: localization of two sources.** For this test case the Riemann-
 295 ian metric is the same as test case 1. There are two point sources x_1^*, x_2^* with
 296 respective activation times $\tau_1^* = 0$ and $\tau_2^* = 0.2$. The observation operator consists
 297 in observing the arrival times on a subset of the mesh vertices composed of 50%
 298 randomly selected vertices. The observations are corrupted by an additive Gaussian

299 noise with standard deviation equal to a fraction of the largest value $\|\phi_x\|_\infty$, either
 300 1% (case 2a) or 10% (case 2b).

301 In order to recover two sources, we implemented the splitting method presented in
 302 [14]. It consists in starting with one single source, and at each iteration to estimate
 303 if an improvement is brought if this source is splitted in two sources. More precisely,
 304 we estimate for a number of $N = 20$ angles the modification of the cost function
 305 in the Voronoi region of the considered source if a) the source is (infinitesimally)
 306 displaced in the given direction b) the source is (infinitesimally) splitted along the
 307 given direction. If the gain observed by splitting is more than 5 times larger than
 308 the gain observed by moving the source, then it is decided to split the source. We
 309 refer the reader to [14] for details, we only emphasize that all the calculations are
 310 straightforward once the Log map w.r.t. the considered source is known.

311 In our implementation, we tried to split the source for the first 4 iterations, then
 312 every iteration count that is 2 modulo 5. We also decided to suppress at every
 313 iteration any source which has an almost empty Voronoi region (less than 5% of the
 314 vertices).

FIGURE 3. Left: location of the successive iterates x^k before splitting (red) and after splitting (green) and the true source points (blue). Center: evolution of the cost function J for cases 2a and 2b. Right: evolution of the distance to the solution in both cases.

315 The initial position of the source is randomly chosen. We present in Figure 3 the
 316 location of the successive iterates, the evolution of the cost function J defined in
 317 (5), and the distance to the true sources for cases 2a and 2b. The distance of a set
 318 $\{x^k\}$ to the true sources x_1^*, x_2^* is defined as $\max(\min_k \|x^k - x_1^*\|, \min_k \|x^k - x_2^*\|)$.
 319 Note that in both cases the exact locations are retrieved. We present in Table 2 the
 320 estimated activation times. The computational time is approx. 275s for case 2a (17
 321 iterations) and 140s for case 2b (9 iterations).

322 **6.3. Test case 3: joint localization of 2 sources and estimation of the**
 323 **metric.** For this test case the Riemannian metric is still defined by the following
 324 parameters: $(\alpha = \pi/3, \kappa = 1.8, d_{\parallel} = 1)$. There are two point sources x_1^*, x_2^* .
 325 The observation operator consists in observing the arrival times on a subset of the
 326 mesh vertices composed of 30% randomly selected vertices. The observations are
 327 corrupted by an additive Gaussian noise with standard deviation equal to a fraction
 328 of the largest value $\|\phi_x\|_{\infty}$, either 1% (case 3a) or 10% (case 3b).

329 The metric is to be recovered, from an initial guess $(\alpha^0 = \alpha + 0.1, \kappa^0 = \kappa +$
 330 $0.1, d_{\parallel}^0 = d_{\parallel} + 0.1)$. The location of the sources is also to be recovered, starting
 331 from one source and applying the same splitting criterion that was used in case 2.
 332 In order to stabilize the algorithm, the metric was not optimized during the first
 333 4 iterations, which amounts to ask to modify the metric only when the source(s)
 334 point(s) are in a "reasonable" region. We present in Figure 4 the location of the
 335 successive iterates, the evolution of the cost function J defined in (5), and the
 336 distance to the true sources for cases 3a and 3b. In Figure 5 we show the evolution
 337 of the parameters of the metric. We present in Table 3 the estimated activation
 338 times.

FIGURE 4. Left: location of the successive iterates x^k (red) and the true source point x^* (blue). Center: evolution of the cost function J for cases 3a and 3b. Right: evolution of the distance to the solution $\|x^k - x^*\|$ in both cases.

FIGURE 5. Evolution of the parameters of the metric (dashed: case 3a, line: case 3b). Note that it is not optimized during the first 4 steps.

339 Here again the perfect location of the sources are retrieved. The computational
 340 time is approx. 3800s for case 3a (14 iterations) and 3200s for case 3b (11 iterations).

True activation times τ^*	retrieved τ for case 3a	retrieved τ for case 3b
0/0.2	0.019/0.214	0.011/0.0215

TABLE 3. Reference and estimated activation times for test case 3

6.4. **Test case 4: mimicking an ECG inversion.** In order to demonstrate that our method can be applied to more realistic problems, we present a case where the observations do not take place at the surface itself, but are obtained similarly as electrocardiograms. The surface \mathcal{M} where the eikonal is solved is the surface of the heart, and observations points are located on the surface of the torso. The nonlinear observation operator is constructed as follows. The space for the observations is

$$Y = \{e_1, \dots, e_N\} \times \{t_1, \dots, t_M\},$$

341 where the e_i are electrodes located on the torso, and t_j are observation instants. At
 342 the instant t_j the electric potential at the surface of the heart is modelled using a
 343 waveform (tanh function) shifted by t_j , applied to the arrival times of the wavefront.
 344 This provides a Dirichlet condition on the surface of the heart for a Laplace equation,
 345 and the value of the solution at each electrodes minus the value at some reference
 346 electrode (first electrode) is the observed potential. The observations are then
 347 corrupted by an additive gaussian noise with standard deviation equal to 1% or
 348 10% of the largest observed value.

349 In this baby simulation that is intended for a proof-of-concept, we used a mesh
 350 composed of 4236 points, with 1712 nodes on the surface of the heart. The number
 351 of electrodes is $N = 30$ and the number of timesteps is $M = 40$.

352 We show in Figure 6 the configuration of the electrodes on the torso and the
 353 synthetic electrocardiogram for the case of 1% noise. Note that even for such a
 354 small value of noise, the measurements are markedly perturbed. We show in Figure
 355 7 the trajectory of the recovered location of the sources, the evolution of the cost
 356 function and of the distance to the solution. The estimated activation time is
 357 $\tau = 0.163$, while the reference is 0. This error is to be compared with the maximum
 358 observed arrival time that is approximately 14.2.

359 The computational time is about 20 minutes.

FIGURE 6. Left: configuration of the torso (electrodes in red) and the heart surface (visible by transparency). Right: observations at the electrodes (mimicking an ECG) obtained with noise-level 1%.

FIGURE 7. Left: location of the successive iterates x^k (red) and the true source point x^* (blue). Center: evolution of the cost function J . Right: evolution of the distance to the solution $\|x^k - x^*\|$ in both cases.

360 **7. Discussion.** We have proposed a method to locate the sources and retrieve the
 361 activation times in the eikonal equation on a manifold, this method also permits
 362 to estimate the Riemannian metric in the case it depends on a few parameters.
 363 This method converges in a small number of iterations, this is due to the use of
 364 Gauss-Newton minimization. In order to compute the Jacobian matrix, we used the
 365 Vector Heat Method that allows to obtain the Log_x map rapidly, without a tedious
 366 geodesic computation. The solution of the eikonal equation is only approximate
 367 but numerical simulations showed satisfactory results. The computation times are
 368 orders of magnitude faster than state-of-the-art methods [14], even though our
 369 Python implementation was not optimized.

370 The activation times were in all cases slightly overestimated. This may be due
 371 to the use of the Heat Method that tends to underestimate the distance close to the
 372 cut-locus. Therefore it has a bias towards underestimating the time needed to fill
 373 the surface, therefore the least-squares fit should tend to overshoot the activation
 374 time. This bias is however relatively small in our test cases.

375 **Appendix: proof of Theorem 3.1.** Let \mathcal{M} be a complete Riemannian manifold,
 376 and let us denote for simplicity $x \in \mathcal{M}$ instead of x^\dagger . The cut-locus of x is denoted
 377 C_x , and let $U_x = \mathcal{M} \setminus C_x$. Then Exp_x is a diffeomorphism between a star-shaped
 378 neighborhood V_x of $0 \in T_x\mathcal{M}$ and U_x [12].

379 We have thus a chart between V_x and \mathcal{M} minus the cut locus. The Christoffel
 380 symbols in this chart are denoted Γ_{ij}^k and are smooth on V_x . This means that the
 381 geodesic equation, for any geodesic that does not intersect the cut locus, is described
 382 as follows. Let $(\gamma(t))_{t \in [0,1]}$ be the parametrization in V_x of some geodesic, denote
 383 $(\gamma^i(t))_{1 \leq i \leq 2}$ the coordinates of $\gamma(t)$. Then $\gamma(t)$ is the solution of the following second
 384 order ODE:

$$\begin{cases} \frac{d^2\gamma^k}{dt^2} + \sum_{i,j} \Gamma_{ij}^k(\gamma(t)) \frac{d\gamma^i}{dt} \frac{d\gamma^j}{dt} = 0, \\ \gamma(0) = \gamma_0, \\ \gamma'(0) = v_0. \end{cases} \quad (9)$$

385 The point $\gamma(0) = \gamma_0 \in V_x$ represents the coordinates of the origin of the geodesic,
 386 and $\gamma(1)$ the coordinates of its final point in the chart defined by Exp_x .

Consider a compact subset $K \subset U_x$, let $y = \text{Exp}_x w \in K$ for some $w \in V_x$. For $\alpha, \eta > 0$ small enough (to be precised later) we define

$$\begin{aligned} \Gamma : B(0, \alpha) \times B(w, \eta) &\longrightarrow V_x \\ (\gamma_0, v_0) &\longmapsto \gamma \text{ that solves (9)}. \end{aligned}$$

We assume that α, η are sufficiently small so that the geodesic remains in V_x . In words, $\Gamma(\gamma_0, v_0)$ is the geodesic in the parameters domain with starting point γ_0 and initial velocity v_0 . Since all the coefficients in (9) are smooth, it follows that Γ is a smooth function of its arguments. We define

$$\Phi(\gamma_0, v_0) = \Gamma(\gamma_0, v_0)(1),$$

it is the endpoint in the parameters domain of the geodesic with starting point γ_0 and initial velocity v_0 . For $\gamma_0 = 0$ and $v_0 = v$ we have by definition of the Exp_x map:

$$\Phi(0, v) = v.$$

387 By smoothness of Φ , for γ_0 sufficiently close from 0 the map $\varphi(\gamma_0) = \Phi(\gamma_0, \cdot)$ defines
 388 a diffeomorphism between $B(w, \eta)$ and its image that contains $B(w, \eta/2)$. Up to
 389 reducing the value of α , we can assume that for every $\gamma_0 \in B(0, \alpha)$, $\varphi(\gamma_0)$ defines a
 390 diffeomorphism between $B(w, \eta)$ and its image that contains $B(w, \eta/2)$.

As a consequence, for every $\gamma_0 \in B(0, \alpha)$ and every $w' \in B(w, \eta/2)$,

$$d_{V_x}(\gamma_0, w') = \int_{t=0}^1 \|\gamma'(t)\|_{\gamma(t)} dt,$$

where $\gamma = \Gamma(\gamma_0, w')$. The notation $d_{V_x}(\cdot, \cdot)$ indicates the distance between points of the parameters domain V_x . All the elements appearing in this formula depend smoothly on γ_0 and w' with bounded derivatives. Therefore the map

$$\begin{aligned} L : B(0, \alpha) &\longrightarrow C^1(B(w, \eta/2)) \\ \gamma_0 &\longmapsto d(\gamma_0, \cdot) \end{aligned}$$

is differentiable. This result can be translated in \mathcal{M} as follows: there exist neighborhoods \mathcal{V} of x in \mathcal{M} and \mathcal{W} of y in \mathcal{M} such that the map

$$\begin{aligned} \bar{L} : \mathcal{V} &\longrightarrow C^1(\mathcal{W}) \\ x' &\longmapsto d(x', \cdot) \end{aligned}$$

391 is differentiable. The result is still true if $C^1(\mathcal{W})$ is replaced by $L^2(\mathcal{W})$ because the
 392 inclusion $C^1(\mathcal{W}) \subset L^2(\mathcal{W})$ is continuous. The result follows by observing that the
 393 compact set K can be covered by a finite number of neighborhoods \mathcal{W} .
