25 **Abstract**

26 In contrast to fairly good knowledge of dissolved ($< 0.45 \mu\text{m}$) and particulate ($> 0.45 \mu\text{m}$) fluxes
27 of carbon, nutrients and metals from the land to the ocean, colloidal (1 kDa - $0.45 \mu\text{m}$) forms of
28 solutes are rarely quantified. This is especially true for Siberian rivers draining into the Arctic
29 Ocean: because of organic-rich soils, colloidal fractions of elements are high and may sizably
30 impact coastal biological processes. However, the main environmental parameters such as
31 seasons, river size, climate, permafrost distribution and landscape parameters of the watershed
32 controlling colloidal distribution of organic carbon (OC) and metals remain totally unknown.
33 Here we used on-site centrifugation combined with ultrafiltration via 3, 30 and 100 kDa pore
34 size membranes and 1 kDa dialysis to characterize colloidal size fractionation of OC and metals
35 in 32 western Siberian rivers, ranging in size from 10 to 150,000 km² watershed area, across a
36 climate and permafrost gradient (from absent to continuous permafrost). The dominant forms of
37 OC and metals was low molecular weight $\text{LMW}_{< 3 \text{ kDa}}$ fraction and medium molecular weight
38 ($\text{MMW}_{3\text{kDa}-30\text{kDa}}$) colloids. The $\text{LMW}_{< 3 \text{ kDa}}$ fraction of OC increased in the order spring $<$ autumn
39 $<$ summer, following progressive replacement of allochthonous medium and high molecular
40 weight colloids in spring by autochthonous LMW organic ligands in summer; the latter possibly
41 occurred due to exometabolites of plankton and periphyton. The LMW OC fraction became low
42 again in autumn, presumably due to appearance of allochthonous DOM washed out by autumn
43 rains from peat soil at maximum thawing depth. The size of the watershed had subordinate
44 influence on colloidal distribution compared to seasons. The effect of landscape parameters of
45 the watershed on the colloidal status of solutes was subordinate to seasonal and permafrost-zone
46 controls. Overall, the ongoing environmental changes in WSL will likely decrease the proportion
47 of mineral (Fe, Al - bearing) colloids of C and trace metals exported by rivers to the Kara Sea.
48 As a result, the flux of dissolved C, micro-nutrients and metal toxicants may become increasingly
49 bioavailable to coastal aquatic biota.

50 **1. Introduction**

51 Due to the high importance of the Arctic Ocean and permafrost-dominated sub-arctic
52 continental zones in Earth's carbon cycle and the high vulnerability of circumpolar zones to the
53 climate warming, numerous works have been devoted to biogeochemistry of dissolved and
54 particulate organic carbon as well as major and trace elements in large Arctic rivers (Gordeev et
55 al., 1996, 2004; Dittmar and Kattner, 2003; Magritsky, 2010, Holmes et al., 2000, 2001, 2012;
56 Tank et al., 2012; Drake et al., 2018). At the same time, main factors controlling the colloidal
57 status of C and major and trace elements in watersheds of the Arctic Ocean, and their response
58 to climate change are in the preliminary stages of our understanding.

59 Colloidal transport of organic carbon (OC) and trace metals in continental waters remains
60 a hot topic in earth surface biogeochemistry despite the sizeable amount of effort devoted to
61 characterizing OC, nutrient and metal distribution among particles and colloids (Aiken et al.,
62 2011; Aufdenkampe et al., 2011; Philippe and Schaumann, 2014; Gottselig et al., 2017).
63 Colloids, operationally defined as few nm (1 kDa) - 0.45 μm , and truly dissolved or the low
64 molecular weight ($\text{LMW}_{< 1 \text{ nm}}$) fraction of total dissolved ($< 0.45 \mu\text{m}$) riverine load, are a major
65 forms of element migration from land to ocean. In this regard, colloids in high-latitude boreal
66 and subarctic zones have received particular attention given their primary importance in C and
67 micronutrient regulation in the Arctic Ocean as well as their vulnerability in the face of on-going
68 changes (Ingri et al., 2000; Stolpe et al., 2013b; Pokrovsky et al., 2016b; Cuss et al., 2018).
69 However, the environmental factors controlling organic carbon (OC) and trace elements (TE)
70 distribution among different colloidal pools and their change over the hydrological seasons still
71 remain poorly understood. Quantitative prediction on the evolution of colloidal and LMW
72 fraction transport of solutes to the ocean under on-going environmental change (climate warming
73 and human impact) is not yet possible.

74 The reason for this knowledge gap is due to the diversity of dissolved organic matter
75 (DOM) depending on seasons, river size and landscape environments; thus, the difficulty in
76 predicting the nature of organic complexes and the proportion of conceptually different
77 allochthonous (terrestrial) and autochthonous (aquagenic) DOM. This is especially true for small
78 rivers and streams where variable residence time of water and solutes diversify the degree of
79 processing of DOM and DOM-metal complexes and colloids via bio-degradation, photolysis and
80 uptake / release by plankton and periphyton.

81 The variability of colloidal status of C and metals is most strongly pronounced in high-
82 latitude boreal and subarctic regions, where seasonal aspects (glacial period of low DOM, spring
83 flood of high allochthonous DOM and summer baseflow when plankton and periphyton activities
84 impact the river ecosystems) create very complex patterns of C and metal concentration and size
85 fractionation (Bagard et al., 2011, Stolpe et al., 2013a, b; Pokrovsky et al., 2010). Further, in
86 contrast to seawater, where organic complexes and colloidal forms of metals can be assessed by
87 electrochemical techniques (cf., Santana-Casiano et al., 2000), the use of these techniques are
88 very limited in freshwaters (Rozan and Benoit, 1999), and thus the two most common methods
89 of colloidal characterization are size-fractionation using ultrafiltration or dialysis (Vasyukova et
90 al., 2010; Pokrovsky et al., 2016a), and on-line field-flow fractionation coupled to ICP-MS
91 (Stolpe et al., 2013a, b; Cuss et al., 2017; Zhou et al., 2016). Extensive use of these techniques
92 in arctic and subarctic inland waters revealed the dominance of organic and organo-mineral (ferric
93 and aluminous) colloids of low and high molecular weight (LMW and HMW), whose
94 proportions vary strongly depending on season and environmental context (Lyvén et al., 2003;
95 Stolpe et al., 2013; Cuss et al., 2017, 2018; Javed et al., 2017). Further, different techniques and
96 even different methodologies within the same technique may produce different results as, for
97 example, the effective cut-off of a filter depend not only on the size of the colloids but also on
98 the composition and concentration of the colloids, the material of the filter, the volume of water

99 passed through the filter etc. As such, only using a unified protocol throughout wide range of
100 environmental parameters can provide reliable information on colloidal variation in space and
101 time. Up to now, few studies provided colloidal speciation of OC and metals across the seasons
102 in boreal and permafrost-draining rivers (Porcelli et al., 1997; Ingri et al., 2000; Pokrovsky et al.,
103 2010; Stolpe et al., 2013a, b) and over the climate gradient in permafrost-free zones (Pokrovsky
104 and Schott, 2002). The lack of information on colloidal riverine transport of OC and metals over
105 permafrost gradient does not allow identification of landscape factors controlling this transport
106 of solutes in rivers and prediction of possible transformation of these fluxes under on-going
107 environmental change.

108 To better understand climatic, permafrost and landscape control on colloidal transport of
109 OC and trace metals in Siberian rivers, we sampled 32 rivers of various size ranges across
110 sizeable climate and permafrost gradient and tested the link between the colloidal / LMW fraction
111 of C and 40 macro- and trace elements and major environmental parameters such as latitude,
112 permafrost distribution, bog and forest coverage for 3 main hydrological seasons of the year. As
113 specific hypothesis of this work, first, we suggested that allochthonous (terrestrial) DOM from
114 soil and vegetation leaching would dominate large-size colloids during spring flood whereas
115 autochthonous (aquagenic) DOM and LMW complexes of C and metals may be pronounced
116 during summer baseflow. Second, it was anticipated that the variation in Fe:C ratio in the
117 colloidal fraction would be primarily dependent on river size (different degrees of underground
118 discharge via hyporheic feeding in the PF zone), seasons, and proportion of bogs and forests at
119 the watershed. Third, we anticipate tracing the increase in active layer thickness (ALT) due to
120 permafrost thawing and enhanced mobilization of colloidal OC and metals from deep frozen
121 horizons through comparison of colloidal speciation at the beginning and the end of the active
122 season. Lastly, using a “substitution of space for time” approach, we predict the future changes

123 in colloidal pattern of OC and metals in WSL rivers and their export fluxes based on
124 contemporary features of dissolved riverine colloidal load.

125

126 **2. Study site and methods**

127 *2.1. Rivers of Western Siberian Lowland*

128 We sampled 32 rivers that belong to the Ob, Pur and Taz watersheds in the Western
129 Siberia Lowland. WSL is a huge peatland (> 2 million km²) situated within the taiga forest,
130 forest-tundra and tundra zones. A map of studied rivers is illustrated in **Fig. 1** and their pertinent
131 climatic and physio-geographic characteristics are presented elsewhere (Krickov et al., 2018).
132 The climate gradient of sampled rivers presents a decrease in mean annual air temperature
133 (MAAT) from -0.5°C in the south (Tomsk region) to -9.5°C in the north (Arctic coast). Annual
134 precipitation is fairly constant ranging between 550 mm in the south and 600 mm at the lower
135 reaches of the Taz River. Because of the strong decrease in evapotranspiration northward, the
136 annual river runoff gradually increases from 160-220 mm y⁻¹ in the permafrost-free region to
137 280-320 mm y⁻¹ in the Pur and Taz river basins located in the discontinuous to continuous
138 permafrost zone (Nikitin and Zemtsov, 1986). Permafrost distribution also follows the MAAT
139 gradient: from absent through isolated and sporadic in the south to discontinuous and continuous
140 in the north. The landscape parameters of sampled catchments were determined by digitizing
141 available soil, vegetation, lithological and geocryological maps (Pokrovsky et al., 2016b;
142 Vorobyev et al., 2017). Sampling was performed during spring flood (17 May – 15 June 2016),
143 summer baseflow (1 – 29 August 2016), and autumn baseflow before ice (24 September – 13
144 October 2016) and covered three main hydrological seasons. Note that the collected data set of
145 colloidal and LMW fraction of WSL river load is unique and independent from previous studies
146 of ‘bulk’ dissolved (< 0.45 µm) WSL river load assessed during several seasons from 2013 to

147 2015 (Pokrovsky et al., 2015, 2016b) and particulate ($> 0.45 \mu\text{m}$) and dissolved fraction of these
148 rivers from May through October 2016 (Krickov et al., 2019).

149

150 *2.2. Colloidal separation and analyses*

151 All the analytical approaches used in this study followed methods developed for western
152 Siberian DOM-rich waters (Pokrovsky et al. 2016a, b; Shirokova et al. 2013). In this work we
153 define colloids as entities having the size between $0.45 \mu\text{m}$ and 3 kDa . Further, we distinguish
154 two group of high-molecular weight (HMW) ($\text{HMW}_{100 \text{ kDa} - 0.45 \mu\text{m}}$ and $\text{HMW}_{30 \text{ kDa} - 100 \text{ kDa}}$),
155 medium molecular weight (MMW) colloids ($\text{MMW}_{3\text{kDa} - 30 \text{ kDa}}$), and low molecular weight
156 (LMW) fraction ($\text{LMW}_{< 3 \text{ kDa}}$).

157 Approximately 1 L of unfiltered surface water was collected in pre-cleaned light-
158 protected polypropylene jars for size fractionation to $0.45 \mu\text{m}$ followed by a centrifugal, non-
159 cascade, ultrafiltration through 100, 30 and 3 kDa NMWL single-used Amicon Ultracell 15-mL
160 cartridges. These disposable 50-mL polypropylene vials were fitted with regenerated cellulose
161 filters which were first treated with 1% HNO_3 , and rinsed 3 times via passing between 50 and
162 100 mL of MilliQ water through the membrane. The DOC and metal blanks were a factor of 3
163 to 10 lower than the minimal concentrations of these components in experimental fluids. The
164 first portion of sample supernatant that passed through Amicon cartridges was rejected. Each
165 fraction of filtrate was sub-divided into non-acidified and acidified portions, for carbon/pH and
166 trace element measurements, respectively. The centrifugal ultrafiltration was run at 20°C using
167 Eppendorf 5920 centrifuge (4000 rpm, 20 min). Vacuum filtration was performed using a
168 Mityvac MV8255 PVC-made hand pump. The filtration and ultrafiltration allowed for separation
169 into two group of high-molecular weight colloids ($\text{HMW}_{100 \text{ kDa} - 0.45 \mu\text{m}}$ and $\text{HMW}_{30 \text{ kDa} - 100 \text{ kDa}}$),
170 MMW colloids ($\text{MMW}_{3\text{kDa}-30 \text{ kDa}}$), and LMW fraction ($\text{LMW}_{< 3 \text{ kDa}}$). The concentrations of

171 elements in the different size fractions were calculated from the differences between
172 concentrations in different filtrates.

173 All filtrations and colloidal separations were run on site, in a protected environment,
174 within 2 h of river water collection. Further methodological details and possible artifacts of
175 centrifugal ultrafiltration are described elsewhere (Oleinikova et al., 2017a). In addition to
176 centrifugal ultrafiltration, approximately 30% of river water samples collected in summer and
177 autumn were processed for dialysis separation of colloids and ‘truly’ dissolved fraction. In-situ
178 dialysis experiments were performed by using 30-ml pre-cleaned dialysis bags (1 kDa or ~1.4
179 nm, Spectra Por 7®), which were placed directly in the river water for 3 days following previous
180 methodologies (Pokrovsky et al., 2016a). The major and trace element composition of the lake
181 water remained stable ($\pm 10\%$) in the course of the dialysis procedure, as verified by 0.45 μm
182 filtration before and after exposure.

183 The pH was measured in-situ. Chloride and sulfate were measured by ion chromatography
184 (Dionex 2000i) with an uncertainty of 2%. The concentrations of DOC and DIC were determined
185 by using a Shimadzu TOC-V_{SCN} Analyzer with an uncertainty of 3% and a detection limit of 0.1
186 mg/L. All elements were measured without preconcentration with an ICP-MS Agilent 7500 ce
187 using the collision cell with helium and hydrogen gas (He and H mode) to diminish the
188 interferences. Indium and rhenium were used as internal standards at concentrations of ~3 $\mu\text{g/L}$
189 and corrections from polyatomic spectral interferences were made for rare earth elements (REEs)
190 and the other trace elements. The typical uncertainty for elemental concentration measurement
191 ranged from 5-10 % at 1-1000 $\mu\text{g/L}$ to 10-20 % at 0.001 – 0.1 $\mu\text{g/L}$. The MilliQ field blanks were
192 collected and processed to monitor for any potential sample contamination introduced by our
193 sampling and handling procedures. The organic carbon blanks of filtrates and ultrafiltrates never
194 exceeded 0.1 mg/L. For all major and most trace elements, the concentrations in the blanks were
195 below analytical detection limits (≤ 0.1 -1 ng/L for Cd, Ba, Y, Zr, Nb, REE, Hf, Pb, Th, U; 1 ng/L

196 for Ga, Ge, Rb, Sr, Sb; ~ 10 ng/L for Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As). The international
197 geostandard SLRS-5 (Riverine Water Reference Material for Trace Metals) was used to check
198 the validity and reproducibility of analysis. No dilution of SLRS-5 was necessary to match the
199 concentrations of DOC- and TE-rich Siberian river samples. All certified major (Ca, Mg, K, Na,
200 Si) and trace elements (Al, As, B, Ba, Co, Cr, Cu, Fe, Ga, Li, Mn, Mo, Ni, Pb, all REEs, Sb, Sr,
201 Th, Ti, U, V, Zn) concentrations of the SLRS-5 standard and the measured concentrations agreed
202 with an uncertainty of 10-20%. The agreement with SLRS-5 for Cd, Cs and Hf was between 30
203 and 50%, although the uncertainty on the analyses of these elements was between 5 and 10%.

204 Statistical analysis was used to quantify the relationship between major and trace element
205 proportion in colloidal or LMW_{< 3 kDa} fraction and % of permafrost, amount of
206 wetlands/lake/forest coverage in the watershed, and the surface area of the watershed ($S_{\text{watershed}}$).
207 Note that applying correlation analysis to proportions can lead to the detection of apparently
208 significant "spurious correlations", since an increase in the proportion of a given constituent may
209 be caused by the increase in the amount underlying that proportion, a decrease in other
210 proportions, or both (e.g., Pawlowsky-Glahn and Buccianti, 2011). To add certainty, we used a
211 confidence level of 99% ($p < 0.01$). We also tested the correlations between element
212 concentrations in the LMW_{< 3 kDa} fraction and the physio-geographical parameters of watershed;
213 the dependencies were essentially the same. However, since the absolute concentrations in WSL
214 rivers are strongly affected by season and latitude (i.e., Pokrovsky et al., 2016b), we chose to
215 show the % fractions for better representation of environmental impact on colloids across various
216 seasons and permafrost zones.

217 Similar to previous work in this region, we distinguished five zones of permafrost
218 distribution in river watersheds: 1) permafrost-free zones located south of 61°N latitude, 2)
219 isolated zones located between 61 and 63.5°N latitude; 3) sporadic zones located between 63.5
220 and 65°N latitude; 4) discontinuous zones located between 65 and 66°N latitude, and 5)

221 continuous permafrost zones located north of 66°N latitude. Correlations between element
222 concentration in various colloidal fractions, the relative proportion of these fractions and main
223 parameters of the watershed (latitude, watershed area, runoff, percentage of bogs, forest and lakes
224 and the permafrost coverage) were tested using both Pearson and Spearman coefficients at $p <$
225 0.05 for rivers of different size ranges ($< 100 \text{ km}^2$, $100\text{-}1000 \text{ km}^2$, $1000\text{-}50,000 \text{ km}^2$, and $> 50,000$
226 km^2) during each season as well as for all 3 seasons simultaneously.

227

228 **3. Results**

229 *3.1. Impact of river size, season, latitude and permafrost distribution on colloidal (3 kDa - 0.45*
230 *μm) fraction of C and TE.*

231 The concentrations of elements in 5 main fractions ($< 1 \text{ kDa}$, $< 3 \text{ kDa}$, $< 30 \text{ kDa}$, < 100
232 kDa and $< 0.45 \mu\text{m}$) averaged over permafrost-free and permafrost-bearing rivers for each season
233 are listed in **Table 1** whereas all raw data for each river are provided at the Research Gate
234 repository (Pokrovsky et al., 2019). Considering all available rivers and dissolved components,
235 no distinct link between $S_{\text{watershed}}$ and concentration of colloids or proportion of LMW fraction
236 could be established (R_{Pearson} is not significant at $p < 0.05$). However, several elements exhibited
237 distinct impact from river size on colloidal (3 kDa - 0.45 μm) fraction. There was a decrease of
238 colloidal fraction of Al, Fe, Ca, P, Mo and U with increase in watershed size, this was especially
239 visible in summer and autumn (**Fig. 2 A-F**). The organic carbon (OC) and divalent metals (Ni,
240 Cu, Mn, Co, Cd, Pb) did not exhibit any statistically significant impact from watershed size on
241 colloidal fraction (not shown). The pattern of element colloidal fraction with latitude or
242 permafrost zone was distinctly different during the 3 seasons studied. In spring, the $80 \pm 20\%$ of
243 colloidal DOC in rivers in the permafrost-absent zone decreased to 20-40% reaching the same
244 proportion as in rivers located north of 66°N, in the continuous PF zone (**Fig. 3 A and Fig. S1**
245 **A**). The colloidal DOC increased from S to N during the summer period (**Fig. S1 B**); this pattern

246 was pronounced in rivers larger than 100 km² also in autumn (**Fig. S1 C**). Al demonstrated
247 systematic decrease of colloidal fraction in PF-free rivers (south of 60°N) in the order spring >
248 summer > autumn; this decrease was also detectable in rivers from permafrost zone (**Fig. 3 B**),
249 north of 60°N (**Fig. S2 A-C**). Fe was essentially present (> 90%) in colloidal forms in permafrost
250 rivers (**Fig. 3 C**). In contrast, in rivers from permafrost-absent zones, the Fe colloidal fraction
251 decreased over active seasons from 95-98% in spring to 10-40% in autumn (**Fig. 3 C, S3 A-C**).
252 Ca, Mg and P also demonstrated the highest fraction of colloids in spring and the lowest fraction
253 of colloids in summer and autumn, especially visible in permafrost-free zones (**Fig. 3 D, E and**
254 **F**, respectively).

255 There was a decrease in colloidal forms of low-soluble trivalent and tetravalent (Ti, Zr, Hf,
256 Th, Ga, Y, REE) elements in summer compared to other seasons, which was visible across all
257 permafrost zones (**Fig. S4**). The divalent metals (Cu, Ni, Co, Mn, Cd, Pb) exhibited a much
258 higher colloidal fraction in spring compared to summer and autumn, detectable throughout all
259 permafrost zones (**Fig. S5**). Neutral molecules, oxyanions and U(VI) demonstrated a similar
260 pattern, although colloidal forms of U were especially low in summer and autumn in the
261 permafrost-free zone (**Fig. S6**).

262 Note that suspended matter concentration in WSL rivers strongly increases during spring
263 flood (Krickov et al., 2019). This can potentially produce so called "particle concentration effect"
264 (Benoit and Rozan, 1999) thus influencing the distribution of colloids amongst the different size
265 fractions, biasing it towards higher proportions in smaller size fractions. However, the proportion
266 of small size fraction of many elements (Al, Ca, Mg, P, divalent metals) was the lowest in spring,
267 which is contrary to what is expected if particle concentration effect could bias the distribution
268 of colloids.

269

270

271 3.2. Dependence of colloidal fraction on forest and bog coverage in the watershed

272 Spring period was characterized by minimal links of element colloidal fraction and
273 watershed parameters such as forest and bog coverage (**Fig. 4**). In the summer and autumn, the
274 colloidal fraction for a number of highly mobile elements (all alkalis (Li, Na, K, Rb) and alkaline-
275 earths (Mg, Ca, Sr, Ba), Co, Ni, As, and Mo) decreased with the degree of forest coverage in the
276 drainage basins. In autumn, the effect was also visible for Al, P, Ti, Th. Other elements did not
277 demonstrate any significant ($p < 0.05$) link of their colloidal fraction to forest coverage of the
278 watershed. Bogs exerted a rather weak control on colloidal forms of elements: DOC weakly
279 increased in spring but had no effect in summer and autumn (**Fig. 5 A**). Alkalis and alkaline-
280 earth elements increased their colloidal fraction with bog increase in summer and autumn (**Fig.**
281 **5 B-D**). For all other elements, the effect of bog coverage was not detectable within the variations
282 between different rivers (not shown). Note that, given relatively low coverage of WSL territory
283 by lakes (~6%, Polishchuk et al., 2017), the role of lake in river watershed on element status in
284 colloids was strongly subordinate relative to bogs and forests, and as such not considered in
285 interpretation of results.

286

287 3.3. Fe:C stoichiometry of colloids

288 The stoichiometry of Fe:C ratios in colloidal (3 kDa - 0.45 μm) and LMW_{< 3 kDa} fractions
289 depended primarily on latitude and season, but were much weaker affected by landscape
290 parameters. Thus, watershed size had little effect on Fe:C ratio in colloidal fraction ($R^2 < 0.2$ -
291 0.3, **Fig. 6 A**) and the Fe:C ratio in LMW_{< 3 kDa} fraction followed the order autumn > summer >
292 spring (**Fig. 7 A**). The Fe:C ratio in colloids (Fe:C)_{3 kDa - 0.45 μm} increased with latitude in spring
293 ($R^2 = 0.50$, $p < 0.01$, **Fig. 6 B**) whereas this ratio in the LMW fraction (Fe:C)_{< 3 kDa} decreased
294 northward in spring and summer (**Fig. 7 B**). Forest coverage yielded weak enrichment in Fe
295 relative to C in colloids in summer and autumn (**Fig. 6 C**) but the effect was absent in spring (not

296 shown). No clear effect of forest coverage on Fe:C ratio in the $\text{LMW}_{< 3 \text{ kDa}}$ fraction was revealed
297 although there was some increase of this ratio ($R^2 = 0.40 \pm 0.03$) in rivers of 100-1000 km²
298 watersheds in autumn (not shown). Finally, the bogs and lakes in the watersheds exhibited no
299 effect on Fe:C ratio in colloids and LMW fraction of river water (not shown).

300

301 *3.4. Size fractionation of colloids*

302 Dialysis through 1 kDa membrane and Amicon centrifugal ultrafiltration (3 kDa)
303 performed in summer and autumn demonstrated virtually identical (within $\pm \leq 10\%$)
304 concentrations of C and metals in 1 kDa and 3 kDa size fractions. This strongly suggests that the
305 LMW colloidal fraction having the size between 1 kDa and 3 kDa represents less than 10% of
306 DOC and $< 2\text{-}5\%$ of all other elements (**Fig. S7 A-H**). This fraction therefore has negligible
307 impact on colloidal speciation and $\text{LMW}_{< 3 \text{ kDa}}$ obtained by centrifugal ultrafiltration for all WSL
308 rivers in this study is thus equivalent to the more frequently used $\text{LMW}_{< 1 \text{ kDa}}$ cutoff. The
309 distribution of elements between different colloidal fractions demonstrated a dominance of
310 $\text{LMW}_{< 3 \text{ kDa}}$ ‘truly dissolved’ forms and medium molecular weight ($\text{MMW}_{3 \text{ kDa} - 30 \text{ kDa}}$) colloids
311 for most components, regardless of season and permafrost type. These distributions are
312 illustrated in **Fig. 8** for major components of colloids (OC, Al, Fe) and Ca. Organic carbon did
313 not demonstrate any systematic change of colloidal forms over different permafrost zones in
314 summer and autumn, but there was a systematic increase in the $\text{LMW}_{< 3 \text{ kDa}}$ form and decrease in
315 $\text{MMW}_{3 \text{ kDa} - 30 \text{ kDa}}$ colloids from PF-free to continuous permafrost zone (**Fig. 8 A-C**). Aluminium
316 demonstrated dominant $\text{MMW}_{3 \text{ kDa} - 30 \text{ kDa}}$ colloids in spring and appearance of $\text{LMW}_{< 3 \text{ kDa}}$
317 colloids in summer and autumn (**Fig. 8 D-F**). There was no change in Al distribution among
318 fractions across various permafrost zones suggesting a primarily seasonal rather than physio-
319 geographical control on Al colloidal status. In contrast, Fe exhibited a sizeable proportion of
320 $\text{HMW}_{100 \text{ kDa} - 0.45 \mu\text{m}}$ and $\text{HMW}_{30 \text{ kDa} - 100 \text{ kDa}}$ colloids in summer and autumn (**Fig. 8 G-I**). However,

321 in spring, Fe was strongly dominated by $MMW_{3\text{ kDa} - 30\text{ kDa}}$ colloids similar to other insoluble TE^{3+}
322 elements. An example of element poorly affected by colloids is Ca which was largely dominated
323 by $LMW_{< 3\text{ kDa}}$ with a sizeable (30-40%) contribution of $MMW_{3\text{ kDa} - 30\text{ kDa}}$ colloids in spring and
324 a negligible (< 2%) contribution of high molecular weight $HWM_{30\text{ kDa} - 0.45\ \mu\text{m}}$ colloids (**Fig. 8 J-**
325 **L**). All other elements which were affected by colloids followed these 2 main distribution types,
326 specifically the OC-like or trivalent metal (Fe, Al)-like. Note that the role of Mn in colloidal
327 composition was highly subordinate to that of Fe and Al as the molar ratio Fe : Al : Mn in the 3
328 kDa - 0.45 μm fraction was typically (1-10) : 1 : 0.01. As such, the change of stoichiometry and
329 TE affinity to main components of colloids can be further assessed by analyzing the progressive
330 decrease of element concentration with respect to that of DOC, Fe and Al during decreasing pore
331 size of fractional separation.

332 The behavior of main colloidal constituents - OC, Fe and Al - during size separation
333 procedure (0.45 μm \rightarrow 100 kDa \rightarrow 30 kDa \rightarrow 3 kDa (\rightarrow 1 kDa)) was distinctly different among
334 the three seasons and various permafrost zones (**Fig. 9**). During spring flood, there was high
335 similarity of Al-DOC and Al-Fe concentration patterns during ultrafiltration; the molar ratio of
336 Fe:Al in colloids was close to 1 regardless of pore size and permafrost zone. During summer
337 baseflow, the colloids became Fe-rich and Al-poor, a pattern which was especially pronounced
338 in continuous PF zone. In autumn, strong differentiation between different permafrost zones was
339 observed as colloids became enriched in Al vs OC and Fe.

340 As for the trace elements, progressive decrease of TE concentrations in the course of
341 fractionation from large to small pore size exhibited two distinct patterns, depending on
342 elemental affinity to either OC or Fe and Al. Two main features of element behavior during
343 ultrafiltration procedure were noted: (1) the changes of element - OC or element - Fe/Al
344 concentration pattern were similar between all studied permafrost zones including the
345 permafrost-free zone, and (2) this pattern varied depending on the seasons as illustrated in **Fig.**

346 **10** for several typical elements. During spring flood period, alkalis and alkaline-earth elements,
347 V, Mo and U decreased their concentrations in parallel with OC. Siderophilic (Cr, Mn, Co, Ni)
348 and chalcophilic (Cu, Cd, Zn, Pb) elements followed the decrease of Fe/Al rather than OC.
349 Trivalent hydrolysates were tightly associated with Fe and Al (indistinguishable between two)
350 whereas tetravalent hydrolysates were essentially bound to Al over Fe (illustrated for Mg and Hf
351 in **Fig. 10 A**). The changes during summer baseflow consisted of the following: *i*) alkalis and
352 alkaline-earth elements were not controlled by colloids as their concentration remains stable
353 during fractional separation, and *ii*) chalcophilic elements (Cu, Cd, Zn, Pb) followed the pattern
354 of OC rather than Fe/Al (shown as example for Mg and Cu in **Fig. 10 B**). In Fall, new features
355 appeared during the size separation procedure: the role of Fe as a colloidal carrier sizably
356 decreased and the divalent metals (Cu, Cd, Zn, Pb), TE^{3+} , TE^{4+} became associated to Al and OC
357 rather than Fe (shown as example of Co and Hf in **Fig. 10 C**).

358

359 **4. Discussion**

360 *4.1. Season and latitude exert stronger control on colloidal fraction than river size*

361 The working hypothesis of this study was that the percentage of colloidal versus LMW
362 fraction and stoichiometry of Fe:C ratio will be primarily dependent on river size, season and
363 landscape parameters of the watershed. Indeed, the river size is expected to control the degree
364 of underground feeding via discharge of underground anoxic Fe(II)-rich waters in the hyporheic
365 zone (Shim et al., 2017). Generally, the permafrost prevents the hydrological connectivity
366 between the groundwaters and the rivers (Walvoord et al., 2012). It is expected that the river size
367 effect will be mostly pronounced in the permafrost zone due to restricted connection between the
368 rivers and shallow surface waters and the lack of talik (unfrozen underground water path under
369 the river bed) in small rivers (Pokrovsky et al., 2015). Further, the residence time of colloids and
370 LMW fraction in the river strongly depends on $S_{\text{watershed}}$ and the biological (heterotrophic

371 degradation of DOM) and physico-chemical (photolysis) processes which are known to be able
372 to strongly modify the colloidal composition of surface waters in boreal and subarctic zones
373 (Oleinikova et al., 2017a, b). The decrease of Fe in the colloidal fraction is indeed observed in
374 summer in watersheds larger than 100 km² (**Fig. 2 B**) which may be due to discharge of LMW
375 Fe(II) ionic forms from underground waters. This discharge is mostly visible at low water level
376 and at the highest depths of unfrozen soil layers. However, in the river water, Fe(II) is likely to
377 be oxidized and coagulate as Fe(III) oxy(hydr)oxide HMW colloids or particles. This is
378 illustrated by the data in **Fig. 8I**, showing that the importance of Fe in large colloids (3-30 kDa
379 and 30 kDa - 0.45 μm) increase during summer and autumn in the permafrost zones. Further,
380 analyses of particulate load of WSL rivers demonstrated that Fe concentration in river suspended
381 particles follows the order spring < summer < autumn, which is especially visible in permafrost-
382 absent zone where the underground input is mostly pronounced (Krickov et al., 2019).

383 The decrease in colloidal fraction of soluble, highly mobile elements (Ca, Mg, P, Mo, U)
384 also observed in summer and autumn (Fig. 2) is due to increased connectivity of underground
385 reservoirs enriched in ionic forms of these elements, mostly pronounced in southern rivers, as
386 was suggested from early analysis of < 0.45 μm river load across the WSL (Frey et al., 2007a),
387 which is especially visible during baseflow period (Pokrovsky et al., 2015, 2016b). The other
388 elements (Ga, Y, REE, Zr, Hf, Th, Mn, Cu, Ni, Co, Cd, Pb, As, Sb) as well as OC did not
389 demonstrate sizeable impact of river size on colloidal fraction. Presumably, the mechanisms of
390 organic colloid generation and scavenging are similar across all studied river sizes. This implies
391 that the colloids formed at the watershed or within the soil/groundwater discharge within the
392 river channel are not subjected to further to bio- and photodegradation during their transport in
393 the river channel.

394 The season is likely to control two main sources of colloidal DOM in rivers: 1)
395 allochthonous, large-size molecules from surface vegetation and plant litter leaching and

396 degradation, which are mostly pronounced in spring during high flow and 2) autochthonous,
397 small size molecules originating from exometabolites of phytoplankton and periphyton in rivers,
398 which are most visible during summer (August). This was reflected by generally higher specific
399 UV-absorbance at 254 nm in spring compared to summer and autumn, as evidenced across all
400 river sizes and permafrost zones (Pokrovsky et al., 2015). Additionally, the late autumn seasons
401 corresponding to maximal active layer thickness may provide the DOM colloids from deep peat
402 horizons typically not visible in spring and summer.

403 The decrease in colloidal fraction of Fe and Al (**Fig. 3B, C**) and many divalent transition
404 metals such as Cu, Ni, Co, Mn, Cd (**Fig. S5**) from spring to autumn could reflect decrease in
405 concentration of allochthonous large-size colloids at the expense of autochthonous LMW ligands
406 that bond metal cations as is known in other boreal taiga rivers (Pokrovsky et al., 2010; Bagard
407 et al., 2011). Note that this was especially pronounced in the permafrost-free zone, where
408 sufficient production of plant leachate could stabilize LMW Fe, Al and divalent metals. Further,
409 high concentration of aquagenic organic LMW ligands from plankton and periphyton in the
410 southern rivers can stabilize Fe in the LMW fraction. This is consistent with the size distribution
411 of DOC in the autumn shown in **Fig. 8 C**: the DOC is dominated by the LMW fraction in the
412 permafrost-free zone, but it is dominated by colloids in all other zones. Alternatively, southern
413 rivers could have sizeable underground feeding by Fe(II)-rich ground waters interacted with
414 soluble sedimentary rocks (limestones). This enhanced underground input in PF-free rivers can
415 stabilize Fe as carbonate and bicarbonate complexes in the LMW fraction. In the course of the
416 season, progressive appearance of these groundwaters could decrease relative proportion of
417 colloidal metals at the expense of LMW ionic forms. This is seen for Ca, Mg, P (**Fig. 3 D, E, F**),
418 and especially U (**Fig. S6**). For the latter, there was almost a 10-fold decrease in colloidal fraction
419 in summer and autumn relative to spring; this decrease certainly reflected high bicarbonate inputs
420 during baseflow of the WSL southern rivers (Frey et al., 2007a; Pokrovsky et al., 2015). The

421 presence of bicarbonate changes speciation of U^{VI} from organic and organo-ferric colloids to
422 uranyl carbonate complexes as it was evidenced by seasonal observations across the boreal
423 regions (Pokrovsky et al., 2010; Bagard et al., 2011).

424 In the permafrost zone, the dominance of colloidal forms (> 90%) of Fe during all seasons
425 essentially reflected river feeding by shallow subsurface waters and supra-permafrost flow over
426 peat soils (**Fig. S 3**) as the underground-sourced Fe(II) is minimal and likely to be quickly
427 oxidized into Fe hydroxide particles and HLW organo-ferric colloids. In contrast, Al
428 demonstrated a notable decrease in colloidal forms from spring to autumn even in permafrost-
429 bearing rivers (compare Figs. **3B** and **3C**). It is possible that, unlike Fe, some mobilization of
430 LMW organic Al complexes from peat soils and shallow mineral layers in permafrost rivers
431 occurred in summer and autumn. The increased importance of LMW-Al during summer and
432 autumn could be a result of that the input of colloidal Al from the top soil decreased, while
433 groundwater-Al remained constant. This is further confirmed by sizeable decrease in Al
434 concentration from spring to summer, visible for permafrost-free rivers; this decrease is much
435 less manifested in the LMW fraction compared to the 0.45 μm fraction and HMW colloids (see
436 **Table 1**). Because the seasonal decrease in colloidal Al was especially pronounced in large rivers
437 ($S_{\text{watershed}} > 50,000 \text{ km}^2$, **Fig. 2 A**) we believe the main driving mechanisms of seasonal Al
438 colloidal transformation in large rivers is underground water discharge accompanied by an
439 increase in pH. This can be especially pronounced in southern, permafrost-free rivers of the
440 regions, where carbonate-bearing rocks can provide elevated CO_3^{2-} concentrations and pH
441 (Pokrovsky et al., 2015) thus transforming insoluble or organically-bound $\text{Al}(\text{OH})_3^\circ$ complexes
442 into more mobile truly dissolved $\text{Al}(\text{OH})_4^-(\text{aq})$.

443 Latitude was the major governing factor of colloidal forms of OC, major and trace
444 elements in WSL rivers. This is due to the fact that latitude integrates many other physio-
445 geographical parameters such as permafrost, temperature, precipitation, and forest line. For

446 example, the increase of colloidal fraction with latitude (northward) could be due to northward
447 decrease of the LMW form input through underground feeding. This occurs due to a general
448 decrease of river connectivity with underground reservoirs northward (Ala-aho et al., 2018);
449 these reservoirs are rich in alkalis, alkaline-earth elements, P and As. The change of underground
450 regime feeding, already evidenced for bulk dissolved ($< 0.45 \mu\text{m}$) major and trace elements
451 (Pokrovsky et al., 2015, 2016), is the most likely explanation for this observed tendency.

452 A decrease in colloidal DOC in rivers north of 66°N observed in spring (**Fig. 3A, S1 A**)
453 could be linked to colloid coagulation and production of LMW organic ligands during freezing-
454 thawing cycles, as is established for permafrost mire waters located in landscape contexts similar
455 to that of WSL (Pokrovsky et al., 2018). Because WSL rivers in the north freeze solid in winter
456 (Pokrovsky et al., 2015), the decrease in colloidal fraction could be linked to this cryo-
457 transformation of colloids. In summer, the southern rivers have shown a generally lower colloidal
458 fraction compared to northern rivers (**Fig. 3A, S1 B**). We interpret this difference as resultant of
459 two main processes: *i*) thawing of peat and release of colloidal OC in the north, which does not
460 occur in the south and *ii*) leaching of LMW OC and metal complexes from abundant plant
461 biomass and LMW exometabolite production by macrophytes, plankton and periphyton in the
462 south. The increase in colloidal fraction of OC in rivers of the permafrost-free taiga zone (south
463 of 60°N) in autumn compared to summer could be interpreted as due to cessation of in-stream
464 primary production and enhanced leaching of HMW OC from peat bogs and from the bottom
465 horizons of peat soil. Indeed, an increased importance of LMW-DOC relative to colloidal-DOC
466 going from the permafrost-absent to isolated, sporadic, discontinuous and continuous zones.
467 could be due to differences in the composition of terrestrial DOM. The latter reflects the
468 differences in vegetation (tundra versus forest) along the S - N gradient. Forests will produce
469 DOM with more lignin, thus larger in molecular size and this is expected to be mostly
470 pronounced in autumn, during litter fall. Note that, while there was a strong contrast between

471 colloidal speciation of many elements between permafrost-free and permafrost zones, permafrost
472 type distribution *per se* (isolated, sporadic, discontinuous and continuous) weakly impacted the
473 proportion of colloids.

474

475 *4.2. Weak role of watershed landscape parameters on colloidal status of elements*

476 The lack of watershed parameters impact on colloidal metals in spring (**Figs. 4, 5**) is
477 presumably due to strong integration of catchment surface conditions during this high flow
478 period. The dominance of surface flow occurring over frozen upper peat horizons and similarity
479 of wetlands ground vegetation (moss, lichens, dwarf shrubs, etc.) across WSL create quite
480 homogeneous conditions that define elemental distribution among colloids and LMW_{< 3 kDa}
481 forms.

482 The negative effect of forest coverage on colloidal transport of alkalis and alkaline-earth
483 elements and also As, V and P in summer and autumn (**Fig. 4**) is interpreted as due to increase
484 in depth of the water path under forests which thereby increases connectivity between
485 groundwater and the river (Ala-aho et al., 2018a). The impact of forest coverage is especially
486 pronounced in the permafrost zone because it creates optimal conditions for soil thaw and
487 enhances input of groundwater constituents to the river (Krickov et al., 2018). Deepening of the
488 active layer increases the connectivity of rivers with underground reservoirs and thus enhances
489 mobilization of soluble, highly mobile elements (Li, K, Rb, Ca, Mg, Sr, Ba, As, V, P, Mo) in
490 ionic form to the river. As a result, the colloidal fraction of these elements decreased with
491 increased forest coverage. Note that this underground feeding effect was mostly pronounced in
492 autumn when surface flow through organic soil and peat horizons was minimal and river
493 discharge was low.

494 The effect of forest coverage on Al, Ti, Y and other trivalent and tetravalent hydrolysates
495 is different from that exerted on the soluble elements. Trivalent and tetravalent hydrolysates

496 could be mobilized from bottom mineral horizons that become progressively available in the
497 course of summer and autumn as the active layer deepens over the organic horizon to underlying
498 mineral deposits. The effect of forest coverage on TE^{3+} and TE^{4+} colloids becomes visible in
499 autumn (**Fig. 4 G, H**), with maximal active layer thickness and minimal feeding of rivers by
500 lateral peat surface overflow. Loiko et al. (2017) observed similar impact of permafrost thaw
501 when the depth of the active layer moved over the organic into mineral soil horizons in sites of
502 abrupt permafrost thaw in the discontinuous permafrost zones.

503 The effect of bogs was clearly pronounced only for alkalis and alkaline-earths, which
504 increased their colloidal fraction with bog coverage. There are two possible mechanisms for bogs
505 control on riverine colloids. First, if bogs decrease the connectivity of rivers to underground
506 reservoirs, this will decrease the delivery of alkali and alkaline-earth elements to the river in the
507 form of ionic forms ($LMW_{< 3 \text{ kDa}}$) thus increasing relative share of colloidal forms. Note that bogs
508 mobilize colloids during all seasons; however, in summer the autochthonous production of LMW
509 organic colloids in rivers can partially mask the effect of bogs. Second, the generation of colloids
510 in bogs is possible due to photo- and bio-degradation of DOM and DOM-Me complexes from
511 active peat layers. Because of the shallow hydrological connectivity of bogs to rivers (Ala-aho
512 et al., 2018a, b), Fe does not follow OC in these aquatic systems and as a result other elements
513 linked to organo-ferric colloids (P, TE^{3+} , TE^{4+}) did not exhibit any relationship to the bog
514 proportion at the watershed. Only the elements that are complexed to DOM colloids, rather than
515 organo-Fe colloids (i.e., alkalis, alkaline-earths), were impacted by bogs.

516

517 *4.3. Colloid stoichiometry and element distribution among different colloidal fractions*

518 The ratio of Fe:C in the colloidal (3 kDa - 0.45 μm) fraction is a useful indicator for
519 climate and environmental control on colloid generation in river water. In summer and autumn,
520 there was an appearance of $LMW_{< 3 \text{ kDa}}$ fraction of Fe which decreased the relative concentration

521 of Fe in colloids during this period. The increase in $LMW_{<3\text{ kDa}}$ forms stemmed from *i*)
522 autochthonous production of Fe-organic complexes as evidenced by large rivers of the region
523 (see section 4.1) and *ii*) Fe(II) influx from underground waters in the riparian/hyporheic zones.
524 The latter is confirmed by the fact that the Fe:C ratio in the $LMW_{<3\text{ kDa}}$ fraction was also highest
525 in autumn. The forest coverage increased the amount of Fe in colloids relative to C during this
526 period, likely due to facilitating a connection to the underground source and enhancing Fe-rich
527 colloid formation at groundwater discharge zones within the river bed or the riparian zone. The
528 presence of forest coverage also increased the Fe:C ratio in the $LMW_{<3\text{ kDa}}$ fraction, although this
529 increase was visible solely in rivers having $S_{\text{watershed}}$ from 100 to 1000 km².

530 The distribution of Fe between different size fractions of colloids changed dramatically
531 from spring to summer-autumn in the permafrost zones as shown in **Fig. 8 G, H, I**. This indicates
532 that the source of colloidal Fe changes from spring to summer-autumn. In high-latitude rivers,
533 the primary source of colloidal Fe during spring flood is typically from through leaching of the
534 top soil, while most colloidal Fe during summer and autumn is derived from groundwater input
535 of Fe(II), rapidly oxidizing and precipitating as colloidal Fe(III)-oxyhydroxide. Indeed, the
536 latitude increased Fe:C in colloids during autumn when deep unfrozen water paths became
537 available and more Fe could be discharged to the river from underground and/or shallow
538 subsurface reservoirs. At the same time, the Fe:C ratio in $LMW_{<3\text{ kDa}}$ fraction decreased
539 northward during this period probably due to enhanced production of LMW organic ligands in
540 the north linked to a massive thawing of frozen peat. Such processes have been documented in
541 previous laboratory experiments (Drake et al., 2015; Mann et al., 2015).

542 An interesting feature revealed by element concentration decrease in the course of
543 ultrafiltration (**Figs. 9, 10**) is the change in the relative role of Fe and Al as colloidal constituents
544 and TE carriers. In spring, the colloids contain similar molar amount of Fe and Al; both of these
545 metals exerted control on a number of TE during size fractionation. In summer, the role of the

546 Al constituent strongly decreased and some divalent metals (Cu, Cd, Zn, Pb) became bound to
547 OC rather than Fe and Al. This may be linked to the appearance of autochthonous organic
548 complexes for these elements. In autumn, the role of Al again became strongly pronounced; this
549 may be due to the increase of the thawing depth and involvement of deep silicate mineral
550 horizons in element mobilization.

551 The HMW_{30 kDa - 0.45 μm} colloids of Fe and insoluble TE³⁺ and TE⁴⁺ elements were
552 dominant during summer and autumn but were in quite low proportion (ca < 20%) during spring
553 (**Figs. 8**). This important observation strongly supports numerous previous findings across
554 permafrost and boreal zones (Pokrovsky and Schott, 2002; Vasyukova et al., 2010; Pokrovsky et
555 al., 2016, Stolpe et al 2013a, b). These studies, performed essentially during baseflow period,
556 suggested HMW Fe-rich colloid generation within the riparian and hyporheic zone due to
557 discharge of partially anoxic deep and shallow ground waters, which contain sizable amount of
558 Fe(II) subjected to oxidation by DOM-rich surface waters. This lead to formation of large
559 molecular size Fe oxy(hydr)oxides, stabilized by organic matter and containing sizeable amount
560 of other trace elements that were co-precipitated with Fe(OH)₃ (Pokrovsky and Schott, 2002). In
561 fact, the coagulation of Fe hydroxide with DOM occurs at redox interfaces in peatlands (Riedel
562 et al., 2013) and at the surface of fens (Koretsky et al., 2006). Given the abundance of peatlands
563 in WSL, we believe that these freshly precipitated Fe hydroxides-DOM compounds can become
564 the main source of HMW colloids during baseflow period. The lack of HMW Fe-rich colloids in
565 WSL rivers during spring flood observed in this study is fully consistent with a lack of
566 hydrological connectivity between deep soil and subsurface waters and rivers during this period
567 of the year (Ala-aho et al., 2018a, b). As a result, because the river water cannot pick up Fe(II)
568 from partially anoxic underground and shallow subsurface waters, formation of HMW Fe(III)
569 hydroxide colloids is strongly suppressed and the majority of colloidal flux is dominated by
570 surface runoff generated from leaching of plant litter and upper soil (peat) horizons.

571 *4.4. Foreseeing the evolution of colloidal status of elements in the context of climate change.*

572 The boreal and circumpolar regions of both European Russia and Siberia contain sizeable
573 amounts of OC in peat soil of bog zones and as forest litter of the highly productive taiga zone.
574 As a result, colloids are the main vectors of transport for most trace insoluble and even major
575 elements (such as Ca) the in the boreal zone. Compared to tropical and temperate zones, colloids
576 in boreal zone are 1) richer in Fe(III) and 2) contain a higher proportion of low molecular weight
577 (LMW_{<1 kDa}) labile organic matter (Pokrovsky et al., 2016). It is currently impossible to predict
578 the degree of colloidal export change against changes in soil temperature, permafrost thaw and
579 vegetation zone shifts. However, a direct empirical approach can be efficiently tested for WSL
580 thanks to its unique physio-geographical situation where permafrost and MAAT zones change
581 similarly from south to north.

582 In order to predict the possible evolution of C and metal distribution between colloidal
583 and LMW (potentially bioavailable) pools, a ‘substituting space for time’ scenario can be applied
584 which is well established in WSL for predicting the evolution of dissolved (< 0.45 μm) C,
585 nutrients and metals concentration and fluxes in rivers (Frey et al., 2007a, b; Pokrovsky et al.,
586 2015; Vorobyev et al., 2017) and soil waters (Raudina et al., 2017, 2018). If permafrost
587 disappears in the sporadic and isolated permafrost zones, this will produce a decrease in riverine
588 colloidal transport of OC, Ca, Mg, P, Fe, Al, Ti, Ni, REEs, As, Mo and U, especially in summer
589 and autumn. The transformation of continuous permafrost into discontinuous and sporadic will
590 not sizably affect colloidal speciation of C and metals, although it is impossible to predict
591 whether or not the contrast between seasons will remain the same or decrease.

592 The role of landscape change (forestation of bogs, drainage of lakes and forest line
593 advancement northward) seems to be lower than that of a permafrost boundary shift northward.
594 However, we expect that the forestation of bogs will inevitably lead to a decrease in colloidal
595 forms of alkalis, alkaline-earth elements, V, P, As, Pb by a factor of 2 to 3. This effect will be

596 mostly seen at the end of active seasons in autumn. Only during this season will the northern
597 rivers become richer in colloidal Fe compared to colloidal C. However, given the relatively low
598 share of autumn flux to the annual C and element discharge by WSL rivers (Pokrovsky et al.,
599 2016), the overall effect of landscape change on colloidal export of solutes from the mainland to
600 the Arctic Ocean may be due essentially to the change in discharge rather than the change in river
601 water colloidal composition and stoichiometry. In the permafrost zone, the increase of the depth
602 of water paths through the organic (peat) horizons into the mineral horizon will bring about an
603 enhanced mobilization of low mobility elements (Fe, Al, other TE^{3+} , TE^{4+}) into the fluid phase.
604 This may enrich riverine colloids in these refractory elements, a process which has been locally
605 observed for sites involving catastrophic thawing of frozen peat (e.g., Loiko et al., 2017).

606

607 **Concluding remarks**

608 Organic and organo-mineral colloids of C and metals in WSL rivers are dominated by
609 medium molecular size fraction of 3 to 30 kDa in spring, whereas in summer and autumn, low
610 (< 1-3 kDa) and heavy molecular weight fraction (30 kDa - $0.45\mu\text{m}$) become highly abundant.
611 We revealed distinctly different behaviors of organo-ferric colloids in permafrost and non-
612 permafrost regions that are dependent upon the season. In continuous permafrost zones in spring,
613 there was a 2 to 3-fold increase in $LMW_{< 3 \text{ kDa}}$ OC relative to other permafrost zones. The
614 appearance of LMW OC north of 66°N during this period could be linked to full freezing of
615 small streams and generation of LMW organic ligands under freeze-thaw cycles. Fe
616 demonstrated distinctly different colloidal pattern depending on latitude and seasons: In
617 permafrost-free zone there was sizeable decrease of colloidal Fe, Al and trivalent hydrolysates
618 fraction in the course of the active season following the order spring > summer > autumn. In the
619 permafrost zone, the colloidal fraction of Fe, Al and Y, REE, Zr, Hf, Th^+ was high ($90\pm 10\%$) in
620 spring but also decreasing to $60\pm 20\%$ in summer. Similarly, divalent metals (Cu, Co, Cd, Pb,

621 Mn) had the highest colloidal fraction in spring and the lowest in summer and autumn, across all
622 permafrost zones. These patterns were observed in all rivers regardless of their size and it could
623 be linked to progressive decrease of allochthonous terrestrial large size colloids that are being
624 replaced by small size aquagenic DOM and metal-DOM complexes.

625 The effect of river size was mostly pronounced in the permafrost-free zone consisting of
626 a decrease in colloidal DOC, Al, Fe, P, Ca, Mg and U in streams larger than 100 km² in watershed
627 area. In the permafrost zone, it was subordinate as compared to season and forest presence.
628 Although the size of the watershed exerted generally low impact on colloidal distribution, there
629 was a decrease in colloidal fraction of Al, P, Mg, Ca in rivers larger than 50,000 km² especially
630 in summer and autumn, probably linked to appearance of autochthonous LMW organic
631 complexes. The groundwater discharge of Fe(II), Ca, Mg, P, Mo, U ionic forms leading to
632 decrease in Fe colloids was visible in streams > 100 km² in the permafrost-free zone.

633 In continuous and discontinuous permafrost zones, the riverine colloids are delivered to
634 the river via lateral flow over suprapermafrost horizons, whereas in permafrost-free and sporadic
635 to isolated permafrost zones, delivery occurs via lateral surface runoff and riparian/hyporheic
636 discharge. Forest coverage increases connectivity with deep underground waters which in turn
637 enriches the river water with ionic forms of soluble elements in LMW (ionic) forms thereby
638 decreasing the fraction of colloids. Because the underground feeding of rivers by LMW forms
639 of soluble elements decreases from south to north in WSL, the relative proportion of colloids
640 increases northward. This underground discharge leads to a sizeable decrease of colloidal forms
641 of DOC, Al, Fe, P, alkaline-earths, Cu, Ni, As and U in summer and autumn as compared to
642 spring. This effect was strongly pronounced in the permafrost-free zone.

643 On a climate warming and further permafrost thaw perspective, the increase in depth of
644 the active layer and connectivity of a river with underground water reservoirs may decrease the
645 colloidal fraction of OC, Fe, Al and number of divalent and trivalent metals as well as tetravalent

646 hydrolysates in the sporadic and isolated permafrost zone which will become permafrost-free.
647 The disappearance of continuous permafrost in the north will not sizeably impact colloidal status
648 of elements in river water. The LMW_{<3 kDa} OC will likely decrease in spring but increase in
649 summer and autumn. The forestation of wetlands and lake drainage may slightly diminish
650 colloidal transport of DOC and metals at the expense of low molecular weight forms. Overall,
651 given the significant role of seasonal and forestation effects on colloidal forms of OC and TE in
652 WSL rivers, major changes in the colloidal nature of riverine C and nutrients under a climate
653 warming scenario in the WSL are likely to be linked to change in vegetation (species, biomass
654 and geographical extension) rather than temperature and hydrology.

886 **Fig. 1.** A map of sampled rivers in Western Siberian Lowland. The latitudinal gradient covers
 887 1700 km traversing taiga, forest-tundra and tundra of permafrost-free, sporadic, isolated,
 888 discontinuous and continuous permafrost zones. All the primary data on major and trace element
 889 concentration in 0.45 μm , 1 kDa, 3 kDa, 30 kDa and 100 kDa size fraction are available from
 890 <https://www.researchgate.net/publication/331928620>; doi: 10.13140/RG.2.2.21502.64321.

893 **Fig. 2.** Box plot of first and third quartiles (25 and 75%) of colloidal (3 kDa - 0.45 μm) proportion
 894 of Al (A), Fe (B), Ca (C), P (D), Mo (E) and U (F) in WSL rivers of different watershed size,
 895 during spring (blue), summer (red) and autumn (green). Here and in figures below, all 32 rivers
 896 from the 5 permafrost zones are included here.

964 **Fig. 9.** Concentration pattern of Al, Fe and DC during colloidal separation by filtration through
 965 0.45 µm and further ultrafiltration through 100, 30 and 3 kDa. Shown are average values of
 966 rivers located in each permafrost zone in the three main seasons. The vertical and horizontal
 967 uncertainties of the average for several rivers (3 in permafrost-free zone, 5 in isolated, 9 in
 968 sporadic, 4 in discontinuous and 5 in continuous permafrost zone).

969

970 **Fig. 10.** Concentration pattern of selected elements (Mg, Cu, Co, Hf, Th) vs DOC or Fe during colloidal separation by filtration through 0.45 μm and 971 further ultrafiltration through 100, 30 and 3 kDa. Shown are average values of rivers located in each permafrost zone in spring (A), summer (B) and 972 autumn (C).
