The present study proposes a new method to predict the ultimate load bearing capacity of structural notched beams subjected to splitting. Reinforced and unreinforced cases are investigated by using a FE-model for splitting failure. The contribution of mode I and mode II in the crack extension mechanisms is implemented in the numerical model by considering a mixed mode criterion established on the R-curves of wood. The influences of the notch and the reinforcements on the resulting quasi-brittle behaviour is analysed. The FE-prediction are compared to experimental data and the current design rules of the Eurocode 5.

18 1. Introduction

19 Notched beams present a stress concentration area which can produce the splitting of wood. This type of failure
20 influences significantly the load-bearing capacity of the elements, which requires some specific design methods. The
21 shape and size of the notch govern the mechanical behaviour of the elements. In order to improve the strength of such
22 structural components and to improve the load transfer in wood perpendicular to the grain, local reinforcements are
23 recommended and requires design rules for engineering. In order to improve the knowledge concerning the failure
24 mechanisms occurring in such elements. It is then necessary to introduce new approaches focusing on the prediction
25 of the load bearing capacity of reinforced and unreinforced notched beams.

26 Nowadays, several design methods exist to estimate the strength of unreinforced wooden notched beams. Most of
27 them are based on the fracture mechanics, but others refer to empirical studies like the Timber Construction Manual [25]
28 and the DIN 1052 of 1988 [12]. As part of fracture mechanics, approaches can be divided in two ways : one may use
29 the energy release rate (G_i) [18], whereas the other consider the stress intensity factor (SIF, K_i) [21]. The Eurocode 5
30 design method [16] refers to the works realised by Gustafsson [19] which proposes the equation 1. In this approach,
31 the critical shear force of the beam is predicted by considering the critical energy release rate ($G_{c,I}$) in mode I and
32 the stiffness evolution of the beam (obtained from the beam theory). For the Eurocode 5, some coefficients were
33 introduced according to the strength grades of timber [15, 14, 1], and the failure property (critical energy release rate)
34 was deduced from research led on free defect Spruce (*Picea abies.*) [19]. Finally, this proposal depends on the notch
35 geometry (Figure 1) and the wood quality (solid wood or glulam). This approach has the advantage to be useful for
36 engineers and design offices. Nevertheless, it may introduce some bias for the prediction of strength, since wood is
37 regarded as a pure brittle material and the crack propagation mainly considered in mode I. Moreover the formulation
38 is not well adapted for notches with important height.

$$V_d = \frac{bah\sqrt{\frac{G_{c,I}}{h}}}{\sqrt{\frac{0.6(\alpha-\alpha^2)}{G_{xy}} + \beta\sqrt{\frac{6(\frac{1}{\alpha}-\alpha^2)}{E_x}}} \quad (1)$$

43 Some other methods based on the stress intensity factors also consider the crack propagation in mixed mode, like
 44 in the Wood Handbook of the Forest Product Laboratory [35]. It is based on the works of Murphy [31], combining
 45 mode I and mode II in mixed mode fracture criterion. This method is similar to the one of the Australian standard [3],
 46 which is proposed by Walsh and Leicester [40, 24]. Most methods consider that the wood has a pure brittle behaviour.
 47 However, some studies [22, 38] using image correlation measurements, showed the quasi-brittleness of wood [28]
 48 in notched beams. The progressive damage is governed by microcracking and crack bridging at notch [7, 28, 30].
 49 Those studies exhibit that the ratio between mode I and mode II of crack extension evolves along the crack path, which
 50 questions the reliability of the methods considering only mode I or a constant ratio for mixed mode. This may explain
 51 why in some design rules, like the DIN 1052 of 1988 [12], several equations can be proposed, according to the notch
 52 geometry, to predict the strength of the beams.

53 Concerning the reinforced beams, no design rules are present in the Eurocode 5. During the World Conference
 54 on Timber Engineering in 2016 (WCTE), some formulations were proposed [11]. They are extracted from the DIN
 55 1052 [5], and they are relative to the use of screws as reinforcement. This expression is based on the works performed
 56 by Henrici [20], which used the beam theory and the plate theory to estimate the tensile force ($F_{t,90,d}$) supported by the
 57 reinforcement [2] and located behind the corner of the notch. This expression was then validated by an experimental
 58 campaign carried out by Blaß and Bejtka [6]. The strength of wood is not taken into account, although Coureau [9]
 59 demonstrated the interest to consider it.

$$F_{t,90,d} = k_1 [3(1 - \alpha)^2 - 2(1 - \alpha)^3] V_d \quad (2)$$

60 The Equation 2 requires the determination of the coefficient k_1 , depending of the orthotropy and the notch geometry
 61 (α , β).

62 The DIN fixed this coefficient equal to 1.3, which gives a conservative prediction of the load-bearing capacity of
 63 reinforced notched beams for $\alpha < 0.8$ and $\beta < 0.2$ [34]. Henrici extended this application field to $\beta < 0.3$, which
 64 is recommended by Dietsch [11] in the proposal for the Eurocode 5. However, the approach is limited to small notch
 65 size. So, Foliente *et al.* [17], by considering more accurately the stress field at the notch corner, proposed a formula
 66 (Equation 3) which can be used for every notch geometry, contrary to the expression of the DIN.

$$F_{t,90} = [3(1 - \alpha) - 6(1 - \alpha)^2 + 4(1 - \alpha)^3] \frac{\beta V_d}{1.12(1 - \alpha)} \quad (3)$$

67 For reinforcements with screws, the mechanical performances of beams are deduced from the ultimate axial load
 68 ($R_{ax,d}$), which depends mainly on the anchorage length and the strength of the steel. By neglecting the strength of
 69 wood, the resulting bearing capacity is proportional to the number of screws, n (Equation 4).

$$V_d = \frac{n \cdot R_{ax,d}}{1.3[3(1 - \alpha)^2 - 2(1 - \alpha)^3]} \quad (4)$$

Jockwer [22] evaluated the horizontal force located in the reinforcement due to the shear force, justifying better the conclusions given in the COLORETIM project [8]. Moreover, during experimental campaign, some failures of the beams are due only to the splitting of timber without presenting damage and failure close to the screws. The author confirmed that the crack propagation initiation occurs at the same strength for reinforced and unreinforced beams, which was previously observed by Coureau [9] in the case of beams reinforced with external Plates of Glass Fiber (GFP). Consequently, by only considering the tensile force in the reinforcements ($F_{t,90,d}$), the expression of the DIN 1052 (Equation 4) can not cover the potential failure mechanism produced by the progressive splitting of wood. Moreover, this method was designed only for screw reinforcements. In order to consider this mechanism Coureau [9] expressed the resulting strength of the reinforced beams (V_u) as a combination (Equation 5) of the load bearing capacity of the unreinforced notched beam and an additional strength produced by the reinforcement (V_r^0). This one was governed by the anchorage strength of the glued GFP. During experimental test, failures of elements were activated by the delamination of the glued interface between timber and GFP.

$$V_u = V_u^0 + V_r^0 \quad (5)$$

Few approaches are proposed for reinforced notches beams. The consideration of the interaction between progressive damage and crack extension in wood and the force supported in reinforcements represents a challenge for new design rules. This study proposes a new approach to predict the ultimate load of reinforced and unreinforced wooden notched beams by taking into account the mechanical performance carried out by strength of the wood and by considering its quasi brittleness. The objective is also to supply some useful design methods for reinforced elements presenting failures, elements which are not currently considered by the design approaches.

2. Fracture mechanics

The fracture mechanics was first presented by Griffith [18] which only considered the case of a brittle material. Thus, this approach is not well adapted to the wood, since a non elastic zone appeared ahead to the crack tip [28, 10, 32]. This damaged area is called Fracture Process Zone (FPZ), and presents micro-cracking and crack bridging [4, 29, 32]. The quasi-brittleness of wood has an effect on the resulting performance, since the energy released by the wooden element is used for damage and crack extension. This type of material can be considered by two different methods, a non-linear one, which is based on the cohesive law (cohesive crack model) [13, 33, 29, 30, 39], and a linear one as part of the equivalent Linear Elastic Fracture Mechanics ($_{EQ}LEFM$), which considers a Resistance to crack growth-curve (called, R-curve) [4, 41, 28, 26, 10].

The cohesive crack models can be implemented in a Finite Element Model (FEM) for crack propagation in pure mode or mixed mode. However, these models require substantial computing resources. Moreover, the properties governing the softening behaviour of the material are not easy to characterise [32], especially the ultimate separation of wood in mode I and II. The $_{EQ}LEFM$ requires less calculation resources, since the crack propagation is computed by considering pure elastic material. The damage and crack extension are determined by energetic balance. This method allows to characterise a crack propagation in mixed mode by using the Resistance-curves (R-curves) [23] in mode I and mode II, which are regarded as mechanical properties of wood.

3. Model for the splitting of wood

3.1. Equivalent Linear Elastic Fracture Mechanic ($_{EQ}LEFM$)

The $_{EQ}LEFM$ consider a crack length (Δa) to describe the fracture mechanisms in a quasi-brittle material. Δa is determined by considering that the compliance variation of the element (λ) -only due to the damaging and the crack propagation- is equivalent to the one ($\lambda_{elastic}$) due to the extension of a single crack in a purely elastic material with the same geometry. Then, the energy release rate (G) can be determined according to the crack length (Δa) (Eq. 6) [28].

$$G(\Delta a) = \frac{P^2}{2b} \frac{d\lambda(\Delta a)}{d\Delta a} \quad (6)$$

The crack propagates when the energy release rate reaches a critical value depending on the material resistance. The difference between brittle and quasi-brittle behaviour can be observed on a $G_R(\Delta a)$ diagram (Figure 2). In the

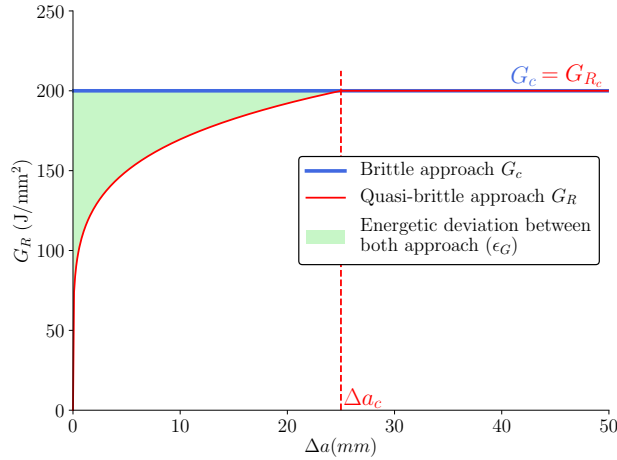

Figure 2: $G_R(\Delta a)$ diagram for brittle and quasi-brittle material

112 case of a brittle material, the crack propagation starts when the critical energy release rate (G_c) is reached, whatever
 113 the crack length is, with G_c as a material property. On another hand, for quasi-brittle material, the crack propagation
 114 in the wooden element depends on an R-curve, which is a function of the critical energy release rate versus (Δa) with
 115 two phases. The first regime (Figure 2), corresponding to an increase of the energy, governs the damage development,
 116 whereas the plateau corresponds to the auto-similar crack propagation, as for a brittle material.

117 This highlights how considering the wood as a pure brittle material can lead to an overestimation of the load-
 118 bearing capacity of the beam. Indeed, if the failure of the element occurs before the plateau is reached (for a crack
 119 length inferior to Δa_c), the brittle approach will overestimate the energy consumed by the crack propagation and the
 120 resulting strength.

121 3.2. Model principle

122 As mentioned previously, the crack propagation in notched beams is produced by mixed mode, in order to supply
 123 a reliable prediction, the quasi-brittle behaviour of wood must be considered in mode I and mode II. The model pro-
 124 posed by Lartigau *et al.* [23] for structural gluing may be adapted to the wooden notched beam configuration. It can
 125 supply a prediction of the load/displacement curve of a structural element by considering its critical R-curve ($G_R^*(\Delta a)$).
 126 This load/displacement curve is determined by considering for each crack length Δa a critical load P_c and a critical
 127 displacement δ_c , obtained by using equations 7 and 8. In this method, the compliance variation $\lambda(\Delta a)$ is computed for
 128 1 N load, as part of linear elasticity, by simulating the propagation of a crack in the considered structure using a finite
 129 element model.

$$110 P_c(\Delta a) = \sqrt{\frac{2bG_R^*(\Delta a)}{\lambda'(\Delta a)}} \quad (7)$$

$$111 \delta_c(\Delta a) = \lambda(\Delta a) \cdot P_c(\Delta a) \quad (8)$$

130 The determination of $G_R^*(\Delta a)$ is defined by using mixed mode criterion (Eq. 9) taking into account the wood
 131 R-curves relative to mode I and II ($G_{R_I}(\Delta a)$ and $G_{R_{II}}(\Delta a)$). It governs the potential damage and crack extension,
 132 producing progressive or sudden splitting mechanism, in the considered element.

$$133 \left(\frac{G_I(\Delta a)}{G_{R_I}(\Delta a)} \right)^p + \left(\frac{G_{II}(\Delta a)}{G_{R_{II}}(\Delta a)} \right)^q = 1 \quad (9)$$

133 This criterion can have different forms, linear ($p=1, q=1$), quadratic ($p=2, q=2$) or semi-quadratic ($p=1, q=2$ or
 134 $p=2, q=1$). In the case of notched beams the mixed mode ratio evolves from mode I to mode II, even more in the case
 135 of reinforced beams. So in order to simplify the expression and in accordance with the phenomenon observed, the
 136 linear criterion was used for this study which leads to the following expression of $G_R^*(\Delta a)$ (Eq. 10).

$$G_R^*(\Delta a) = \left(\frac{G_I(\Delta a)/G_{I+II}(\Delta a)}{G_{R_I}(\Delta a)} + \frac{G_{II}(\Delta a)/G_{I+II}(\Delta a)}{G_{R_{II}}(\Delta a)} \right)^{-1} \quad (10)$$

137 In this expression $G_{I+II}(\Delta a)$ is the global energy release rate, in the meaning of the EQLEFM, calculated, for each
 138 crack length Δa as the sum of $G_I(\Delta a)$ and $G_{II}(\Delta a)$ the energy release rate for both pure modes I and II ($G_{I+II}(\Delta a) =$
 139 $G_I(\Delta a) + G_{II}(\Delta a)$).

140 The expression of the R-curves in pure mode is a two part function of three parameters, with a power law following
 141 by a plateau value [27, 10] (Eq. 11). The critical energy release rate $G_{R_{c_i}}$, the critical crack length Δa_{c_i} and the law
 142 factor β_i must be determined on the considered wood species for each pure mode i (Figure 2).

$$G_{R_i}(\Delta a) = \begin{cases} G_{R_{c_i}} \left[\frac{\Delta a}{\Delta a_{c_i}} \right]^{\beta_i} & \text{if } \Delta a < \Delta a_{c_i} \\ G_{R_{c_i}} & \text{if } \Delta a \geq \Delta a_{c_i} \end{cases} \quad (11)$$

143 This approach comes with some hypotheses. At first, the crack path is supposed to be known, which is in accor-
 144 dance with the splitting failure. The propagation occurs along the wood grain and the crack initiation is located at the
 145 singularity (stress concentration area). Moreover, this model is performed by assuming plane strain, which implies
 146 that the crack tip is perpendicular to the span of the beam. For a sack of simplicity, we consider here that the splitting
 147 of wood is produced only by shear stress along the grain and tensile stress perpendicular to the grain direction. Mode
 148 III of crack propagation is neglected at first. During experimental campaign, some measurements were performed to
 149 check this hypothesis.

150 3.3. Notched beam application

151 In the case of unreinforced notched beams, the approach aims at evaluating the critical energy curve ($G_R^*(\Delta a)$)
 152 of the structural element in function of the notch geometry (α and β) and the mechanical properties of timber (elastic
 153 moduli and R-curves). In the case of reinforced beams, the state of the art shows that several failure mechanisms may
 154 occur. However, by taking into account the splitting of wood, it is possible to improve and to complete the existing
 155 predictions.

156 As a first approximation, the effect of the reinforcement can be implemented in the FEM by considering kinemat-
 157 ically the perfect connection between two opposite nodes at the lips of the crack on the reinforcement axis (Figures 3
 158 and 4). Consequently, there is no relative displacement between the opposite nodes, so the vertical and horizontal
 159 stiffness (K_v and K_h) of the reinforcement are considered infinite. It is possible to obtain the progressive load transfer
 160 between wooden substrate and screws. The closure located on the crack path suggests that no damage occurs in the
 161 reinforcement and that the crack can propagate ahead and behind it. The potential complexity of the damage zone
 162 around the reinforcement locality is regarded only by assuming the compliance variation of the specimen.

163 In reinforced cases, the proposed model leads to a deviation of the compliance evolution (λ) according to the
 164 crack length (Δa) in comparison with an unreinforced beam (Figure 5). This deviation produces the bifurcation of the
 165 propagation modes from the mode I to the mode II (Figure 6). Indeed, the local closure on the crack path produces a
 166 new repartition between the crack propagation mechanisms at the tip of the crack.

167 Consequently, the splitting of wood is governed by a new mixed mode ratio which favours the mode II rather
 168 than the mode I. Thus, the resulting strength of the component is modified, without considering any damage in the
 169 reinforcement (Figure 7). This increase of $G_R^*(\Delta a)$ leads to an increase of the load-bearing capacity of the beam
 170 (P_u). The rise of the mechanical performances is mainly due to the difference of energy necessary to propagate a
 171 crack in mode II rather than mode I (Figure 8). Indeed, the fracture energy in mode II is 3 or 4 times higher than the
 172 mode I, depending on the wood species [2, 37]. As part of linear fracture mechanics (Equation 7), this difference of
 173 energy leads to an improvement of the load by a factor 2, in comparison with the strength of unreinforced element.

Prediction of the ultimate load-carrying capacity of wooden notched beams with and without reinforcements using a splitting model

Figure 3: Boundary conditions imposed on the crack path to model the reinforcement system

Figure 4: Example of a mesh deformation observed at the crack tip locality with an amplification of 1.10^3

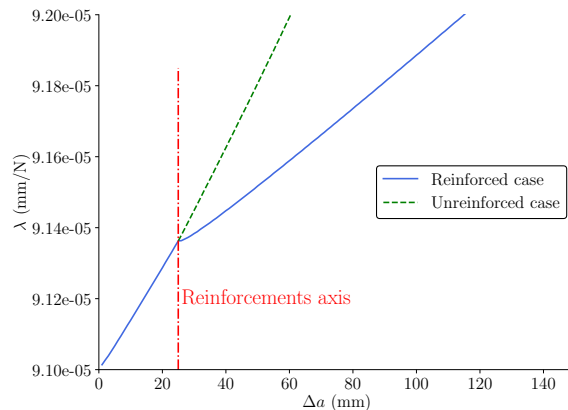

Figure 5: Comparison between the evolution of the compliance for a reinforced and an unreinforced beam of the same geometry

174 Consequently, the recommendations given in literature and standard are more justified by this observation, since they
 175 limit the strength of reinforced beams with a similar ratio [11]. Moreover, figure 6 illustrates that crack propagates
 176 between the corner of the notch and the reinforcement axis with the same ratio of mode I and II than the unreinforced
 177 beam (curves are superimposed). This induces that the crack initiation occurs for the same load level in both cases,
 178 which was experimentally observed by Coureau [9] and Jockwer [22].

Prediction of the ultimate load-carrying capacity of wooden notched beams with and without reinforcements using a splitting model

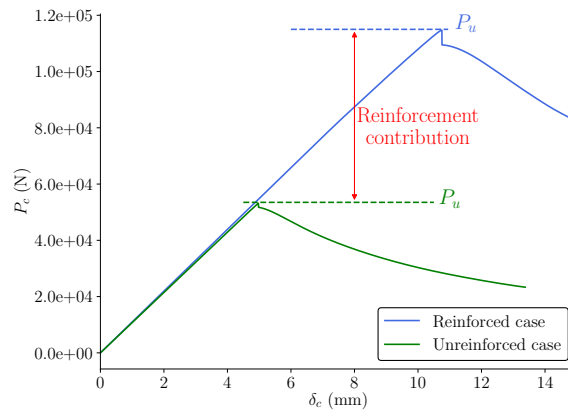

Figure 7: Comparison between the predictive load/displacement curves of a reinforced and an unreinforced beam of the same geometry

179 **4. Validation by experiments**

180 The first aim of the experiments carried out in this study is to validate the hypotheses made by the proposed
 181 model and in a second time to compare the relevance of the prediction of the model to the one of the current design
 182 rules proposed for notched beams with and without reinforcement. In this part of the article only the validity of
 183 the hypotheses are discuss and the comparison with the current design rules will be made in a second part. Two
 184 experimental campaigns were carried out on GL24h (Spruce) by performing three points bending test (Figure 1) in
 185 controlled displacement (2mm/min) with a force cell capacity of 250 kN. The first one was performed on small beams
 186 of $168 \times 89 \text{ mm}^2$ and 990 mm span. The parameters of the notch were $\alpha = 0.5$ and $\beta = 0.6$. Two different reinforcement
 187 configurations using SFS WT-T6.5X160 screws were tested. One with a single screw and another one with three screws
 188 located along the width of the beam (placed at 20 mm behind the corner of the notch). The second experimental
 189 campaign was carried out on larger beams of $495 \times 115 \text{ mm}^2$ and 3500 mm span. Two different notch geometry are
 190 chosen for the unreinforced case ($\alpha = 0.66$ and $\alpha = 0.8$) for a given β equal to 0.6. For reinforced beams, two
 191 configurations were tested for a given notch size $\alpha = 0.66$ and $\beta = 0.6$: two screws and three screws along the
 192 width were placed in the structural element. SFS WR-T-9X350 reinforcements are used for this. The location of the
 193 reinforcement follows recommendations given by Dietsch [11], with an axis at a distance of 25 mm behind the notch
 194 corner. The ultimate shear strength of the beams tested are given by tables 1,2 and 3.

195 During test, the displacement under the load axis was measured, by avoiding the crushing at supports, in order to
 196 measure accurately the mechanical energy released by the damage and the potential crack extension in the component

197 (Figure 9(a)). An image correlation system was also used to measure the strains fields around the notch (Figure 9(b)).

198 4.1. Reinforced case

199 The image correlation measurement shows that the out-of-plane displacements are negligible. These observations
 200 are in accordance with the hypothesis taken in the proposed model. The failure of the beam is due to a sudden instabil-
 201 ity of the crack produced by splitting, which generates a significant loss of stiffness. Moreover, as shown by the model,
 202 the crack propagation initiates at the same load level for reinforced notched beams and unreinforced ones. The rein-
 203 forcement has no effect for crack length located between its axis. The failure of the beams is only due to the splitting
 204 of wood and there is no visible opening on the crack path close to the screws. So, the reinforcement integrity remains

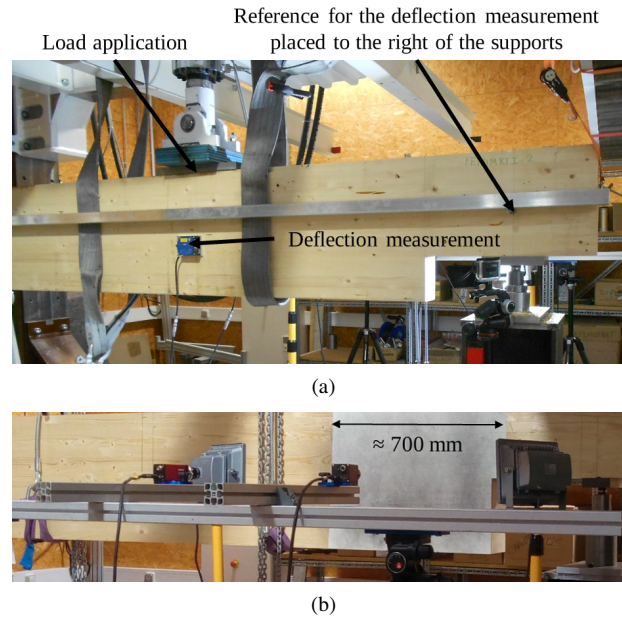

Figure 9: Experimental device (a) with the stereo-vision measurement system (b)

205 intact and no failure nor excessive displacements are observed. For this configuration, timber is the weakness link but
206 still contributes to the mechanical performances of the reinforced beams. The average gain obtained experimentally is
207 close to 100% (Tables 1 and 2).

208 Screws prevent the opening of the crack, as it can be observed with the image correlation measurement around the
209 notch (Figure 10). Strains due to the tensile stress perpendicular to the grain (ϵ_{yy}) is stopped forward the reinforcement
210 axis, whereas strains due to shear (ϵ_{xy}) is not fully prevented.

211 However, for reinforcement composed of only one screw the crack may propagate in the vicinity of it. In this case,
212 a macro crack appears on each side of the beam, and the strains produced by the mode II seems to be less important
213 (Figure 11) than for the configuration with 3 screws (Figure 10). This is due to a non-fully block of the local crack
214 opening which induces a more active mode I. As a consequence, the mode I requiring less energy to create a crack
215 extension in the macro splitting mechanism than the mode II, the resulting strength of the beam is lower than the one
216 with 3 screws.

217 In the case of reinforced beams with a crack opening perfectly locked on the reinforcement axis, along the width
218 of the beam. The proposed model indicates that compared to unreinforced beams, the mixed mode crack propagation
219 ratio evolves from mode I to mode II (Figure 6). This was observed experimentally by using image correlation (Figure
220 10). For a given notch, the decrease of mode I along the crack path is close to 20% (Figure 6). Experiments found
221 in the literature illustrate that the mechanical performance of reinforced elements depends on both reinforcement and
222 wood strength [22]. Consequently, several failure mechanisms should be predicted and the splitting of wood in the
223 reinforced notched beams should be part of it as a potential failure scenario.

224 The model for the splitting of wood proposed in this article uses the R-curves and so takes into account the quasi-
225 brittle behaviour of wood. This is a new tool to appreciate the mechanical performance of the reinforced solutions.
226 It describes better the mechanisms acting on the improvement of the resulting strength of beams, which is mainly
227 due to a new distribution between mode I and II on the crack path. The bridging produced by the screws reduces
228 the part of mode I, which improves the mechanical performance. When splitting governs the failure of the beam, the
229 number of screws is not directly proportional to the load bearing capacity. This observation is illustrated in the second
230 experimental campaign, where the mean ultimate load remains the same for a two or three screws reinforcement system
231 (Table 2).

232 In this case, the improvement of the strength between reinforced and unreinforced elements is governed mainly
233 by the increase of the energy release rate produced by the local crack closure. So, the increase of the ultimate load

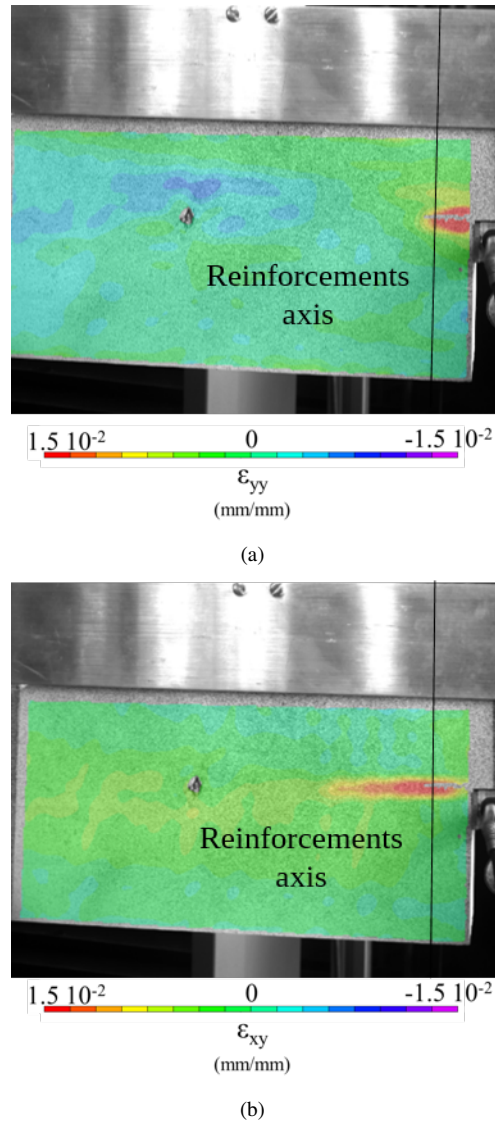

Figure 10: ϵ_{yy} (a) and ϵ_{xy} (b) strains fields for a beam reinforced with three screws, one second before its failure

234 depends on the ratio between mode I and mode II : the higher the mode II is, the higher the load bearing of the beam is.
 235 Consequently, the maximum increase of the resulting strength is limited by the R-Curve of wood in mode II according
 236 to the geometry. This phenomenon is taken into account in the model by equation 10.

237 4.2. Unreinforced case

238 The unreinforced beams present a progressive decrease of the stiffness, which is observed by a non-linear regime
 239 at the end of the load/displacement curves. The damage is initiated at the corner of the notch. It is significant and
 240 influences the ultimate load of the notched beams (Figure 12). Consequently, the use of R-curve for the prediction
 241 seems to be a really appropriated characteristic to evaluate the mechanical performance of those elements.

242 By considering mixed mode crack propagation using R-curves the proposed model helps to predict the load-bearing
 243 capacity of structural element, when splitting contribute to the strength. For notched beams the contribution of mode
 244 I and mode II in splitting is relative to the shape and size of the notch (α and β). For important α , the mode II is more
 245 active and requires more energy than the mode I to damage and propagate a crack in wood. This leads to an increase
 246 of the strength of the beam governed by the function (G_R^*) and the R-curves (wood fracture properties). Experimental

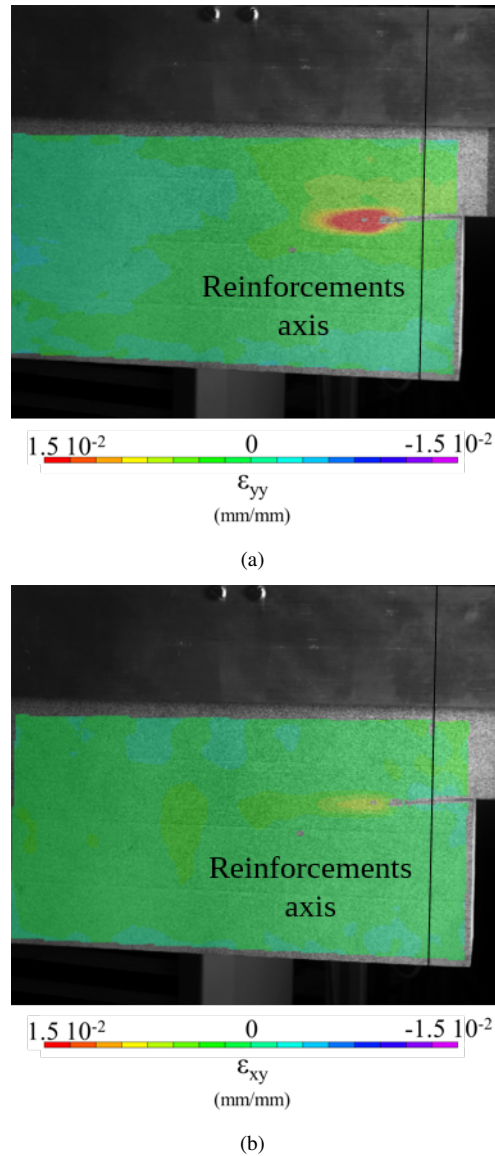

Figure 11: ϵ_{yy} (a) and ϵ_{xy} (b) strains fields for a beam reinforced with one screw, one second before its failure

247 results confirm this tendency (Table 3). When β increases for a given notch height, mode I rises and performance
 248 declines. Consequently, the splitting of wood appears in all configurations but the mixed mode contribution (given by
 249 equation 9) leads to different strength levels according to the geometry of notched beams. The proposed method takes
 250 into account these variations.

251 To conclude, the experimental observations made are in accordance with the proposed model hypotheses and
 252 principle. So, the corresponding predictions can be compared to those obtained with the current design rules and the
 253 experimental data. In order to appreciate the different approaches, the input material properties implemented in the
 254 models are presented in the tables 4, 5 and 6.

255 5. Comparison with current design rules

256 In order to compare the relevance of two predictive methods, the comparison must be done for every test. Indeed
 257 the comparison of the mean values does not show if the prediction is always conservative. This can lead to an over-

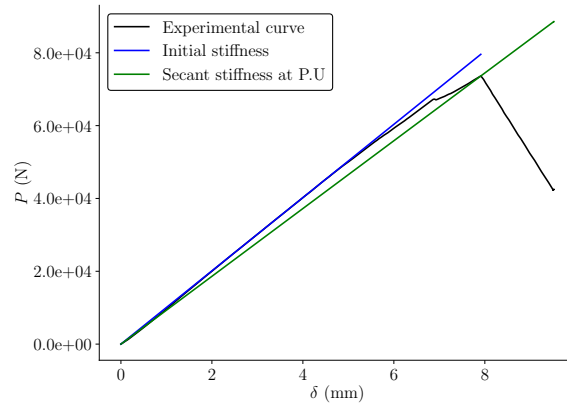

Figure 12: Example of an experimental curve with the initial stiffness (elastic behaviour) and the secant stiffness at ultimate load of an unreinforced beam

First campaign	Second campaign
20 mm	25 mm

258 estimation of the load-bearing capacity for some element and can question the safety of the method. So, in order to
 259 compare the relevance of the proposed method to the one of the current design rules, a relevance ratio was determined
 260 for each test (Eq. 12).

$$R_{relevance} = \frac{V_{exp}}{V_{approach}} \quad (12)$$

261 In this expression V_{exp} is the experimental shear force, and $V_{approach}$ the predictive shear force given by the proposed
 262 model, and by the Gustafsson's formula (Equation 1) for unreinforced beams or the DIN 1052 formula (Equation 4)
 263 for reinforced beams.

264 5.1. Unreinforced case

265 In order to make a comparison, the elastic properties implemented in the Gustafsson's design rule are similar to the
 266 ones used in the model (Table 4). The critical energy release rate in mode I ($G_{c,I}$) is taken equal to the plateau value
 267 of the R-curve in mode I (G_{RcI}) (Table 5). The cumulative frequency distribution of the relevance ratio are presented
 268 in figure 13. It shows that the proposed model is globally more conservative than the Gustafsson's approach and that
 269 two predictions made by the Gustafsson's approach are non-conservative against only one for the proposed model.

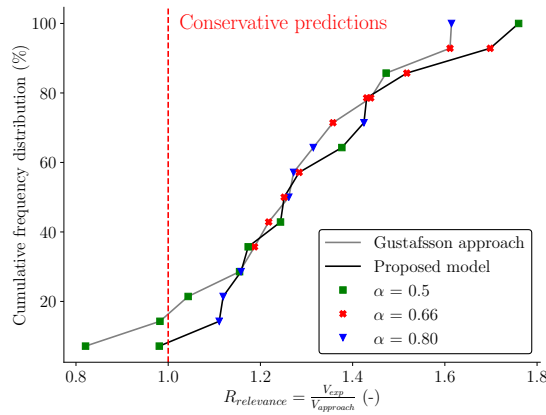

Figure 13: Cumulative frequency distribution of the relevance ratio ($R_{relevance}$) for the proposed model and the Gustafsson's approach

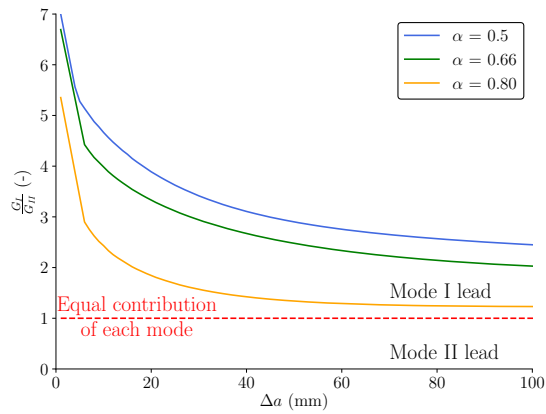

Figure 14: Evolution of the mixed mode ratio for different α parameter (results obtained from the numerical model)

270 However, simulations made for different values of α parameter show that the mode I and II distribution is different
 271 according to the notch geometry, with a greater contribution of mode II for higher values of α (Figure 14). So, for
 272 example if α is equal to 0.8, the Gustafsson's approach, which only consider the mode I, will be more conservative
 273 (Figure 15). But, this approach is not well adapted for splitting where the mode II is predominant. On the contrary, the
 274 equation 10 takes into account, by using $G_I(\Delta a)$ and $G_{II}(\Delta a)$, the influence of the notch geometry (α and β parameters)
 275 on the mixed mode ratio.

276 Moreover, Smith and Springer [36] explained that the evolution of the stiffness is crucial to predict correctly the
 277 ultimate load using the fracture mechanics, and that its current determination in the Eurocode 5 design rules may
 278 represent a bias in the method. So, to prevent such bias, the mode II and its corresponding R-curve must be considered
 279 in the splitting of wood mechanisms. Indeed, although its contribution in structural component geometry may be low,
 280 by being much more energetic, the mode II concentrates a non-negligible part of the global energy released by the
 281 element, and so limits the crack extension in mode I. By considering the mode II in equation 10, the proposed model
 282 provides a useful tool for prediction, nevertheless the R-curves of the material are required.

283 5.2. Reinforced case

284 The FE-model is compared to the approach of the DIN 1052 (Equation 4), which only considers the strength of the
 285 reinforcement (screws), which characteristics are presented in table 7.

286 The cumulative frequency distribution of the relevance ratio ($R_{relevance}$) relative to both approaches (Figure 16)
 287 shows that the expression of the DIN 1052 overestimates the strength of the beams reinforced by three screws of

Prediction of the ultimate load-carrying capacity of wooden notched beams with and without reinforcements using a splitting model

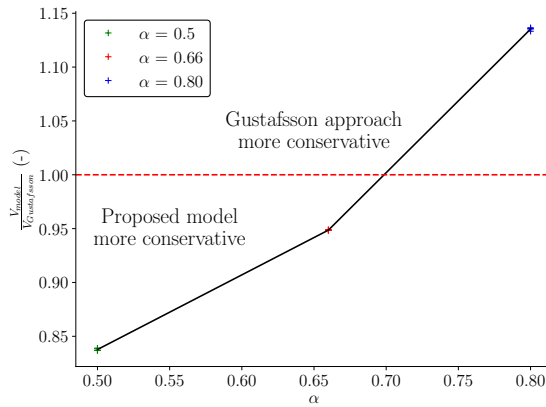

Figure 15: Comparison between the prediction made by the proposed model and the Gustafsson's approach

Table 7

Characteristics of the reinforcement

Parameters	WT-T-6.5X160	WR-T-9X350
External diameter (mm)	6.5	9
Length (mm)	160	350
$f_{ax,k} (N/mm^2)$	12.9	12.8
$R_{t,u,k} (kN)$	14.4	35.9

Figure 16: Cumulative frequency of the relevance ratio ($R_{relevance}$) for the proposed model and the DIN 1052 approach

288 about 20%. But for the two screws reinforcements, the predictions are conservative. On another hand, the proposed
 289 model provides conservative predictions for almost every test. Moreover, the two and three screws reinforcements are
 290 distributed in a more homogeneous way. This difference is due to the failure scenario considered in each approach.
 291 Indeed, the DIN 1052 only considers the failure of the reinforcement system, when the proposed model only considers
 292 the failure caused by a crack propagation in the wood, which was the only scenario experimentally observed.

293 The values of V_{exp} and $V_{approche}$ are provided in tables 8 and 9 to be more explicit. For the proposed model and
 294 the Gustafsson's formula, the elastic properties are corrected by a coefficient calculated on the initial stiffness for each
 295 specimen. This correction method was proposed by Morel *et al.* [29].

296 So, in conclusion, the DIN 1052 can lead to an overestimation of the load-bearing capacity of reinforced notched
 297 beams, if the crack extension in wood is not considered. On another hand, the proposed model provides a useful tool,
 298 which could be added to the current Eurocode 5 proposal [11] in order to give a better prediction of the potential failure

Table 8

Experimental and predictive shear strengths (in kN) of unreinforced beams

Configuration	V_{Gus} (CoV)	V_{model} (CoV)	V_{exp} (CoV)
$\alpha = 0.5$	8.7 (2%)	7.3 (8%)	9.5 (22%)
$\alpha = 0.66$	28.2 (2%)	26.8 (2%)	39.5 (13%)
$\alpha = 0.8$	42.8 (2%)	48.6 (2%)	48.6 (2%)

$\alpha = 0.66$ (2 screws)	59.0 (0%)	54.0 (6%)	84.5 (13%)
$\alpha = 0.66$ (3 screws)	88.6 (0%)	56.2 (5%)	74.8 (14%)

299 mechanism.

300 6. Conclusion

301 The splitting of reinforced and unreinforced structural timber beam is investigated in this study. Numerical compu-
 302 tations are proposed to evaluate the strength of beams, in which crack may propagate in mode I and mode II. In order
 303 to take into account the quasi-brittleness of wood, R-curves are implemented in a mixed mode criterion, which governs
 304 the macro-splitting of the element. Experiments performed are in good agreement with the prediction for reinforced
 305 and unreinforced cases. So, the assessment of R-Curves allows to understand the contribution of mode I and mode
 306 II on the splitting of wood mechanisms and the corresponding mechanical performances. To summarize, if the mode
 307 II is preponderant, the load-bearing capacity of the beam is higher. Moreover, the study exhibits that a change in the
 308 boundary conditions on a potential crack path, by the addition of reinforcement for example, modifies the mixed mode
 309 distribution at the crack tip.

310 The numerical computations exhibit a good accordance with experiments and a better prediction than the one
 311 extracted from literature. Finally, it is possible to predict splitting failure scenarios which are not covered by Eurocode
 312 5 or DIN 1052, in the case of reinforced beams. It supplies also, better prediction of the ultimate load bearing capacity
 313 which are characterised by R-curve in mode I and II.

314 To conclude, the proposed approach gives a new tool to evaluate the load-bearing capacity of structural elements
 315 in which splitting may occur. Moreover, by using the equivalent linear elastic fracture mechanics, the variability of
 316 wood can be considered in the compliance (elastic properties) and the R-curves (fracture properties). Consequently,
 317 this approach can be used to calibrate some predictions for the reliability of structural components.

318 7. Acknowledgments

319 The authors wants to thank the Reasearch National Agency of France (ANR) for its participation across the Xylo-
 320 plate project (ANR-10-EQPX-16), the CODIFAB for its financial supports and the SFSintec company for its generous
 321 donations of screws.
