Abstract

Argentina is known for having one of the most extensive areas with high arsenic (As) concentration in groundwater in the world. These areas correspond to two main geological provinces, the Puna plateau and the Chaco-Pampean plain. In this large territory, there are some specific environments where the As concentration in groundwater is lower, and in some cases within the recommended limits for drinking water. In our study, we analyze and interpret the low arsenic concentrations reported for the Lerma valley, the easternmost intermontane basin of the Cordillera Oriental, located between the aforementioned high-arsenic geological provinces. The groundwater from this valley is used for the consumption of more than 600.000 inhabitants in the city of Salta and nearby towns. The incipient development of the valley since the late Miocene and the subsequent tectonic and climatic evolution favored low As concentrations with respect to the Puna and the Chaco-Pampean plain. The high-energy sedimentary environments that characterized the area during Plio-Quaternary times and the composition of the sediments have controlled the characteristics of sediments the multilayered aquifer. Moreover, the absence of geogenic arsenic sources, climate, high rain infiltration rate, near neutral pH, redox conditions, and wells construction with screens settled in coarse productive layers favor groundwater of good quality. The geological and tectonic evolution of the Lerma valley could be extrapolated to other similar valleys in the NW of Argentina and can be useful as tool for exploration of good quality groundwater. This is of high importance in Latin American territories with high As concentration in groundwater such as Argentina.

- 46 groundwater geochemistry, Northwest Argentina

1. Introduction

Arsenic (As) is an element that can be found in groundwater linked to geogenic sources 49 (Nordstrom 2002, Smedley and Kinniburgh 2002). Chronic exposure to high levels of As is toxic 50 for human health producing variety of cancers, cardiovascular disease, and neurologic 51 52 impairments in exposed populations (Figueiredo et al., 2010; Mitchell, 2014). A large number of people in different parts of the world are exposed to As via drinking water (e.g. China, India, 53 Bangladesh, USA, Mexico, Chile). Argentina was the first Latin American country where As 54 occurrence in groundwater was reported, and the first in the world to document As poisoning 55 from natural sources known as HACRE (Hidro Arsenisísmo Crónico Regional Endémico, 56 according to its Spanish initials) (Goyenechea 1917, Bundschuh et al., 2012). In Argentina, 57 58 extensive areas with high As concentration in surface and groundwater are related mainly to two main geological provinces, the Altiplano-Puna plateau and the Chaco-Pampean plain (Ramos, 59 60 2017). The origin of As in these environments is linked to geogenic sources derived from Andean 61 orogeny and volcanism, a large scale geological processes affecting in some level most of the 62 Argentinian territory. Only in the Chaco-Pampian plain approximately 2 - 8 million inhabitants 63 are potentially affected by As (Nicolli, 2012). Here, the origin of As (and fluorine) in the 64 groundwater is related to the leaching of volcanic components present in the loess sediments 65 with important quantities of volcanic glass, volcanic minerals and volcanic lithic fragments 66 (Nicolli et al., 2012). Consequently, HACRE develops, sometimes associated with dental and/or 67 skeletal fluorosis. In the Altiplano-Puna plateau, As is found in most of the water types of the 68 region (i.e. groundwater, rivers, lakes, brines, salines, thermal waters, and acid mine drainage) 69

70 indicating multiple natural (volcanic-mineralogical-geothermal) and anthropogenic origins for As (Murray et al., 2018). San Antonio de Los Cobres town (located 250 km to the west of the 71 Lerma valley) is an emblematic case where As concentrations measured in drinking water are 72 around 200 µg/L. 73 However, in this extended territory, especially in the Chaco-Pampean plain, there are some 74 75 specific environments (e.g. fluvial plains, sand-dunes) where the As concentration in 76 groundwater is lower than the Argentinian guidelines for As in drinking water of 0.05 mg/L (CAA, 2012), and in some cases lower than the World Health Organization limits of 0.01 mg/L 77 (WHO, 2017) (Becher Quinodóz and Blarasín, 2014; Giacobone et al., 2018) . This is related to 78 hydrogeological and geochemical aspects of the aquifers that promote low As concentration in 79 groundwater. These sites are of special interest due to the lower preventive activities that 80 81 authorities must promote for preserving public health. However, these areas require of more 82 investigation and delimitation, and a better understanding of the geological-geochemicalhydrological characteristics (Giacobone et al., 2018). 83 This study focuses on the Lerma valley the easternmost intermontane basin of the Cordillera 84 Oriental geological province. The Cordillera Oriental is situated in northwestern Argentina, lying 85 between the Altiplano-Puna plateau and the Chaco-Pampean plain (Fig. 1). The groundwater of 86 the Lerma valley which is the main source of drinking water, has been qualified as good quality 87 (Baudino 1996). The largest urban area corresponds to the city of Salta, located in the northern 88 89 part of the valley with more than 600.000 inhabitants. It is the capital of the homonymous 90 province and corresponds to the seventh most populated city in Argentine (Argentinian National Census, 2010). Smaller rural towns of the Lerma valley which also consume groundwater are 91 Vaqueros, Rosario de Lerma, Campo Quijano, Cerrillos, La Viña (Fig. 1). The major threatsto 92

groundwater quality are related to urban contamination (Rocha and Baudino, 2002), overexploitation of the aquifers, and in some areas (Arenales Aquifer) anthropogenic contamination with boron, with values that reach 3 mg/L (Bundschuh et al., 1994). Low As concentrations in the Lerma valley groundwaters are described by de Sastre et al. (1992). The authors highlighted the difference with the Puna and the Chaco-Salteña plain (North area of the Chaco-Pampian plain, Fig. 1) where high As concentration in groundwater can be found. In the As-risk map published by the Secretariat of Water Resources of Salta province (Secretaría de Recursos Hídricos), low As concentrations for the Lerma valley are also observed (Hoyos, 2013). Moreover, a study of metabolism of inorganic As in children comparing the villages of San Antonio de los Cobres (Altiplano-Puna plateau), Taco Pozo (Chaco-Pampean plain) and Rosario de Lerma (Lerma valley), highlight the difference in As concentrations and health effects among the regions (Concha et al., 1998). The group of children from Rosario de Lerma was selected as a reference group due to their low As intake (0.65 µg/L of As in drinking water), while children form San Antonio de los Cobres, and Taco Pozo (>200 µg As/L in drinking water), had the highest concentration of As in blood and urine ever recorded for children (on average 9 µg/L for blood, and 380 µg/L for urine) (Concha et al., 1998). The aim of this study is to analyze possible geological, structural, sedimentary, hydrological and geochemical, processes that favor low As concentrations in the Lerma valley in a regional context of high As. n order to attain that goal, local and regional factors and processes are analyzed. Among them, the existing data related to the aquifer composition, the origin of the sediments, the geological and structural evolution of the valley, the hydraulics of the aquifer, and the geochemical characteristics of groundwaters. A map of As concentrations in the Lerma valley with data provided by different government offices and from our own sampling work is

also presented. In the world-wide context of increasing population, and demand of water resources, this work highlights the importance of a better understanding of the natural processes that create conditions and reservoirs where good quality of groundwater can be found. This is of high importance in territories such as Argentina with extended regions of high arsenic in groundwater.

2. Geological setting

116

117

118

119

120

- 122 2.1. Stratigraphy of the Lerma valley
- The stratigraphy of the region can be divided in four main sequences (Fig. 2): 1) Early to Middle 123 Cambrian basement (Lerma, Mesón, and Santa Victoria Groups) composed of low grade 124 metamorphic rocks of the Puncoviscana Formation (Turner and Mon, 1979; Escayola et al., 125 126 2011); 2) Cretaceous-Paleogene continental strata with conglomerates, sandstones, mudstones and limestones of the Salta Group rift sequence (Marquillas et al., 2005); 3) Synorogenic 127 Neogene to Pleistocene strata composed of reddish sandstones and mudstones, and brownish 128 129 conglomerates alternated with mudstones of the Guanaco and Piquete Formations (Orán Group), respectively (Gebhard et al., 1974); and 4) Late Quaternary deposits including thick alluvial 130 conglomerates with alternating sandy and muddy layers (La Viña Formation; Gallardo et al., 131 1996). 132
- 133 2.2. Location and formation of the Lerma valley
- The Lerma valley is the easternmost intermontane basin of the geological province of Cordillera
 Oriental, northwestern Argentina (Fig.1). The Cordillera Oriental is limited by the AltiplanoPuna plateau to the west and by the Subandean ranges and Santa Bárbara System to the east
 (Fig.1). Eastwards, the Chaco-Pampean plain represent the foreland basin of the Andes. The

Lerma valley is bounded by uplifted basement-cored thrust sheets; the Mojotoro and Castillejo ranges to the east (2,500 m) and by the Lesser range (4,800 m) and lower elevations (Vaqueros and Altos de la Laguna ranges) to the west (González Bonorino and Abascal, 2012; García et al., 2013). Low-temperature thermochronology indicates that the Mojotoro and Castillejo ranges started to be exhumed by late Miocene times (Pearson et al., 2013) but probably at low rates as there are no sedimentary evidences of the closure of the valley by that time. The growth strata geometries found both sides of the valley in the upper section of the Piquete Formation synorogenic conglomerates are the main evidence for the establishment of this intermontane basin during late Pliocene-early Pleistocene times (Gallardo et al., 1996, Monaldi et al., 2008; González Bonorino and Abascal, 2012; García et al., 2013, 2019).

2.3. Aquifer systems in the Lerma valley

Seven aquifer systems are recognized in the Lerma valley, from north to south these are named: La Caldera, Arenales, Portezuelo, La Isla, Rosario, La Viña and La Florida (Baudino 1996). Each one has distinctive characteristics such as the recharge area, porous media (grain size), and the chemical water type. However, the levels exploited for drinking water and irrigation correspond to the Quaternary sediments of La Viña Formation (Gallardo et al., 1996). The characteristic of this deposit composed of thick alluvial conglomerates with alternating sandy and muddy layers makes it an heterogeneous multilayered aquifer. The thickness of the La Viña Formation in the basin is difficult to calculate because its transitional contact with the Piquete Formation. A maximum thickness of 240 m has been inferred from water wells located some kilometers southward from Medeiros hills, between the Cerrillos San Miguel and the western edge of the basin (Baudino, 1996) and from seismic records (González Bonorino et al., 2003;

Hain et al., 2011). However, most of the drilled wells are around 200 m depth, the wells generally intersect the of different granulometry layers of La Viña Formation.

3. Methodology

- 163 3.1. Data compilation
- Water analyses from wells in the Lerma valley has been compiled in this work. The information
- 165 collected includes data from the Secretariat of Water Resources and Aguas del Norte company
- 166 from Salta province (Table 1, 2 and 3).
- 167 3.1.1 Aguas del Norte company
- 168 This company (public and private capital) is the provider of the drinking water and sanitation
- service of the Salta province. The data obtained correspond to twenty-two (22) well samples of
- the period 2016 (Table 1). The chemical analyses for As, K, and Na were performed in their own
- 171 laboratories with ICP-OES (Inductively coupled plasma optic emission spectroscopy). The
- 172 detection limits for As were variable according to the calibration curves between <0.015 and
- 173 <0.035 mg/L. For these samples, Ca, Mg, and HCO₃ were not analyzed.
- 174 3.1.2. Secretariat of Water Resources
- 175 The Secretariat of Water Resources is the water resources control agency in Salta Province. The
- 176 company Merco Aguas, performs the well drilling service. The chemical analyses obtained from
- this source comprises twenty-eight (28) water samples taken between the periods 2008 to 2017
- 178 from the wells (Table 1). Data of the wells (depth, static level of well, granulometry of the
- productive layers) was also compliled (Table 1 and 3). Each performed well has between 4 and
- 180 11 screens. The screens were mainly situated in the coarse sediments layers of the multilayered

aquifer that were qualitative described during drilling (Table 3). The transmissivity (T) of the wells (Table 3) were calculated in this study with the information of the technical reports of each well using the Jacob method (Cooper and Jacob, 1953). At each well, the chemical analyses correspond to the mix of waters from the different productive layers where the screens were situated (Table 1 and 2). The water analyses were performed in different external laboratories. The method used for As analysis was spectrophotometry with a detection limit of 0.05 mg/L. This detection limit could be considered high, since the recommended value by the WHO is 0.01 mg/L (WHO, 2017). However, it is in the range for local analyses since the permitted value for drinking water in Argentina is 0.05 mg/L (CAA, 2012). Major ions were measured with AAS (Atomic Adsorption Spectrometry) for Na and K with detection limits of 0.5 mg/L. For Ca, Mg, HCO₃, and Cl the method was titration with detection limits of 0.1 mg/L for Ca and Mg, 3 mg/L for bicarbonates and 2 mg/L for chlorine. Finally, SO₄ was determined with turbidimetry with a detection limit of 0.5 mg/L.

3.2. Water sampling (this study)

Fifteen (15) water samples were collected during 2010 from groundwater and surface water in the northernmost Lerma valley (north of the Vaqueros river) (Fig. 2), and are presented in Table1. The samples were taken *in situ*, the wells were pumped 10 minutes before taken the sample. The samples were filtered with Millex-HV-Durapore-PVDF type of 0.45μm pore size. The samples were acidified with HNO₃, and preserved at 4 °C until being analyzed at ActLabs laboratories (Canada). The analytical method was ICP-MS (Inductively coupled plasma - mass spectroscopy) for and As. The detection limit for As was 0.03 μg/L. Cations and anions were determined by titration according to the standards methods described in Eaton et al., (1998).

4. Results

The data compiled and obtained in this study correspond mainly to the center and Northern areas of the Lerma valley (Fig. 3). Data provided by the Secretariat of Water Resources, and Aguas del Norte company show that As concentration in groundwater is mostly below detection limits (0.05 mg/L) (Table 1). In the cases where As is detected, samples labeled as 25 and 68, the concentration vary between 0.01 and 0.022 mg/L respectively (Table 1, Fig. 3).

The samples obtained in this study situated in the northernmost Lerma valley (From the Mojotoro river to the North) show low As concentrations between 0.0001 and 0.004 mg/L in groundwater, and between 0.0004 and 0.001 mg/L in rivers (Table 1). This values are within the permitted range of concentrations for As in drinking water of WHO and CAA.

The data presented in this study is consistent with previous studies carried out by de Sastre et al. (1992) which map shows samples without As in the Lerma valley in contrast to high natural concentration of As in the Altiplano-Puna plateau and the Chaco-Pampean plain regions. In the map of As risk of the Secretariat of Hydric Resources of Salta province, the samples in the Lerma valley have As concentrations < 0.01 mg/L with some samples between 0.01 and 0.03 mg/L (Hoyos, 2013). In a sampling performed during a research of metabolism of As in children from Rosario de Lerma city (Fig. 3), the concentration of As measured in drinking water are around 0.0001 mg/L (Concha et al., 2010).

Regarding to the geochemistry of major ions, most of the waters samples are HCO₃-Ca-Mg type with a normal evolution to HCO₃-Na-K (Table 2, Fig. 4). A sample in the North of the valley has SO₄-Ca as dominant ions (sample 82), which is attributed to dissolution of secondary gypsum present in the sediments of the Orán Group (Hoyos, 2005; Lopez, 2017). The sample 63 which has high SO₄ can also interpreted as more evolved since it is located in the central part of the valley. Baudino (1996) associates the presence of SO₄-Cl type groundwaters in La Viña aquifer

(Southern portion of the valley) with the dissolution of salts present in the Cretaceous sediments 227 of the Salta group formations (Fig. 2). In groundwater the mean pH value is 7.16 with an extreme 228 value of 8.4 also for the sample 82 located in La Caldera aquifer (Table 1, Fig. 3), the mean 229 value for conductivity is 334 µS/cm, with an extreme of 830 µS/cm (sample 19) (Table 1, Fig. 230 3). In rivers the mean pH value is 6.33 and the mean conductivity is 182 µS/cm, in both cases 231 lower than in groundwater. Previous data from Baudino (1996) indicates pH values between 5.5 232 233 and 7.8 and conductivities in a range of $350 - 850 \mu \text{S/cm}$ for groundwater. The performed wells have static levels between 11 and 114 m depth from the ground surface 234 with a maximum drilled of 260 m depth (Table 1 and 3, Secretariat of Water Resources data). 235 Concerning the lithology of the productive levels of the wells, these are mainly composed of 236 gravels, conglomerates and sands (Table 3). The transmissivity values calculated for the wells 237 238 performed by the Secretariat of Water Resources varies between 0.2 m²/day - 371 m²/day (Table 3). Baudino (1996) indicates medium to very high transmissivity values for the different aquifer 239 systems in the Lerma valley (i.e. Arenales = 250 m²/day; El Portezuelo = 55 - 217 m²/day; La 240

242 5. Discussion

241

- For the low As concentration in the groundwater of the northern Lerma valley we analyze the following possibilities: The absence of geogenic sources of arsenic in comparison to the situation in the Puna and the Chaco-Pampian plain, and the climate contributions to the geological processes, the characteristics of the aquifer, and groundwater geochemistry.
- 247 5.1. Comparison of the Lerma valley with the surrounding areas of high arsenic content

Isla = $140 - 2{,}000 \text{ m}^2/\text{day}$; La Viña = $170 - 280 \text{ m}^2/\text{day}$).

248 5.1.1.Puna

In general, the sources of As in groundwater and drinking water in the Altiplano-Puna plateau 249 are attributed to the weathering of the extensive Cenozoic volcanic rocks (de Sastre et al., 1992; 250 Farías et al., 2009), sulfide deposits, mining wastes, and the discharge of thermal waters (Tapia 251 et al., 2019, this issue; Murray et al., 2019 this issue). 252 The Altiplano-Puna plateau (Fig. 1), has been characterized by active volcanism since, at least, 253 254 Oligocene times. In general, the sources of As in groundwater and drinking water in the 255 Altiplano-Puna plateau are attributed to the weathering of the extensive Cenozoic volcanic rocks cropping out there (de Sastre et al., 1992; Farías et al., 2009). The Cenozoic volcanism, is one of 256 the distinctive features of this region (Ramos, 2017). Volcanism in the Puna has records from 257 ~26 Ma, and it intensified from ~15 Ma to the present (Grosse and Guzmán, 2018). During the 258 Miocene, volcanic calderas generated important volumes of pyroclastic flows deposits 259 260 (ignimbrites), but domes and stratovolcanoes were also important (Grosse and Guzmán, 2018; 261 Guzmán and Montero-López 2015). The Miocene to Quaternary silicic ignimbrite field in the Altiplano-Puna plateau forms one of the largest ignimbrite provinces on Earth (Kay et al., 2010). 262 263 Tapia et al., (2019, this issue) indicates that fluvial sediments originated from Neogene volcanic rocks erosion in the Altiplano-Puna exhibit the highest concentrations of As (351 mg/kg) when 264 compared to fluvial sediments originated from erosion of other geologic periods and/or rock 265 types (112 mg/kg). This last value is already higher than the average of the upper continental 266 crust (5.7 mg/kg; Hu and Gao, 2008) highlighting the Altiplano-Puna anomaly in As, especially 267 related to Neogene volcanic rocks. 268 269 In the Lerma valley there is a lack of Cenozoic volcanism as known in the Puna. Despite the Neogene volcanism had episodes of expansion with volcanic manifestations that reached the 270

eastern edge of the Puna including the Cordillera Oriental geological province (Hongn et al.,

2018), the lack of volcanic rocks is observed in the stratigraphy of the Lerma valley (section 2.1). During the middle to upper Miocene, the Lerma valley was included in the fragmented foreland basin after the exhumation of the Mojotoro and Pascha mountain ranges and between 12 and 8 Ma the fluvial dynamics in the valley was very energetic (conglomerates in the Guanaco and Piquete Formations) (Gallardo et al., 1996, Monaldi et al., 1996; González Bonorino and Abascal, 2012; Pearson et al., 2013) (Fig. 5). The synorogenic Neogene sediments in the Lerma valley are composed of reddish sandstones and mudstones, and brownish conglomerates interbedded with mudstones of the Guanaco and Piquete formations, respectively (Gebhard et al., 1974) with a general lack of volcanic components. The distinctive geomorphology of the Puna with closed and endorreic basin systems make the Puna an isolated geological province where there is a lack of transference of sediments and chemical components such as As outside of the system. This natural characteristic of the Puna preserves the surrounding areas such as the Lerma valley out of the direct transference of As. Instead, in the Puna region, the closed basin and its high evaporation rates produces an enrichment in the depocenter of the basins reflected in high concentration of As in brines, salines, and lakes (Tapia et al., 2019, this issue). Another important geogenic source of arsenic in the Puna are sulfide mines (Tapia et al., 2019, this issue). Sulfide mines (Pb, Zn, Cu, Au, Ag, Sn) in the Puna are in many cases related to the Cenozoic volcanism (Allmendinger et al., 1997; Richards et al., 2006; Caffe and Coira, 2008). These mineral deposits contain As in gangue minerals as well as in ore minerals. Arsenic is present in pyrite, arsenopyrite, and other rich As mineral accessories. Rich As-pyrite and arsenopyrite is also present in epithermal and alluvial rich gold mineralization hosted in marine shales from the Ordovician period (Rodriguez et al., 2010). The natural weathering of these sulfide deposits releases As into the surrounding environment in the Pozuelos basin (Murray et

al., 2019, this issue). Arsenic is also present in the mining wastes of sulfide mining sites that were exploited between the 70' and 90' decades, as well as in the acid mine drainage (AMD) generated by oxidation of the wastes. Examples of inactive mines and AMD generation in the Puna are La Poma treatment plant, La Concordia, and Pan de Azúcar mines, which affect the basins of San Antonio, Tajamar, and Cincel rivers, respectively (Kirschbaum et al., 2012; Murray et al., 2014; Murray et al., 2019 this issue). In the Lerma valley there is a lack of sulfide deposits (García et al., 1997). In comparison with the Puna, the absence of this important geogenic source appears to be another important reason that favors the low arsenic concentration in groundwater and surface water. However, the strong arsenic anomaly related to the sulfide mineralization in the Puna which is also extended to the Bolivian Altiplano, is reflected in the geochemical composition of rainwater in the city of in the Lerma valley. Gaiero et al., (2013) indicates that strong WNW winds from the Altiplano-Puna to the Atlantic Ocean generates deflation and transport of important volumes of dust. Romero et al., (2017) indicate that anomalies of As (0.63 µg/L) and other elements (Ca, Cu, Zn, Sb, and Pb) create a unique signature of rainwater in the Lerma valley. The origin of these metals in the rain water is associated to the rainout of dust that is transported from the Altiplano-Puna plateau to the east, in particular during the dry season where scarce vegetation cover, and strong westerly winds favor the transport of rich As and metallic dust to the east of the Altiplano-Puna. Statistical analyses indicate a direct correlation between As and Ca, Cu, Zn, Sb, and Pb, similar to those observed in the polymetallic ore deposits hosted in the Altiplano-Puna. The Puna region is also characterized by the presence of numerous hot springs (Pesce and Miranda, 2003). Thermal waters are also natural sources of arsenic (Nordstrom 2002; Smedley

and Kinniburgh 2002; Bowell et al., 2014). Despite only few studies measured As in the thermal

waters, some examples can be mentioned in the Argentinian Puna such as the hot springs near San Antonio de Los Cobres (9,490 μ g/L) (Hudson-Edwards and Archer, 2012) and in Vilama (6,170 μ g/L) (Peralta Arnold et al., 2017). El Tatio geothermal site in the Chilenian Puna is also well known by the high arsenic concentrations (45,000 – 50,000 μ g/L) (Webster and Nordstrom 2003). There are no hot spring sites registered for the Lerma valley (Pesce and Miranda 2003).

5.1.2. Chaco-Pampian plain

All areas of the Chaco-Pampean plain are affected in different grade by the presence of As in groundwater, especially the north-northwest and the center-south regions show the highest concentrations (Nicolli et al., 2012). In the Chaco-Salteña plain (northern Chaco-Pampian plain), limited by the Pilcomayo River in the North, the Salado river in the South, and the Paraguay and Paraná rivers in the East (Fig. 1), As concentrations in groundwater vary from 10 to 800 µg/L affecting the peri-urban and rural population (about 311,500 inhabitants). In the town of Taco Pozo As concentrations in the blood of local inhabitants ranged from 9.1 to 11 µg/L after a long-term consumption of groundwater containing >200 µg/L As (Nicolli et al., 2012). The aquifers are hosted in superposed sequences of aeolian loess and fluvial sediments of Tertiary and Quaternary ages. The geogenic source of arsenic are volcanic components present in the aeolian loess and loessoid (reworked loess or loess-like deposits). In the Chaco-Pampean plain the aeolian loess and loessoid cover an area of approximately 500,000 km², with a thickness of 40 – 50 m making it one of the biggest sedimentary basin in the southern hemisphere for loessic or loessoid sediments deposited during the Cenozoic (Zarate 2003).

The beginning of the loessoid sedimentation cycle has been related to a phase of Late Miocene (~10 Ma) orogeny of the Andes resulting in the elevation of the Cordillera, which acted as a barrier to moisture-laden Pacific winds (Zarate, 2003). According to Ramos (1999),

accumulations of synorogenic sediments several hundred meters thick, derived from erosion of the uplifted Cordillera were deposited during the Late Miocene and the Pliocene. Loess deposition was furthermore related to a multistage transport mechanism, involving fluvial and aeolian processes with westerly and southwesterly wind directions, as dominant carriers of the aeolian deposits (Zarate 2003). However, westerly tropospheric winds and northerly winds were also important (Iriondo, 1990, 1997) In the Lerma valley Lapiana et al. (2016) interpreted the lower section of Lumbrera Superior Formation (Eocene-Oligocene) as a pre-Miocene sandy-loess. These deposits with participation of volcanic ashes are located in the southern part of the valley and are thought to be related to the first stage of a proto volcanic arc located to the west. There is not data of wells located in the south area of the valley in this work (Fig. 3). However, in the As-risk map published by the Secretariat of Water Resources, the concentration of As in this region show values <0.01 mg/L (Hoyos, 2013). These Eocene-Oligocene loess sediments are probably deep in the stratigraphic column of the valley, and the exploited groundwater only reaches the Quaternary aquifer sediments. Regarding to the Miocene arsenic-rich loess (as known in the Chaco-Pampian plain), there is no mention of its presence in the Lerma valley. This is probably related to the structural and sedimentary evolution of the valley at that time. During the middle to upper Miocene, the incorporation of the Lerma valley in the fragmented foreland basin established a very energetic fluvial dynamics characterized by conglomeratic deposits of Guanaco and Piquete Formations (Fig. 2 and Fig. 5). This environment was not favorable for the accumulation of thick successions of silty material. This situation was maintained throughout the Pleistocene, when conglomerates of the Calvimonte (conglomerates, sandstones and brown-reddish pellets), La Viña and Portezuelo Formations were deposited (Gallardo et al., 1996). Only towards the end of the

362

Pleistocene (ca. 16 kyr) the sedimentation environment changed to a much less energetic one, controlled by the partial closure of the drainage of the valley towards the foreland that made the accumulation of fine material possible (Fig. 5). The northern Lerma valley is coated by siltysandy sediments with a variable thickness ranging from 2 to 4 meters, and developing soils and representing the arable land of the region. These deposits were studied by García et al. (2019) in the Carabajal farm (west of Rosario de Lerma town) (Fig. 1) obtaining AMS ¹⁴C ages ranging between 9,593 to 10,176 years cal BP and correlating them with the loess of the Urundel Formation (Iriondo, 1997). The stratum type of Urundel formation is located in the Chaco-Salteña Plain with a maximum thickness of 16 meters and an age of 16 kyr (14C, Iriondo, 1990, 1997). It is composed of quartz (60/80%), hornblende, altered plagioclases, no volcanic glass shards, and has an origin in the Bolivian Andes rocks during glaciations periods (Iriondo, 1990, 1997). In the Lerma valley the thickness of these fine deposits increases southwards. In the extreme north of Finca Carabajal it is 2-3 meters thick including some soil levels, while in Guachipas-La Viña area, it reaches 5-6 meters, and the original sedimentary structures (lake environment) are better preserved. There is not data about the presence/absence of volcanic ash or arsenic content for this new loess.

380 5.2. Influence of weather, aquifer composition and granulometry, and groundwater 381 geochemistry

The Lerma valley is characterized by a meso-thermal and sub-humid climate with dry season and little annual change in temperature (Burgos and Vidal, 1951). The wet season occurs during the austral summer from November to March. In contrast with the Chaco-Pampian plain and the Puna regions with arid or semiarid regimes and a low annual rainfall and a high evaporation (Nicolli et al., 2012; Tapia et al., 2019) The Lerma valley has an average annual precipitation

between 700-800 mm (Romero Orué et al., 2017). Most of the recharge of the exploited aquifers occurs due to infiltration of rainfall (Baudino, 1996). The infiltration of rainwater measured in La Caldera aquifer in the North of the valley (where samples with < 0.01 mg/L of As were obtained) is high > 60% and contribute to fresh water recharge (López, 2017). In The Chaco-Pampian plain and the Puna, climate plays an important role, affecting dissolved As through evaporation during the dry season (Nicolli et al., 2012; Tapia et al., 2019 this issue; Murray et al., 2019 this issue). Moreover, in those regions, poorly drained flat plains, lowlands and closed depressions that concentrate shallow unconfined groundwater, of form salars depressions, are affected by a slow drainage and a delayed runoff, or closed systems making them preferential landforms for Asaccumulation (Nicolli et al., 2012, Tapia et al., 2019 this issue; Murray et al., 2019 this issue). The conductivities of the groundwater $(350 - 850 \mu s/cm)$, the pH (5.5 - 7.8), and the composition of major ions (HCO₃-Ca-Mg with normal evolution to HCO₃-Na) (Table 1, Fig. 4) indicates that these groundwaters are little evolved as well as indicated by Baudino (1996) who also suggest a little time of circulation and/or circulation by inert materials. In the Lerma valley, the most productive levels of the multilayered aquifer are placed in Quaternary layers composed of fine gravels and sands to fine sands Baudino (1996). The grain size favor high porosity, permeability and circulation of the groundwater with medium to high transmissivity values which implies low residence times (Table 3). Another important fact for lowe As in groundwaters is that the aquifer sediments in the Lerma valley have an origin in the erosion of the early to middle Cambrian basement composed of low grade metamorphic rocks of the Puncoviscana Formation, the Cretaceous-Paleogene continental strata with conglomerates, sandstones, mudstones and the limestones of the Salta Group rift with a lack of geogenic arsenic sources (sections 5.1.1 and 5.1.2). An example of similar free arsenic

407

408

conditions can be observed in the Chaco-Pampean plain in some specific environments where low As concentration in groundwater can be found. These natural free arsenic conditions are created by the presence of fluvial sediments layers interbed in the aeolian loess deposits. The fluvial sediments do not contain arsenic and contribute to higher porosity and permeability and circulation of the groundwater. In the paleo-channels of the Cuarto river located in Córdoba Province, Giacobone et al. (2018) describe a scarcely evolved groundwater of HCO₃-Ca to HCO₃-Na type. These waters result from high velocities flows that circulate in coarse fluvial sediments composed of inert mineralogy with low interaction time resulting in a low As (1 - 10)μg/L) concentrations in groundwater. In the south of Córdoba province, Becher Quinodoz and Blarasin (2014) described fresh HCO₃-type groundwater in active dunes sediments that conform a fluvial-aeolian environment linked to local flows with current precipitation recharge. In this case, As concentrations are still above the limits for human consumption, but with lower values than in the surrounding loessoid environments, where high concentrations of As are related to brackish-salty groundwater (SO₄-Cl type), as the result of long existing regional flows and long interaction time with the loess. In the Lerma valley, even if sediments with As minerals in very small quantities were present in the silty-sandy sediments comparable to Urundel Formation, the geochemical environment most probably do not entirely contribute to put As in solution. If volcanic glass with As were present in the loess, the pH range of the groundwater (5.5 - 7.8) is not high enough to favor the processes of dissolution of volcanic glass and As leaching as described in the Chaco-Pampian plain where grundwaters with pH from near 7.00 up to 9.24 favor that process (Nicolli et al., 2012).

Moreover, under the circum-neutral pH of the Lerma valley groundwater if As is present, it is favorable adsorbed onto the surface of Al- Fe- and Mn-oxides and hydroxides (such as hematite, goethite, Fe(OH)₃(a), magnetite, and gibbsite) that could precipitate in the aquifer and be removed from groundwater. In the Chaco-Pampian plain the oxidation-reduction (redox) potential phenomena is observed as mechanism of regulation of As concentration (Nicolli et al., 2012). There is no data of redox potential for the compiled samples of the Lerma valley, which is of high importance to understand the mobility of As. In the case of oxidative conditions, which is most likely possible in the coarse productive layers, As sorption processes by secondary Al- Feand Mn-oxides and hydroxides minerals will be enhanced. However, coarse aquifer materials have less surface area for adsorbing arsenic, and thus less arsenic available for potential mobilization (Erickson and Barnes, 2005). If As is present in the loess sediments of the Lerma valley (i.g. the loess comparable to Urundel Formation) and groundwaters were under reductive conditions, the release of As to groundwater could be favored via reductive dissolution of metal hydroxides and reductive desorption. This process has been observed in the fine sediments aguitards layers of the multilayered glacial aguifers described by Erickson and Barnes (2005); Thomas et al. (2008); and Nicholas et al. (2017) in the Northeast of United States. However, in these environments, arsenic was also observed to be removed from groundwater by precipitation of sulfide minerals, which occurs under sulfate-reducing conditions (Thomas et al., 2008). All these examples show that oxidation-reduction (redox) potential is an important factor to have in account to understand As mobility, and should be analyzed with more detail in the Lerma valley. Finally, the characteristics of the wells construction with several screens situated in the coarse sediments layers can also favor to low As concentration in the Lerma valley. That is the case in multilayered glacial aquifers where construction practices such as exploiting a thick, coarse

aquifer and installing a long well screen yield good water quantity for public water system wells (Erickson and Barnes, 2005). Moreover, in that environment wells with long screens set at a distance from an upper confining unit are at lower risk of exposure to geochemical conditions conducive to arsenic mobilization via reductive mechanisms such as reductive dissolution of metal hydroxides and reductive desorption of arsenic. Exploiting the coarse sediments in the Lerma valley seems to ensures extraction of the good quality groundwaters. However, the wells with higher As values of 0.01 and 0.02 mg/L (wells 25 and 68) could indicate that may exist groundwater with higher As content (released either by local higher pH or reductive conditions). Therefore, a better understanding of the redox conditions, mineralogy and geochemistry of the sediments (i.e. the loess present in the Lerma valley) and a better correlation between the wells characteristics and the exploited levels will be necessary to understand the processes that increase As concentrations in the mentioned wells.

467 5.3. Other similar intermountain valleys in Northwest Argentina

Low As concentrations in surface and groundwaters are also reported in the Sub Andine valleys located to the north of the Lerma valley in the Cordillera Oriental and Subandinas geological provinces where As range between 6 – 10 µg/L (de Sastre et al., 1992; Farías et al., 2009). Some examples are Las Maderas, Los Alisos, and La Cienaga dams; groundwater in Jujuy and Palpalá cities; and Xibi-Xibi, Perico, and del Molvado rivers (Farías et al., 2009). Even though Cordillera Oriental and Subandinas geological provinces have different structural and geomorphological characteristics, their intermountain valleys share similar conditions for the deposition of Mid-late Miocene to Quaternary sediments (Ramos, 2017). Further understanding of the natural processes that have created these natural reservoirs of low As concentration and how similar or different are with respect to the Lerma valley is necessary.

The concentrations of As in Lerma valley are within the recommended values for drinking water in Argentina (0.05 mg/L) and are remarkably lower in comparison to the Puna and the Chaco-Pampian plain surrounding regions. Low As concentration in the groundwater of the Lerma valley can be attributed to a combination of natural processes related to the geochemistry of groundwater (mainly HCO₃-Ca type, near neutral pH, and most probably oxidative conditions), the absence of the typical geogenic sources (Cenozoic volcanism, sulfide deposits, thermal water sources, and the rich-As volcanic ash Miocene loess), high fresh rain water infiltration rates, low residence times, and the characteristics of the wells construction (with screens settled in coarse inert sediments layers). The absence of the Mio-Pliocene loess was favored by the high-energy sedimentary environments that characterized this region during that time. However, a better understanding of the redox conditions, mineralogy, and geochemistry of the sediments (i.e. the loess present in the Lerma valley) with a better correlation between the wells characteristics will be necessary to understand the wells with the higher As values (0.01 and 0.02 mg/L). The geological, geochemical, and tectonic characteristics of the Lerma valley could be extrapolated to other similar valleys in NW of Argentina such as the Cordillera Oriental and Subandinas geological provinces. In the context of increasing population, and demand of water resources, a better understanding of the natural processes that create reservoirs for groundwater of good quality can be useful as an exploration tool. This is of high importance in territories with high As concentration in groundwater such as Argentina.

Acknowledgments

The authors want to thanks to Aguas del Norte company and Secretaría de Recursos Hídricos form Salta province that provided part of the data used in this research. We also appreciated the helpful discussions with Dr. Fernando Hongn and the contribution of anonymous reviewers that highly improved this manuscript. This research was funded by the Argentinians projects PICT-

FONCYT 2015-1069, CIUNSA N° 1859 and PIP-CONICET N° 2011-01-00189.
