25 Abstract

26 Among dinoflagellates responsible for benthic harmful algal blooms, the genus *Ostreopsis*
27 primarily described from tropical areas has been increasingly reported from subtropical and
28 temperate areas worldwide. Several species of this toxigenic genus produce analogs of palytoxin,
29 thus representing a major threat to human and environmental health. The taxonomy of several
30 species needs to be clarified as it was based mostly on morphological descriptions leading in some
31 cases to ambiguous interpretations and misidentifications. The present study aims at reporting a
32 benthic bloom that occurred in April 2019 in Tahiti island, French Polynesia. A complete taxonomic
33 investigation of the blooming *Ostreopsis* species was realized using light, epifluorescence and field
34 emission electron microscopy and phylogenetic analyses inferred from LSU rDNA and ITS–5.8S
35 rDNA regions. Toxicity of a natural sample and strains isolated from the bloom was assessed using
36 both neuroblastoma cell-based assay and LC-MS/MS analyses. Morphological observations showed
37 that cells were round to oval, large, 58.0–82.5 μm deep (dorso-ventral length) and 45.7–61.2 μm
38 wide. The cingulum was conspicuously undulated, forming a ‘V’ in ventral view. Thecal plates
39 possessed large pores in depressions, with a collar rim. Detailed observation also revealed the
40 presence of small thecal pores invisible in LM. Phylogenetic analyses were congruent and all
41 sequences clustered within the genotype *Ostreopsis* sp. 6, in a subclade closely related to sequences
42 from the Gulf of Thailand and Malaysia. No toxicity was found on the field sample but all the
43 strains isolated from the bloom were found to be cytotoxic and produced ostreocin D, a lower
44 amount of ostreocins A and B and putatively other compounds. Phylogenetic data demonstrate the
45 presence of this species in the Gulf of Thailand, at the type locality of *O. siamensis*, and
46 morphological data are congruent with the original description and support this identification.

51 **1. Introduction**

52 Tropical regions are endemically affected by outbreaks of ciguatera fish poisoning (CFP)
53 linked to the proliferation of the toxic dinoflagellate genus *Gambierdiscus* R.Adachi & Y.Fukuyo
54 (Berdalet et al., 2017; Chinain et al., 2020). Other benthic dinoflagellate genera, such as *Ostreopsis*
55 Johns. Schmidt, *Prorocentrum* Ehrenberg and *Coolia* Meunier, have been shown to regularly co-
56 occur with *Gambierdiscus* in epiphytic/benthic assemblages in tropical areas (*e.g.*, Besada et al.,
57 1982; Chinain et al., 2016; Smith et al., 2017). The genus *Ostreopsis* was originally described from
58 plankton samples from the Gulf of Thailand (Schmidt, 1901), but it received little attention for
59 about 80 years. It gained a new interest when Fukuyo (1981) conducted a survey of benthic
60 dinoflagellates potentially responsible for CFP in islands of the Pacific region. Since this date, the
61 number of described *Ostreopsis* species has continued to increase, with frequent occurrence reports
62 from tropical ciguateric areas (Bagnis et al., 1985; Carlson and Tindall, 1985; Ballantine et al.,
63 1988).

64 Although the first report of an *Ostreopsis* bloom in the Mediterranean by F.J.R. Taylor can be
65 dated back to 1972 (GEOHAB, 2012), since the 90s, blooms have become more frequently
66 mentioned along the Mediterranean Sea, Atlantic, New Zealand, Japanese, Russian and Australian
67 coasts (*e.g.*, Tognetto et al., 1995; Vila et al., 2001; Mangialajo et al., 2008; Shears and Ross, 2009;
68 Selina and Orlova, 2010; Cohu et al., 2011; Sato et al., 2011; Parsons et al., 2012; David et al.,
69 2013; Accoroni and Totti, 2016; Verma et al., 2020). The apparent expansion of *Ostreopsis* for the
70 past 30 years is mainly attributable to the species *O. cf. ovata* and *O. cf. siamensis* in temperate
71 (Accoroni and Totti, 2016) and subtropical areas (Nascimento et al., 2012; Tibiriçá et al., 2019;
72 Verma et al., 2020). *Ostreopsis* blooms have been consistently described as forming an apparent

73 brownish mucilaginous and filamentous matrix covering macroalgae or substratum, sometimes
74 extending over large areas, and which can detach and float freely (Vila et al., 2001; Shears and
75 Ross, 2009; GEOHAB, 2012; Tibiriçá et al., 2019).

76 The massive blooms of the genus *Ostreopsis* cause threats to human health in certain
77 urbanized, temperate areas and are responsible for health concerns and beach closures (Tester et al.,
78 2020). Respiratory illness and skin irritation have been associated with *Ostreopsis* blooms in the
79 Mediterranean and its adjacent seas (*e.g.*, Tichadou et al., 2010; GEOHAB, 2012; Berdalet et al.,
80 2017). These effects have been attributed to analogues of palytoxin (PITX), a highly toxic and water
81 soluble molecule originally described from the zoanthid *Palythoa toxica* (Moore and Scheuer,
82 1971). A considerable number of analogs have been identified in *Ostreopsis* spp., such as ostreocins
83 (OSTs) (Usami et al., 1995; Terajima et al., 2018a) and ovatoxins (OvTXs) (Ciminiello et al., 2008;
84 Tartaglione et al., 2017). However, the effects of these molecules on human health still need to be
85 investigated more deeply (Tester et al., 2020). Indeed, OvTXs were detected in aerosols (Ciminiello
86 et al., 2014) and can also be bio-accumulated in marine organisms (Amzil et al., 2012; Brissard et
87 al., 2014). In tropical areas, fatalities have been attributed to PITX-like molecules, and it has been
88 suggested that *Ostreopsis* spp. are involved in a particular type of poisoning called clupeotoxism
89 (Alcala et al., 1988; Onuma et al., 1999) which is still controversial (Randall, 2005). Besides effects
90 to humans, blooms have caused mortality among benthic invertebrates such as sea urchins in Brazil
91 (Ferreira, 2006) and New Zealand (Shears and Ross, 2009). Moreover, a negative impact of
92 *Ostreopsis* spp. has been shown on several benthic organisms (Guidi-Guilvard et al., 2012; Neves et
93 al., 2018; Pavaux et al., 2019), which may lead to modifications of benthic communities in the
94 concerned areas.

95 Toxicity of *Ostreopsis* species has been shown to vary within and among species, from non
96 toxic to producing up to 468 pg [total OvTXs] per cell (*e.g.*, Nascimento et al., 2012; Tartaglione et
97 al., 2017). In addition to natural variability, some contradictory reports of their toxicity and toxin

98 content are likely due to the existence of cryptic species or possible misidentifications (Tester et al.,
99 2020). Studies aiming at collecting physiological and toxicological data from genetically identified
100 isolates of *Ostreopsis* species are critically needed (Tester et al., 2020). As emphasized by many
101 authors (Rhodes, 2011; Parsons et al., 2012; Hoppenrath et al., 2014; Tester et al., 2020), the
102 taxonomy of *Ostreopsis* genus is problematic and requires a major revision. One of the challenges is
103 to reconcile traditional taxonomy based on morphological features and molecular taxonomy that has
104 allowed to unveil several genotypes not yet fully characterized (Sato et al., 2011; Chomérat et al.,
105 2019). Hence, resolving the issues of *Ostreopsis* taxonomy is fundamental for efficient monitoring
106 of their distribution trends and to interpret environmental influences on their population dynamics
107 in a context of climate change (Berdalet et al., 2017; Tester et al., 2020).

108 The diversity of *Ostreopsis* has been only poorly studied in the islands from the mid-Pacific,
109 including French Polynesia since it was not considered problematic contrary to *Gambierdiscus*. To
110 date, only two species have been reported, namely *O. ovata* Y.Fukuyo and *O. lenticularis* Y.Fukuyo
111 (Fukuyo, 1981). Bagnis et al. (1985) investigated the population dynamics of three benthic
112 dinoflagellates in French Polynesia and suggested that *O. lenticularis* became the major component
113 of the reef dinoflagellate community following *Gambierdiscus* bloom. Moreover, in contrast with
114 *Gambierdiscus*, *O. lenticularis* was suspected not to be toxic (Bagnis et al., 1985), which has been
115 fully confirmed recently (Chomérat et al., 2019). Except for the first observations by Fukuyo (1981)
116 in French Polynesia and New Caledonia, no additional data concerning *O. ovata* have been reported
117 from French Polynesia and this species definitely deserves more thorough investigations. More
118 recently, Rhodes et al. (2017) identified another genotype, *Ostreopsis* sp. 3, in the poorly studied
119 Kermadec Islands (a New Zealand territory), 1000 km northeast of New Zealand, but genetic data
120 also showed its presence in the Cook Islands which are closer to French Polynesia. By contrast, in
121 the western Pacific, Sato et al. (2011) made a remarkable study and identified a wider diversity,
122 including several undescribed genotypes that still need to be assigned taxonomically.

123 In April 2019, a very unusual benthic bloom was detected during a field survey conducted on
124 the western coast of Tahiti Island. Preliminary observations revealed it was dominated almost
125 exclusively by *Ostreopsis* cells, although some pennate diatoms were also visible. The present study
126 provides a taxonomic identification of the *Ostreopsis* species responsible for the bloom and
127 describes its toxic potential. To this end, scanning electron microscopy (SEM) observations
128 combined with phylogenetic analyses were performed on field samples. In addition, the toxic status
129 of the wild bloom sample and monoclonal cultures further established from this bloom was assessed
130 using the mouse neuroblastoma cell-based assay (CBA-N2a) in parallel with liquid chromatography
131 coupled with tandem mass spectrometry (LC-MS/MS) to identify the toxic compounds, if any.

132

133 2. Material and methods

134 2.1 Sampling area and description of the wild bloom

135 The benthic bloom described in this study occurred at Toaroto Beach (17.64046°S;
136 149.610259°W) in the municipality of Punaauia, Tahiti Island (Fig. 1). It was discovered on April
137 2019, at the end of the rainy season, on the reef located *ca.* 20 m off the Toaroto Beach. It covered
138 the entire reef over a radial of *ca.* 30 m between the shore and the barrier reef, and presented as a
139 thin, filamentous and mucilaginous brownish mat covering abiotic (*e.g.*, bedrock) and biotic
140 substrates including macroalgae (*e.g.*, *Turbinaria ornata*, *Dictyota bartayresiana*), sponges and
141 corals (*e.g.*, *Porites*, *Pocillopora*) (Fig. 2A–C).

142 The bloom was sampled between 0-2 m depth using two classical methods: cells found floating
143 on the surface attached to mucus threads were skimmed using a dip net (100 µm porosity)
144 positioned facing the current. Epiphytic cells of *Ostreopsis* were dislodged and collected from *T.*
145 *ornata* by gently shaking macroalgal samples nearby a dip net. The sea water temperature at the
146 time of sampling was 27 °C. Both samples were then pooled and transferred into a 1 L double-cap

147 container. Three sub-samples were taken for further *in vitro* culturing assays, SEM observations
148 (preserved in 2.5% glutaraldehyde) and DNA amplification and sequencing (preserved in Lugol's
149 solution), respectively. The remaining bloom sample was freeze-dried for 20 h at -20°C, 1 mbar,
150 then 4 h at -60°C, 0.01 mbar (Martin Christ, Beta 1-8 LDplus). The resulting dry sample was
151 weighted (11 g) and stored at 4°C until further extraction.

152

153 2.2 *In vitro* culturing of *Ostreopsis*

154 *Ostreopsis* clonal cultures were established from single cells isolated from field samples of the
155 bloom, using an inverted microscope. They were routinely maintained in Fernbach flasks seeded
156 with 100 mL of cell inoculum and 1 L of f10k enriched natural seawater (NSW) culture medium
157 (Holmes et al., 1991), at 26 ± 1 °C, a salinity of 36, under 60 ± 10 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$ irradiance,
158 in a 12 h light:12 h dark photoperiod. After a growth period of ≈ 35 days, cells were harvested at
159 their stationary growth phase by filtration and centrifugation. Cell counts were achieved using a
160 Coulter counter (Beckman) and the resulting cell pellets freeze-dried and weighted for toxicity and
161 toxin analyses.

162 Eight strains were analyzed in the present study (PNA19-1 to -4 and PNA19-6 to -9). These
163 strains are part of the algal collection of the Laboratory of Marine Biotoxins of the Institut Louis
164 Malardé (Tahiti, French Polynesia), where cultures are deposited. All the following experiments
165 were conducted on non-axenic acclimated batch cultures.

166

167 2.3 *Microscopy observations*

168 Light microscopy (LM) observations were conducted on live cells of 5-10 days of age using a
169 Leica DMLB microscope (Leica, Wetzlar, Germany) equipped with a D850 DSLR camera (Nikon,
170 Tokyo, Japan). Epifluorescence images were realized with a Universal microscope (Zeiss,

171 Oberkochen, Germany) after staining cells with Solophenyl Flavine 7GFE500. A small drop of the
172 stock solution (0.1% w/v) was added to a drop of water containing isolated cells fixed in Lugol's
173 solution. Epifluorescence observations were carried out using a FITC (blue excitation/green
174 emission) filter set (Chomérat et al., 2017).

175 Cells isolated from the bloom were observed using field-emission SEM (FE-SEM). Prior to
176 scanning electron microscopy, cells fixed in 2.5% glutaraldehyde from the field sample were first
177 isolated using a micropipette, rinsed several times in distilled water and processed according to
178 Chomérat and Couté (2008). Briefly, cells were trapped between two polycarbonate membranes
179 (Isopore RTTP, pores 1.2 μm , Merck Millipore, Molsheim, France) attached with a paper clamp, so
180 they can be processed with minimum losses. Dehydration was carried out in ethanol baths of 15%,
181 30%, 50%, 70%, 95% vol. ethanol (about 20 min in each bath), and several baths of absolute
182 ethanol (100%) and then cells were critical point dried using an EMS 850 (Electron Microscopy
183 Sciences, Hatfield, PA, USA) critical point drier. Dried membranes were then mounted onto 12 mm
184 SEM stubs using carbon adhesive and coated with gold using a Cressington 108Auto (Cressington,
185 Watford, UK) sputter coater. Cells were then observed using a FE-SEM Zeiss SIGMA 300 (Carl
186 Zeiss Microscopy GmbH, Jena, Germany). Measurements were realized directly with the
187 microscope or on digital images using ImageJ software (Rasband, 1997). For measurements of the
188 curved apical pore plate (Po), the arc length was measured in apical view.

189

190 *2.4 DNA amplification and sequencing*

191 For DNA amplification, direct cell PCR approach was applied using single cells from bloom
192 sample fixed in Lugol's solution, or a few cells from the cultures in early exponential growth phase
193 preserved in ethanol 70%. Under the inverted microscope, fixed cells were pipetted and rinsed in
194 several drops of nuclease-free distilled water, and then transferred into a 0.2 mL PCR tube.

195 Due to the low amount of DNA, a first round of PCR was realized using ITS-FW (Nézan et al.,
196 2014) and Dino-RB (5'-TTGGGACTTCTGCGTCTCAA-3', this study) primers , allowing the
197 amplification of the ITS1–5.8S rDNA region (ITS1–5.8S–ITS2), LSU rDNA D1–D3 and D8–D10
198 regions. A second round of PCR (nested PCR) was realized using 1 µl of the amplicon produced in
199 the first step as template. Primers used for the second amplification are given in Nézan et al. (2014)
200 and Chomérat et al. (2019). PCR reactions were realized in 20 µL using KOD Hot Start Master Mix
201 (Novagen-Merck KgaA, Darmstadt, Germany), according to the manufacturer's instructions. For
202 both PCR rounds, the cycling conditions comprised an initial 2 min heating step at 95°C to activate
203 the polymerase, followed by 30 cycles of 95 °C for 20 sec, 50 or 56 °C depending on primers, for
204 20 s, and a final extension at 70 °C for 150 sec. For Prior to sequencing, amplicons were visualized
205 on an agarose gel after electrophoresis and the positive samples were purified using the ExoSAP-IT
206 PCR Product Cleanup reagent (Affymetrix, Cleveland, OH, USA).

207 For sequencing of the amplicon generated at the second PCR round, the Big Dye Terminator
208 v3.1 Cycle Sequencing Kit (Applied Biosystems, Tokyo, Japan) was used after removal of the
209 primers and excess dye-labeled nucleotides using the Big Dye X-terminator purification kit
210 (Applied Biosystems, Foster City, CA, USA). Sequencing products were run on an ABI PRISM
211 3130 Genetic Analyzer (Applied Biosystems). Forward and reverse reads were obtained.

212

213 *2.5 Alignment and phylogenetic analyses*

214 For the three genetic markers studied, parameters of the matrices used for phylogenetic
215 analyses are given in Supplementary Table S1. Alignments were realized using the MAFFT
216 algorithm with the selection of the q-ins-i strategy (Kato and Standley, 2013).

217 Prior to phylogenetic analyses, the search for the most appropriate model of sequence evolution
218 has been performed using jModeltest2 v. 2.1.7 (Darriba et al., 2012). Two methods of phylogenetic

219 reconstruction were used. Maximum Likelihood analysis (ML) was performed using PHY-ML v. 3
220 software (Guindon et al., 2010), and a bootstrap analysis (1000 pseudoreplicates) was used to assess
221 the relative robustness of branches of the ML tree. Bayesian Inference analysis (BI) was realized
222 using MrBayes 3.1.2 software (Ronquist and Huelsenbeck, 2003). Parameters of the models for ML
223 and BI analyses are given in Supplementary Table S1.

224 Genetic distance (uncorrected genetic p distance) calculations among and within the *Ostreopsis*
225 clades were estimated from the LSU rDNA D8–D10, LSU rDNA D1–D3 and ITS–5.8S rDNA
226 matrices used for phylogenetic analyses, using the p -distance model in MEGA X: Molecular
227 Evolutionary Genetic Analysis across Computing Platforms v. 10.0.5 (Kumar et al., 2018). Gaps
228 and missing data were treated with the pairwise deletion option in MEGA X.

229

230 2.6 Toxicity analysis

231 2.6.1 Extraction procedures

232 The field sample (bloom) and eight clonal strains of *Ostreopsis* were further tested for their
233 toxicity. Aliquots of 15 mg of freeze-dried cultured cell pellets corresponding to a total cell biomass
234 $\approx 10^6$ cells, and 50 mg of the freeze-dried field sample were extracted under sonication in 670 μ L of
235 methanol (MeOH)/water (1:1, v/v) for 15 min in an ice bath. Once cell disruption was completed,
236 the sample was centrifuged at 10,000 g at 4 °C for 10 min. The resulting supernatant was carefully
237 recovered and the cell pellet extracted again in 670 μ l of MeOH/water (1:1, v/v). Both supernatants
238 were pooled (total volume recovered: ≈ 2 mL) and centrifuged at 10,000 g at 4 °C for 15 min.
239 Finally, a 1.6 mL aliquot was sampled, evaporated to dryness at room temperature under nitrogen
240 flux, and weighed. Supplementary Table S2 gives dry extract weight (DEW) obtained for each dry
241 extract following this extraction step. Each dry extract was resuspended in MeOH/water (1:1, v/v)
242 at a concentration of 10 mg·mL⁻¹ and stored at -20°C until tested for further toxicity analyses.

243

244 2.6.2 Neuroblastoma cell-based assay (CBA-N2a)

245 The toxicity of *Ostreopsis* samples was assessed using the CBA-N2a following the protocol
246 previously described in Chomérat et al (2019). First, a qualitative screening was performed by
247 testing each extract at a unique concentration of 47,619 ng·mL⁻¹ (corresponding to 10 µL of a 1:10
248 dilution of each dry extract stock solutions) in the absence vs. presence of 200 µM ouabain (final
249 concentrations) (O⁻ and O⁺ conditions, respectively), each point run in triplicate in a single
250 experiment. Next, quantitative CBA-N2a analyses were conducted only on extracts showing a
251 cytotoxic activity. For each toxic extract, eight distinct concentrations ranging from 8.7 to 19,047.6
252 ng·mL⁻¹ for cell samples and 4.4 to 9,523.8 pg·mL⁻¹ for a standard of PITX (Wako, Ref. 165-26141)
253 were tested in triplicate in three independent experiments, to obtain full dose-response curves.
254 Following a 20–22 h incubation period, cell viability was assessed using 3-(4,5-dimethylthiazol-2-
255 yl)-2,5-diphenyl tetrazolium bromide (MTT) assay according to Darius et al. (2018). Resulting
256 coloration was measured at 570 nm on a plate reader (iMark Microplate Absorbance Reader,
257 BioRad, Marnes-la-Coquette, France). One microplate in three independent experiments were
258 examined for the purpose of inter-assay variability comparison, allowing the calculation of
259 coefficient of variation (CVs).

260 For each quantitative CBA-N2a, the absorbance data for PITX standard and cell extracts were
261 fitted to a sigmoidal dose-response curve (variable slope) based on the 4-parameter logistic model
262 (4PL), allowing the calculation of EC₅₀ values defined as the concentration inducing 50% of
263 viability between the top and bottom of the curve, using Prism v8.1.2 software (GraphPad, San
264 Diego, CA, USA). The toxicity (T) of *Ostreopsis* sp. 6 samples (expressed in pg PITX equiv. cell⁻¹)
265 was estimated using the following formula: $T = (EC_{50,PITX}/EC_{50,sample}) \times (DEW/\text{total biomass}$
266 analyzed).

267

268 *2.6.3 Liquid Chromatography coupled with tandem Mass Spectrometry (LC-MS/MS)*

269 Aliquots of the aqueous methanolic extracts from the 8 strains and 1 field sample used for the
270 CBA-N2a test were screened for the presence of PITX and related known structural analogues at
271 Ifremer Phycotoxins Laboratory (Nantes, France). After resuspension in MeOH 50%, extracts were
272 ultrafiltered (0.20 μm , Nanosep MF, Pall, Mexico). LC-UV-MS/MS analyses using the MRM
273 (Multiple Reaction Monitoring) mode of acquisition were conducted as in Chom rat et al. (2019)
274 with minor modifications. In total, two LC-MS/MS and one LC-UV-MS/MS methods were used to
275 detect PITX, 42-OH-PITX, 12 OvTXs (-a to -k), 4 OSTs (OST-A, -B, -D and -E1), 3 McTXs (A to
276 C) and OTX-1 and -3.

277 A focus was performed on OSTs and the following precursors giving fragment A (m/z 313.2)
278 were added: m/z 1317.2; 1309.2; 1300.2 and 878.5; 873.1; 867.1 (corresponding to $[\text{M}+2\text{H}-\text{H}_2\text{O}]^{2+}$
279 and $[\text{M}+3\text{H}-\text{H}_2\text{O}]^{3+}$ ion species for OST-A/-B, -D and -E1, respectively).

280 To confirm the identity of OSTs, we used both the EPI (Enhanced Product Ion) mode of
281 acquisition on the $[\text{M}+2\text{H}-\text{H}_2\text{O}]^{2+}$ and $[\text{M}+2\text{H}]^{2+}$ precursors (CE = 20 eV) and LC-HRMS (High
282 Resolution Mass Spectrometry) as in Georges des Aulnois et al. (2019).

283 **3. Results**284 *3.1 Morphology of Ostreopsis cells*

285 Microscope observations of fresh samples revealed the bloom was dominated by *Ostreopsis*
286 cells, although assemblages of diatoms dominated by *Haslea* sp. were also visible (Fig. 2D).

287 The shape of *Ostreopsis* cells from strain PNA19-9 and wild sample varied from typical tear-
288 shaped (pointing ventrally) to almost round in apical and antapical views (Figs 3A–B, D–E, 4A–D).
289 They were biconvex, flattened and undulated, with the cingulum slightly sigmoid in lateral view

290 (Figs 3C, G, H, 4E–I). Cells from wild sample were 58.0–82.5 μm (mean 71.5 μm ; s.d. 4.5 μm , $n =$
 291 30) deep (dorso-ventral length, DV) and 45.7–61.2 μm (mean 51.2 μm ; s.d. 3.3 μm , $n = 25$) wide
 292 (width, W). The DV/W ratio was 1.1–1.5 (mean 1.4; s.d. 0.1, $n = 23$).

293 The thecal plate pattern was APC 3' 7" 6c 4's 5''' 2''', and thecal plates were clearly visible both
 294 with light epifluorescence microscopy on strain PNA19-9 (Fig. 3D–I) and SEM on the field sample
 295 (Figs 4A–I, 5A–J). The apical pore complex (APC) consisted in a narrow, elongated and slightly
 296 curved Po plate (Figs 5A–B) bearing a slit and two rows of pores. It was located parallel to the left
 297 mid-lateral to dorsal cell margin. The Po plate was 15.6–19.5 μm (mean 17.5 μm ; s.d. 1.1 μm , $n =$
 298 14) long. Related to the DV length (depth) of the cell, the Po/DV ratio was 0.22–0.27 (mean 0.25;
 299 s.d. 0.02, $n = 14$). The first apical plate (1') was hexagonal, elongated, located mostly on the left
 300 side of the cell (Figs 3D, 4A, C). On its dorsal part, it is slightly protruding over the APC (Figs 4A,
 301 5A–B). The second apical plate (2') was narrow and elongated, and located below the APC,
 302 extending dorsally the Po plate and reaching the precingular plate 4" (Figs 3I, 4H, 5A–B). The third
 303 apical plate (3') was pentagonal in shape, in contact with 1', 2', 4", 5" and 6" but also had a very
 304 short contact with Po plate (Figs 4A, 5A–B). Of the precingular series, 1" plate was the smallest
 305 while 6" plate was the largest (Figs 3D, 4A, C). All precingular plates were four-sided except 2" and
 306 6" plates that were pentagonal (Fig. 4A). The cingulum was narrow, slightly descending and
 307 undulated (Figs 3C, G, 4E–I). In the ventral view, the cingulum appeared with a V shape (Fig. 4E–
 308 F) while it was slightly sigmoid in lateral views (Figs 3G–H, 4H–I). The postcingular plate series
 309 comprised 5 plates (Figs 3E, 4B, D), 1''' being small and more conspicuously visible ventrally and
 310 laterally (Fig. 4E–H). The remaining four postcingular plates were large (Figs 3E, 4B, D). Among
 311 postcingular plates, 1''' was three-sided (Figs 4E, G–H, 5D), 2''' five-sided, and 3''', 4''' and 5''' four-
 312 sided (Fig 4B, D, H–I). The two antapical plates were unequal in size, 1'''' plate being small and
 313 covering part of the sulcus, while 2'''' plate was elongated, oriented in a slightly oblique direction in

314 regard with the dorsoventral axis, and with its sutures with 2^{'''} plate and 5^{'''} plate nearly parallel (Figs
315 3E–F, 4B, D).

316 The cingulum consisted of 6 distinct plates not studied in detail (Fig. 4H–I). The sulcus was
317 studied partially and four plates only could be observed. The posterior sulcal plate (Sp) was small
318 and roughly pentagonal, in contact with the posterior right sulcal plate (Sdp), 5^{'''} plate, 2^{'''} plate and
319 overlapped by 1^{'''} plate (Fig. 5D–G). The anterior right sulcal plate (Sda) contacted at least six
320 plates, including last cingular plate c₆ (Fig. 5E–G). It formed a conspicuous thick list oriented
321 obliquely to the left along its suture with the anterior left sulcal plate (Ssa), below the ‘ventral
322 opening’ (Vo) (Fig. 5C–G). This round opening with a thick border was 1.2–1.8 μm in diameter, and
323 consisted in deep indentation with a Latin upsilon letter shape within Ssa plate, closed anteriorly by
324 the epithelial 1^{''} plate (Fig. 5E–G). Another plate (Sdp), seen partially as a narrow extension without
325 any thecal pore, was present between Sp and Sda plates (Fig. 5E–G). The presence of other platelets
326 could not be revealed due to the overlap by the 1^{'''} plate (Fig. 5G).

327 The thecal surface was smooth and plates possessed pores of two kinds. Large pores were
328 numerous, scattered all over thecal plates and well visible in LM (Figs 3F, 4A–I, 5A–I). They
329 consisted in round pores 0.34–0.65 μm in diameter (mean 0.46 μm; s.d. 0.07 μm; *n* = 31),
330 surrounded by small depressions in the plates forming like a rim on the edge of the pore (Fig. 5A–
331 B, H, I). This feature was not visible from the inside (Fig. 5J). Small pores, 49–80 nm in diameter
332 (mean 66 nm; s.d. 8 nm; *n* = 31) were sparsely scattered on the surface of thecal plates (Fig. 5A–B,
333 H–I) but appeared more numerous on the internal side (Fig. 5J). A density of approximately 6.9
334 (5.4–7.8) and 7.4 (4.1–10.9) pores per 100 μm² (calculated on five specimens) was observed for
335 large and small pores, respectively. As it is generally the case, the small pores could not be seen in
336 LM and epifluorescence microscopy due to their small size (Fig. 3F).

337

338 3.2 Molecular phylogenies

339 For the phylogenetic analyses inferred from LSU rDNA D8-D10, D1-D3, and ITS-5.8S
340 sequences, a total of 14, 6, and 6 new sequences from Tahiti, French Polynesia, as well as reference
341 sequences retrieved from GenBank, were used (i.e. LSU rDNA D8–D10: IFR19-631/IFR20-173 to
342 -178, and PNA19-1 to -4/PNA19-6 to -9 acquired from six single cells isolated from the wild bloom
343 and eight cultured strains, respectively; LSU rDNA D1–D3 and ITS-5.8S: IFR20-173 to -175 and
344 PNA19-6, -8 and -9 acquired from three single cells isolated from the wild bloom and three cultured
345 strains, respectively). Parameters of the alignment and model chosen for the analyses are
346 summarized in Supplementary Table S1.

347 Both analyses performed with ML and BI gave the same tree topology and identical
348 relationships among *Ostreopsis* clades. Hence, only the majority-rule consensus trees of the ML
349 analyses are shown (Figs 6, 7, 8).

350

351 3.2.1 LSU rDNA D8–D10 regions

352 All 14 sequences acquired from Tahiti clustered within *Ostreopsis* sp. 6 which was a well-
353 supported clade (ML = 98, BI = 1.00), sister to *O. lenticularis* (Fig. 6). Sequences acquired from
354 single cells of the bloom and cultured strains were nearly identical and clustered in a new subclade
355 A of *Ostreopsis* sp. 6 (Fig. 6). This subclade of 14 sequences corresponded to a sister clade of two
356 sequences from Thailand (strains TF29OS and TF25OS, subclade B) with a moderately high
357 support (ML = 95, BI = 0.90). Two sequences from Japan (strains s0587 and s0595, subclade D)
358 branched with a strong support (ML = 96, BI = 1.00) at the base of the subclades A and B. Another
359 group of five sequences from Japan (OU8, IR33, IR49, and OU11) and Korea (17JJ0906) formed a
360 subclade E which appeared as a sister clade to the subclades A, B, and D with a moderate support
361 (ML = 96, BI = 0.66) (Fig. 6).

362 A low genetic divergence was observed within each subclade, with p -distances varying from
363 0.000 (subclade A) to 0.002 (subclade C, Table 1). The p -distances between subclades showed the
364 subclades A (Tahiti) and B (Thailand) were the most closely related with a p -distance of 0.002. In
365 contrast, the subclades D and E (Japan/Korea) appeared more divergent from other subclades A and
366 B with p -distances of 0.012 to 0.013 (Table 1).

367

368 3.2.2 LSU rDNA D1–D3 regions

369 The 6 sequences acquired from the Punaauia bloom clustered within *Ostreopsis* sp. 6 which
370 was a fully supported clade (ML = 100, BI = 1.00), sister to *O. lenticularis* (Fig. 7). The six
371 sequences from Tahiti formed a well-resolved subclade A within *Ostreopsis* sp. 6 (ML = 90, BI =
372 0.96), and two sequences from Malaysia (OIPR01, subclade B) and Viet Nam (NT013, subclade C)
373 appeared closely related and more basal (Fig. 7). These eight sequences formed a well-supported
374 subclade of *Ostreopsis* sp. 6 (subclades A-C) (ML = 88, BI = 1.00), and three sequences from Japan
375 (OA21, subclade D/E?) formed a sister clade with a maximal support (Fig. 7). In absence of other
376 sequences for other markers allowing comparisons with subclades D and E, sequences of strain
377 OA21 are putatively ascribed to ‘D/E?’.

378 A low genetic divergence was observed within each subclade, with p -distances varying from
379 0.001 (subclade A) to 0.023 (subclade D/E?, Table 1). The p -distances between subclades showed
380 the subclades A (Tahiti) and B (Malaysia) were the most closely related with a p -distance of 0.032.
381 In contrast, the subclades C (Viet Nam) and D/E? (Japan) appeared more divergent from subclades
382 A and B with p -distances of 0.046 to 0.105 (Table 1).

383 Of note, there is currently no reference sequence for D1-D3 LSU rDNA from the Gulf of
384 Thailand whereas only one sequence (in same subclade B with ITS–5.8S rDNA region) ascribed to
385 ‘*O. lenticularis*’ (already mentioned) is presently available from Malaysia (OIPR01) (Fig. 7).

386

387 *3.2.3 ITS–5.8S rDNA phylogeny*

388 All the 6 sequences acquired from Tahiti clustered as a basal subclade A within *Ostreopsis* sp. 6
389 (Fig. 8). The most closely related sequences were in subclade B which included two sequences from
390 Thailand (TF29OS and TF25OS) and two from Malaysia (OlPR01 and VGO87, Fig. 8). Two
391 sequences from Viet Nam (NT011 and NT012) were more divergent and included in the subclade C,
392 while three sequences from Japan (s0587, IR33 and OU11) formed the subclades D and E, but
393 support was low (Fig. 8).

394 Except for the subclade E, a low genetic divergence was observed within each subclade, with
395 *p*-distances of 0.002 (subclade A), 0.004 (subclade B) and 0.008 (subclade C, Table 1). The *p*-
396 distances between subclades showed the lowest *p*-distance was observed between the subclade A
397 (Tahiti) and B (Thailand/Malaysia) with a value of 0.008. In contrast, the subclade A was more
398 divergent from the subclades D (*p*-distance 0.147) and E (*p*-distance 0.127), including sequences
399 from Iriomote and Okinawa islands, Japan (Table 1).

400

401 *3.3 Toxicity and toxin analyses*402 *3.3.1 Toxicity analyses using the CBA N2a*

403 At the screening step, no toxicity was detected in the field sample, whereas all eight strains
404 tested were found toxic in O⁻ and O⁺ conditions. When doing quantitative analyses, the PITX
405 standard displayed a dose-response curve with a vertical negative slope in O⁻ conditions and a
406 sigmoidal dose-response curve with a negative slope in O⁺ conditions, giving EC₅₀ values of 1,074
407 ± 23 and 156 ± 17 pg·mL⁻¹ (*n* = 3), respectively (Fig. 9A). The composite toxicity of the eight
408 strains of *Ostreopsis* sp. 6 showed a pattern similar to that of PITX standard (Fig. 9B). The

409 estimated toxin contents ranged from 1.73 ± 0.31 to 2.48 ± 0.22 pg PITX equiv. cell⁻¹ in O⁻
410 conditions ($n = 3$), and from 1.08 ± 0.09 to 1.40 ± 0.14 pg PITX equiv. cell⁻¹ in O⁺ conditions ($n =$
411 3) (Table 2). A good reproducibility of toxin contents was observed between experiments, with
412 coefficients of variation (CVs) ranging from 4.2 to 17.8 % in O⁻ conditions and from 2.9 to 10.6%
413 in O⁺ conditions (Table 2). Comparison of the toxicity data between strains indicate slight
414 differences, with a mean toxicity of 2.16 ± 0.25 and 1.27 ± 0.12 pg PITX equiv. cell⁻¹ in O⁻
415 conditions (CV of 11.5%) and O⁺ conditions (CV of 9.2%), respectively. Of note, the curves
416 obtained in O⁺ conditions showed the best agreement with the 4PL model used in Graphpad
417 software, so only these values should be considered for further comparison with the toxicity data
418 available in the literature.

419

420 3.3.2 Analyses by LC-MS/MS

421 Among the PITX-like compounds screened for, we could detect OSTs in the eight strains
422 cultivated but not in the field field sample (Supplementary Fig. S1). Total OSTs varied from 21 to
423 28 pg PITX equiv. cell⁻¹ (Fig. 10). The OST profile was dominated by OST-D (>90%) followed by
424 OST-A and -B in all strains tested.

425 As no OST standard is commercially available, we tried to confirm the identity of OSTs by
426 both low and high resolution mass spectrometry. While EPI scan confidently proved the identity of
427 OST-D (Fig. S2) when compared to fragments reported by Terajima et al. (2018a), the intensity for
428 the other analogs was unfortunately too low. In addition, exact masses obtained by HRMS analyses
429 unambiguously confirmed the presence of OST-A and -B (Δ ppm: -3.1 to +1.9, Fig. S3). The HRMS
430 spectra showed a characteristic pattern, with the forms $[M+2H-H_2O]^{2+}$ and $[M+H+Na]^{2+}$ being more
431 abundant. However, the $[M+H+Na]^{2+}$ exact mass corresponding to OST-E1 was missing, suggesting
432 its absence in the OST profile of the strains studied here. Finally, as OST-A and -B are isomers and

433 due to the absence of a published chromatogram, their identity was defined based on their retention
434 time (OST-A eluting first).

435

436 4. DISCUSSION

437 4.1 Phylogeny and taxonomy of the bloom forming species from Tahiti Island

438 4.1.1 Phylogenetic position

439 Molecular data and phylogenetic analyses revealed that the species responsible for the bloom
440 belongs to the *Ostreopsis* sp. 6 clade, originally proposed by Sato et al. (2011) and subsequently
441 used by several authors (Tawong et al., 2014; Zhang et al., 2018; Chomérat et al., 2019; Lee and
442 Park, 2020). So far, this genotype has been found in various areas of southwestern Asia, including
443 the Gulf of Thailand, especially at the TF site (Tawong et al., 2014) which corresponds roughly to
444 the type locality of *O. siamensis* Johs. Schmidt, in Malaysia (subclade B), Viet Nam (subclade C),
445 and several islands of Japan (subclades D-E; Sato et al., 2011). Very recently, Lee and Park (2020)
446 reported the presence of this species (subclade E) in the subtropical area of Jeju island, South
447 Korea, which is the northernmost record to date. Hence, the present study is the first report of this
448 species from the mid-Pacific area. Genetic distances among the different subclades revealed that
449 there are some divergences between the subclades, suggesting that *Ostreopsis* sp. 6 might actually
450 represent a complex of closely related species, as is the case for the *O. cf. ovata* clade. Nevertheless
451 further studies will be necessary to resolve this issue.

452 Sequences from French Polynesia (subclade A) appeared more closely related to the sequences
453 from the Gulf of Thailand/Malaysia (subclade B in present analyses), than to sequences from other
454 origins (Viet Nam, Japan, Korea: subclades C, D and E). Consequently, the low genetic divergence
455 between subclades A and B can likely be interpreted at an intraspecific level. For instance, the ITS–
456 5.8S region sequences of subclades A and B diverged by 0.008 which is much lower than the

457 threshold value of 0.04 proposed by Litaker et al. (2007) to separate two given dinoflagellate
458 species. In contrast, the sequences from Viet Nam and Japan (subclades C, D, E) were more
459 variable and divergent from subclades A and B (ITS *p*-distances exceeding 0.04), which suggest
460 they likely represent different species. Nevertheless, more detailed studies including comparisons of
461 the ITS2 secondary structure of the different ribotypes would be necessary to resolve this question
462 in the future.

463

464 4.1.2 Identity of *Ostreopsis* sp. 6

465 In previous studies, the clade *Ostreopsis* sp. 6 was left unnamed since the morphology of the
466 strains was not studied or confusing. By way of example, the phylogeny inferred from ITS–5.8S
467 region includes two sequences from Malaysia originally ascribed to *O. labens* M.A. Faust & S.L.
468 Morton (VGO897) and *O. lenticularis* (OIPR01), respectively. Of note, this latter identification later
469 proved erroneous since strain OIPR01 clusters within *Ostreopsis* sp. 6 and not with *O. lenticularis*
470 (Chomérat et al., 2019). Moreover, these sequences were almost identical to sequences from the
471 Gulf of Thailand (TF25OS and TF29OS) which likely correspond to *O. siamensis* since they were
472 acquired from the area studied by Schmidt (1901), near Koh Wai Island. Although Tawong et al.
473 (2014) did not provide a detailed morphological SEM description of strains TF29OS and TF25OS,
474 they reported a dorsoventral (DV) length (= depth) size range of 49.9–84.3 μm for TF29OS, and
475 also highlighted a conspicuous undulated shape in lateral view (Fig. 4 in Tawong et al., 2014). This
476 feature is typical of *O. siamensis* as showed by Schmidt (1901) although this author mentioned a
477 DV length of 90 μm without any indication of the size variation range. Morphological features of
478 strain TF29OS appears in good agreement with the original description but, unfortunately, it has
479 been lost (T. Nishimura, pers. comm.), so further investigations to clarify whether it could be
480 ascribed to *O. siamensis* or not, is no longer possible. However, since genetic data clearly show that

481 strains from the Gulf of Thailand and those from Tahiti Island (subclades B and A, respectively)
482 belong to the same species, the present morphological data are therefore useful to complete the
483 previous study by Tawong et al. (2014).

484 The specimens from the bloom at Toaroto beach, Tahiti were in the same size range than those
485 reported for strain TF29OS by Tawong et al. (2014). The larger DV length (depth) mean value
486 found in the present study (71.5 μm vs. 62.4 μm in Tawong et al., 2014) can easily be interpreted by
487 our observation of field specimens from the bloom (i.e. a natural population) while Tawong et al.
488 (2014) values were obtained from a culture. Although the size is lower than the value from the
489 original description by Schmidt (1901), it fits perfectly with the interpretation of *O. siamensis* by
490 Fukuyo (1981) who gave a DV length range of 60–100 μm . The single value reported by Schmidt
491 (1901) should be considered cautiously and is likely due to the low cell densities in the plankton
492 samples he examined at station 2 (between Koh Kahdat and Koh Kut), and even lower densities
493 found at stations 3 and 6 (South of Koh Chang). Moreover, cell specimens from the bloom and
494 strains from Tahiti displayed a variable outline, from almost round to tear-shaped, consistent with
495 the original drawings by Schmidt (1901). Several authors (e.g., Accoroni and Totti, 2016)
496 hypothesized that these drawings could well represent different taxa with different shapes but this
497 hypothesis likely results from a misinterpretation of the shape as a distinctive feature between *O.*
498 *siamensis* and *O. lenticularis*. As noted previously, Fukuyo (1981) never indicated that the outline
499 can distinguish these species (Chomérat et al. 2019). The present data confirm that such variability
500 exists in *Ostreopsis* sp. 6, both in a field sample and in cultured strains.

501 Additionally, the undulated (slightly sigmoid) cingulum observed in the specimens from Tahiti
502 Island is in good agreement with the report by Tawong et al. (2014). This remarkable feature,
503 resulting in a slightly concave hypotheca, fits extremely well with the original drawings (Fig. 7 in
504 Schmidt, 1901) and with the description indicating an ‘inferior valve a little concave’ (Schmidt,
505 1901).

506 The presence of conspicuous thecal pores was confirmed on the specimens from Tahiti, where
507 larger thecal pores had a diameter of 0.34–0.65 μm , as reported for TF29OS (Supplementary Table
508 S2 in Tawong et al., 2014). This large size makes them perfectly visible in light microscopy, which
509 is again consistent with the drawings by Schmidt (1901) and interpretation of *O. siamensis* by
510 Fukuyo (1981). However, our study also showed the presence of very small thecal pores that are
511 impossible to resolve in LM, which may explain their absence both in the original description and
512 re-interpretation of *O. siamensis* (Schmidt, 1901; Fukuyo, 1981), but also in the study by Tawong et
513 al. (2014).

514 However, our observations do show several discrepancies compared to the original description
515 of *O. siamensis* with regard to the APC and the second apical plate 2'. In the original drawing, the
516 APC appeared rather short compared to the DV length (depth) of the cell (Po/DV of 0.22 measured
517 in Schmidt's Fig. 5) while slightly larger values were found in our study. In comparison, Tawong et
518 al. (2014) indicated a Po plate length of 16 μm in their Supplementary Table S2, which is in the
519 lower range of our observations. Using the average DV value, the Po/DV of strain TF29OS was
520 0.26, which is in the range found in the present study. Furthermore, the apical 2' plate appeared to
521 be short, and nearly of the same length as Po plate in Fig. 5 by Schmidt (1901). This seems in
522 marked contrast with our observations which described a narrow and very elongated 2' plate
523 reaching the dorsal precingular plate 4". Such a long 2' plate was reportedly observed only in *O.*
524 *heptagona* and the recently described species *O. fattorussoi* and *O. rhodesiae* (Norris et al., 1985;
525 Accoroni et al., 2016; Verma et al., 2016a). This is no longer true since extensive observations on *O.*
526 *cf. ovata* have revealed that several populations also display a long 2' plate (Besada et al., 1982;
527 Parsons et al., 2012; Tibirićá et al., 2019). Moreover, in the largest species of the genus, *O.*
528 *mascarenensis*, our previous study showed that the 2' plate is actually long and it reaches 4" plate
529 (Chomérat et al., 2020), which contradicts the original description by Quod (1994). All these
530 findings suggest the actual shape of this plate was probably overlooked in previous studies. In *O.*

531 *siamensis*, Fukuyo (1981) interpreted a small, long and narrow 2' plate as reported in the original
532 drawing by Schmidt (1901), but the exact shape and length are not clearly visible from LM pictures.
533 So whether the 2' plate was actually short in the population or the interpretation was influenced by
534 the original description could not be determined. As previously emphasized by Chomérat et al.
535 (2020), the study of this plate is extremely difficult due to its narrowness and recessed position
536 below the APC. The relevance of this plate has also significantly increased with the descriptions of
537 new *Ostreopsis* species characterized by rather close plate pattern. Indeed, the need to identify
538 consistent diagnostic features and the development of more and more powerful techniques such as
539 epifluorescence or SEM has rendered the study of the APC and 2' plate more prominent in modern
540 taxonomy. When Schmidt (1901) described *O. siamensis*, the morphology of this new genus was so
541 unusual and different from all other known dinoflagellates, that there was probably no need to study
542 this tiny and recessed plate with as many details as today, therefore original drawings should be
543 taken cautiously. To support this statement, it should be mentioned that Schiller even omitted to
544 report the APC and 2' plate in the illustration of the genus *Ostreopsis* in his monograph (Fig. 543b
545 in Schiller, 1937).

546 All the above morphological features reported for the specimens from Tahiti are in rather good
547 agreement with the description of *O. siamensis*, and the fact that it is genetically almost identical to
548 a strain from the type locality strongly argues in favor of this identity. Nevertheless, most of these
549 features fit also quite well with the description of another species, *O. labens* which also has a
550 conspicuous undulation and is very difficult to separate from *O. siamensis*. The type locality of *O.*
551 *labens* is Man of war Cay, Belize but Faust and Morton (1995) indicated the presence of this species
552 in several places from Japan (Iriomote, Ishigaki Islands) and East China, and this distribution was
553 extended to southwestern Indian Ocean (Faust et al., 1996). The reasons why *O. labens* has been
554 separated from *O. siamensis* are unclear, and the main difference between them appears to be the
555 anteroposterior length reported as 60–86 μm in *O. labens* (Faust and Morton, 1995), which is higher

556 than for *O. siamensis* (Hoppenrath et al., 2014). Nevertheless, this feature is doubtful since it does
557 not correspond to the illustrations provided by Faust and Morton (1995) and based on the scale bar,
558 the cell illustrated in their Fig. 8 had an estimated width of 67 μm and an AP length of 44 μm ,
559 which is surprisingly outside the range given in the description. Hence, the diagnostic features of *O.*
560 *labens* appear to be questionable, and the dimensions must be regarded cautiously. In their
561 description of *O. labens*, Faust and Morton (1995) reported a DV length (depth) of 81–110 μm but
562 this was surprisingly further reported to 86–98 μm one year later (Faust et al., 1996). Thus, it is
563 mostly in the range given by Fukuyo (1981) for *O. siamensis* (60–100 μm). Moreover, as discussed
564 earlier, Faust et al. (1996) likely made a major confusion between *O. siamensis* and *O. lenticularis*
565 and all their data reported for ‘*O. lenticularis*’ (our quotation marks) actually fit better with *O.*
566 *siamensis*, while the data for ‘*O. siamensis*’ concern *O. lenticularis* (Chomérat et al., 2019).
567 According to Faust et al. (1996), ‘*O. lenticularis*’ (likely *O. siamensis*) has a DV length of 65–75
568 μm which is not only in the range given by Fukuyo (1981) for *O. siamensis* but also in the range of
569 *Ostreopsis* sp. 6 [strain TF29OS (Tawong et al., 2014) and field cells observed in the present study].
570 Unfortunately, Faust et al. (1996) did not report the AP length for this species, preventing any
571 further comparison with *O. labens*. Except for size, no striking difference can be found between *O.*
572 *labens* and ‘*O. lenticularis*’ (likely *O. siamensis*) in Faust et al. (1996). They both possess a similar
573 thecal arrangement, an undulated cingulum (undescribed but visible on the illustrations), and large
574 thecal pores in depressions and surrounded with a rim (Faust et al., 1996). This structure of large
575 thecal pores is remarkably similar in *Ostreopsis* sp. 6 (e.g., Fig. 29 in Fukuyo, 1981; Fig. 2H in Lee
576 and Park, 2020, present study), *O. labens* and ‘*O. lenticularis*’ (Faust and Morton, 1995; Faust et
577 al., 1996), indicating their probable taxonomic proximity and possible conspecificity. The presence
578 of very small thecal pores observed in the present study may have been overlooked in older studies
579 since these pores are rare on the cell surface and they require that the amphiesmal and cell

580 membranes to be well removed. In any case, these small pores are impossible to see in LM, and
581 their scarcity on thecal plates makes a major difference from *O. lenticularis* (Chomérat et al., 2019).

582 In the light of the molecular data showing that *Ostreopsis* sp. 6 encompasses cryptic diversity,
583 one of the subclades D or E might correspond to *O. labens* since Faust and Morton (1995)
584 designated paratypes from Iriomote and Ishigaki islands, Japan. Phylogenetic analyses revealed that
585 great diversity exists at Iriomote-Kohama-Ishikagi Islands which are part of the Ryukyu
586 archipelago, and sequences clustering in the subclades D and E are both present. Since Fukuyo
587 (1981) studied specimens from this area, he may have reinterpreted *O. siamensis* in a broad sense,
588 encompassing cryptic (or pseudocryptic) species within *Ostreopsis* sp. 6, and possibly *O. labens*.
589 However, to confirm this hypothesis and clarify the delineation of *O. labens*, additional molecular
590 data are needed from the type locality (Man of war Cay, Belize).

591 The molecular data from the Gulf of Thailand and type locality of *O. siamensis* (Tawong et al.
592 2014), together with the detailed morphological description herein bring new evidence that the
593 subclades A and B of *Ostreopsis* sp. 6 likely correspond to the real *Ostreopsis siamensis*, as
594 described by Schmidt (1901). Nevertheless, in the absence of a culture of this species from the type
595 locality in the Gulf of Thailand, it is impossible to define a neotype yet. In contrast with the recent
596 review by Tester et al. (2020), this study demonstrates unambiguously that *Ostreopsis* sp. 6 should
597 not be considered as a cryptic species of *O. lenticularis* (= *Ostreopsis* sp. 5), and instead,
598 corresponds to a fully separated species, most likely *O. siamensis*. This novel report from Tahiti
599 Island is extremely interesting as only two morphospecies are currently reported from French
600 Polynesia so far, namely *O. ovata* and *O. lenticularis* (Fukuyo, 1981; Chomérat et al., 2019). In his
601 study, Fukuyo (1981) clearly indicated that *O. siamensis* was not present in the samples from Tahiti
602 and Gambier Islands.

603

604 4.1.3 Taxonomic comparison with '*Ostreopsis cf. siamensis*' from temperate locations

605 The nomenclatural combination '*Ostreopsis cf. siamensis*' has been used to designate a clade
606 that includes sequences from the Mediterranean, Atlantic-Iberian peninsula, northern New Zealand,
607 Russia and Australia which all classify in temperate (Cf) to warm Mediterranean climates (Csa) and
608 subtropical humid (Cwa) according to the Köppen-Geiger climatic classification (Table 3, Peel et
609 al., 2007; Beck et al., 2018). In contrast with *Ostreopsis* sp. 6 for which genetic divergence is
610 relatively high and may indicate the existence of cryptic species, molecular data for '*O. cf.*
611 *siamensis*' show a lower level of variation among populations from the different temperate areas.
612 Hence '*O. cf. siamensis*' can be interpreted as a single species, related to *O. rhodesiae* in
613 phylogenies, but very recently, Verma et al. (2020) showed the existence of low genetic variability
614 and identified two subclades within '*O. cf. siamensis*' from Australia. Despite this relative genetic
615 stability, morphology reported for this species is rather variable and sometimes conflicting features
616 have been mentioned but it is likely that several confusions were made and the taxonomic identity
617 was not ascertained. The lack of molecular data for previous reports from the temperate areas (*e.g.*,
618 the northern part of New Zealand, Chang et al., 2000; Rhodes et al., 2000) prevents to clarify their
619 actual identity and morphological data were not detailed enough to conclude. Nevertheless, it is
620 likely the same temperate species that clusters in the clade '*O. cf. siamensis*' since it was found in
621 the northern part of New Zealand for which genetic data have been further acquired (Sato et al.,
622 2011). In contrast, the species identified morphologically as *Ostreopsis cf. siamensis* by Holmes et
623 al. (1988) from subtropical Australia (Heron and Lady Elliot islands) likely correspond to another
624 taxon, presumably *O. siamensis*, as shown by size and characters (Table 3). Although the presence
625 of '*O. cf. siamensis*' has also recently been confirmed at Heron Island (Verma et al., 2016a) the cells
626 had different morphological characters (Table 3). In this area of Coral Sea, which corresponds to
627 the limit of the tropical area, both genotypes may be sympatric. Hence, it appears that the

628 combination '*Ostreopsis cf. siamensis*' may have been used for different taxa and is highly
629 confusing.

630 As summarized by Verma et al. (2016b), the sizes reported for temperate specimens (excluding
631 all reports from tropical waters that likely correspond to other species, Table 3) were quite variable,
632 depending on whether observations used cultured material or field fixed specimens. The DV length
633 varied between 34 μm (e.g., cultured cells from Merimbula, Australia, Verma et al., 2016b), to 90
634 μm (e.g., field specimens from the Mediterranean Sea, Penna et al., 2005). This suggests that size is
635 a poor taxonomical character to distinguish temperate '*O. cf. siamensis*' from tropical *O. siamensis*
636 and *Ostreopsis* sp. 6 due to the overlap (Table 3). Besides, as for almost all *Ostreopsis* species, the
637 plate pattern does not exhibit any major difference (Parsons et al., 2012). Interestingly, in their Fig.
638 2f, Verma et al. (2016b) illustrated a short 2' plate, not reaching the precingular 4" plate, very
639 similar to Schmidt's illustration, but their SEM micrograph of the 2' plate (cf. Fig. 3c in Verma et
640 al., 2016b) is not clear and seems to indicate a contact between 2' and 4" plates. In contrast, Selina
641 and Orlova (2010) and David et al. (2013) illustrated a conspicuously long 2' plate, as shown in our
642 study. Consequently, the length of 2' plate does not constitute a good character to distinguish '*O. cf.*
643 *siamensis*' from *Ostreopsis* sp. 6 and it appears necessary to reinvestigate this feature for all
644 *Ostreopsis* species as the interpretation may have been mistaken.

645 Two important features should be better evaluated for the discrimination of species from the
646 tropical area (*O. siamensis* / *O. labens* / *Ostreopsis* sp. 6) from the more temperate '*O. cf.*
647 *siamensis*'. The first feature seems to be the cingulum undulation, which is conspicuous in the
648 original description of *O. siamensis* and the present study of *Ostreopsis* sp. 6. As shown in Table 3,
649 when studied carefully, the conspicuous undulation is found in tropical populations of *O. siamensis*,
650 *O. labens*, and *Ostreopsis* sp. 6 whereas in populations of '*O. cf. siamensis*', this feature has been
651 rarely emphasized. Several authors indicated that cells were flat and not undulated (Penna et al.,
652 2005; David et al., 2013; Verma et al., 2016b) while Aligizaki and Nikolaidis (2006) reported that

653 cells were sometimes undulated. The undulation showed in Fig. 4A by Aligizaki and Nikolaidis
654 (2006) appears very faint and roughly similar to the observations by Selina and Orlova (2010).
655 Nevertheless, in these studies, the illustrations do not show the same degree of undulation as
656 illustrated by Schmidt (1901) or shown in the present study. Consequently, the degree of undulation
657 may constitute a good feature to separate temperate '*O. cf. siamensis*' from the tropical *O. siamensis*
658 / *Ostreopsis* sp. 6. Additionally, thecal pores may constitute another important taxonomic feature, to
659 help separate these taxa. As shown in Table 3, the size of large and small thecal pores may be an
660 interesting feature to consider, although this is variable among populations. It is striking that large
661 thecal pores have the same size in *Ostreopsis* sp. 6 from the Gulf of Thailand (Tawong et al., 2014)
662 and Tahiti (this study). This large size (0.4–0.7 μm) compares well with Schmidt's statement that
663 plates are coarsely porous, like that of '*Ceratium tripos*' (Schmidt, 1901), who observed them only
664 with LM. From the original drawings (cf. Fig. 6 in Schmidt, 1901), the thecal pores illustrated on
665 the hypotheca have a roughly estimated size of 0.6–0.7 μm , considering the DV length of the cells
666 ca. 90 μm . As observed in the present study, rounded cells were generally much smaller, and in
667 absence of a scale bar in the original description, the pores size could not be estimated from the
668 epitheca (Fig. 5 in Schmidt, 1901), or some exceed 1 μm if the DV is considered to be 90 μm . By
669 contrast, the values for '*O. cf. siamensis*' appear lower in all studies. Penna et al. (2005) made
670 extensive measurements of thecal pores of *O. cf. siamensis* from the Mediterranean Sea, but despite
671 a large range of variation of 0.11–0.55 μm , the predominant size was 0.2–0.4 μm which is below
672 the measurements in *Ostreopsis* sp. 6 (Tawong et al., 2014; this study). In addition to the size, the
673 structure of these pores, with a depression and collar rim around the opening appears conspicuous in
674 *Ostreopsis* sp. 6, but it has never been shown in the temperate '*O. cf. siamensis*' which has simple
675 pores without collar rim. Thus, this feature should be further considered to separate these species.

676 Therefore, in the light of the phylogenetic data presently available and the morphological data
677 from the present study, we conclude the name *O. siamensis* should be used for a species within the

678 clade *Ostreopsis* sp. 6 (putatively the subclades A and B), while there is a need to rename '*O. cf.*
679 *siamensis*' from temperate areas since this designation is a source of additional confusion in the
680 complex taxonomy of *Ostreopsis*.

681

682 4.2 Toxicity and toxin profiles

683 As previously found by Pawlowicz et al. (2013), Cañete and Diogène (2008) and Kerbrat et al.
684 (2011), the cytotoxic effect of PITX on N2a cells was enhanced by the presence of ouabain which is
685 in marked contrast with Ledreux et al. (2009) who concluded in a protective effect of ouabain
686 against PITX action. In French Polynesia, the composite toxicity detected by CBA-N2a showed that
687 all the strains isolated from the bloom were toxic in O⁻ and O⁺ conditions with a mean production of
688 at least 1.27 pg PITX equiv. cell⁻¹ estimated in O⁺ condition and very little difference between the
689 eight strains (9.2%). This composite toxicity was confirmed by LC-MS/MS analyses revealing the
690 presence of three OST analogs in all strains of *Ostreopsis* sp. 6 from Tahiti: OST-A, OST-B, and
691 OST-D, this latter composing the most important part of the toxin profile ($\approx 90\%$). The average
692 toxin production of the eight strains as assessed by LC-MS/MS was estimated at 25 pg equiv. PITX
693 cell⁻¹ i.e. 19-fold higher than with the CBA-N2a. This bias could be explained by the use of PITX as
694 the reference standard to estimate the toxin production (since OST standards are currently
695 unavailable). The use of PITX could not allow estimating the real cytotoxic potential of these three
696 OSTs (-A, -B and -D) on mouse neuroblastoma cells via the CBA-N2a, as-yet-unknown. Depending
697 on the model and exposition routes, considerable differences have been found between PITX and
698 OST-D (Ito and Yasumoto, 2009). For instance, *in vivo* experiments on mice (intra-tracheal
699 administration) have shown that OST-D was five times less potent than PITX (Ito and Yasumoto,
700 2009). Using keratinocytes (HaCaT cells), Pelin et al. (2016) also noticed a lesser cytotoxicity of
701 OST-D in comparison with PITX, and suggested that a missing hydroxyl group on C44 of OST-D,
702 present in PITX, may cause this major difference in toxicity.

703 In previous studies, crude methanolic extracts of the strain s0587 (subclade D) from Haemida,
704 South of Iriomote Island (latitude $\approx 24^\circ\text{N}$), in tropical waters of Okinawa, Japan (Sato et al., 2011)
705 and the strain TF29OS (subclade B) from Thailand (Tawong et al., 2014) belonging to *Ostreopsis*
706 sp. 6 and genetically closely related to the strains from Tahiti, exhibited toxicity to mice although no
707 quantification was given. The same strain s0587 was also known to produce OST-D, around 3.5 pg
708 PITX equiv. cell⁻¹ (Suzuki et al., 2012) using LC-MS/MS, which is *ca.* 7 times lower than for the
709 French Polynesian strains. These levels are rather similar, albeit lower compared to other *Ostreopsis*
710 species like *O. cf. ovata* from the northern Adriatic Sea showing high levels of PITXs up to 75 pg
711 cell⁻¹ in natural benthic microalgal populations (Accoroni et al., 2011). Interestingly, Suzuki et al.
712 (2012) did not detect any toxins in strains IR33 and OU11 (subclade E) of *Ostreopsis* sp. 6, which
713 contrasts with subclades A, B and D.

714 Regarding the toxin profiles, the presence of OST-D as the major analogue found in the strains
715 from French Polynesia (this study) is consistent with results obtained previously for Japanese
716 strains, including the strain s0587 (Suzuki et al., 2012), but also with the data by Ukena et al. (2001,
717 2002) who isolated and purified OST-D from the strain SOA1, collected at Aka Island, Okinawa,
718 Japan. In addition, the presence of at least three analogues within a single strain is also consistent
719 with the recent studies of Terajima et al. (2018a, b) who purified the four OSTs known so far from
720 the same SOA1 strain. Although this strain comes from the same island than strain OA21 (subclade
721 D/E? in Fig. 7), no sequence has been provided for strain SOA1 which prevents a genetic
722 comparison. Phylogenetic data suggest that there is a great diversity in the area of Iriomote-
723 Kohama-Okinawa islands, including several genotypes of *Ostreopsis* sp. 6 (Sato et al., 2011; this
724 study). In all phylogenetic analyses, sequences from Japan do not cluster in the same subclade as
725 those from the Gulf of Thailand and Tahiti, which could indicate different species. Further work
726 will thus be needed to clarify this and ascertain the presence of OST-E1 in strains from Tahiti. To
727 date, the lack of published profiles limits further comparisons of the toxin profile found for

728 *Ostreopsis* sp. 6. Nonetheless, results obtained in this study clearly indicate that comparing toxicity
729 and toxin composition of tropical strains of *Ostreopsis* sp. 6 with temperate strains of '*O. cf.*
730 *siamensis*' (e.g., Tester et al., 2020) should be very cautious since they concern two widely
731 divergent taxa. Such apparent conflicting reports of toxicity may result from misidentifications, and
732 we recommend that future works on toxicity always include a molecular characterization of the
733 strains studied to ensure their correct identification.

734 While all the strains isolated from the bloom exhibited toxicity, the absence of noticeable
735 toxicity and no detection of toxins from the field sample raises questions. Since the observations of
736 the bloom sample showed that several diatoms were co-occurring with *Ostreopsis* sp. 6, it is likely
737 that the dried biomass represented by *Ostreopsis* cells was rather low and probably insufficient to
738 induce a cytotoxic effect and to detect toxins. In addition, it has been shown that toxicity is highly
739 dependent on the bloom dynamics, and Gémin et al. (2020) reported that the toxin content increased
740 during the exponential and stationary growth phases of a bloom of *O. cf. ovata*. Hence, the toxin
741 content per cell in the bloom at Toaroto beach could have been low if sampling was done at an early
742 stage. In any case, further investigations will be necessary to confirm such findings, both *in situ* and
743 in laboratory conditions, as this has major implications in terms of risk in a given area.

744

745 **5. Conclusions**

746 In the context of climate change and global warming, understanding the ecological preferences
747 and niche of harmful benthic microalgae is an important challenge in order to predict future changes
748 (Tester et al., 2020). Among these taxa, the genus *Ostreopsis* represents a serious threat since
749 several species are toxic not only to human but also to marine organisms. The present observation
750 of a bloom of *Ostreopsis* sp. 6 in French Polynesia constitutes a new record for this species since, to
751 date, only *O. ovata* and *O. lenticularis* have been mentioned from French Polynesia (Fukuyo, 1981;

752 Bagnis et al., 1985; Chomérat et al., 2019). Hence, the finding of a new, toxic species, in Tahiti
753 increases the potential risk linked to the proliferation of *Ostreopsis*. The fact that no toxicity was
754 found in environmental samples whereas all clonal strains established from the bloom were toxic
755 with a relatively similar profile, dominated by OST-D, raises important questions about the basis of
756 toxin production in this species. While *O. cf. ovata* is likely the most toxic species, the risk to
757 human populations in the Mediterranean seems manageable, but the situation may be very different
758 in tropical areas (Tester et al., 2020). As emphasized by Deeds and Schwartz (2010), PITX-like
759 molecules may accumulate and contaminate tropical fishes and their ingestion by humans can have
760 dramatic health impacts, in addition to the well-known risk of CFP. Hence, further studies aiming at
761 better evaluate the distribution of *Ostreopsis* sp. 6 in French Polynesia, and determine the ecological
762 conditions which stimulates its proliferation now appear crucial for a better assessment of its
763 potential impacts on the coral-reef ecosystems but also risk management purposes.

764

765 **6. ACKNOWLEDGEMENTS**

766 We thank Maurice Loir for his help in the identification of the diatoms co-occurring with the
767 *Ostreopsis* bloom and Frederic Zentz for designing the new primer Dino-RB. The four anonymous
768 reviewers are acknowledged for their suggestions improving significantly the manuscript. The
769 Regional Council of Brittany, the General Council of Finistère and the urban community of
770 Concarneau-Cornouaille-Agglomération are acknowledged for the funding of the Sigma 300 FE-
771 SEM of the station of Marine Biology in Concarneau.

772

773 Funding

774 This work is part of the TATOO project and was supported by funds from the Délégation à la

775 Recherche de la Polynésie Française (Conv. n°02400/MTF/REC of April 9th, 2018).

1096 **Figure legends**

1097 **Fig. 1.** Map of French Polynesia (South Pacific Ocean) and Tahiti island, showing the location of
1098 the Toaroto beach (Punaauia) where the *Ostreopsis* bloom was observed and sampled.

1099

1100 **Fig. 2.** Photographs of the benthic bloom at Toaroto beach showing the filamentous and
1101 mucilaginous brownish biofilm covering abiotic and biotic substrates including (A) macroalgae
1102 (*Turbinaria ornata* and *Dictyota bartayresiana*, (B) sponges and (C) corals (*Porites*, *Pocillopora*).
1103 (D) Light micrograph of a sample of the bloom dominated by *Ostreopsis* cells and diatoms. Scale
1104 bar: 50 μm .

1105

1106 **Fig. 3.** Light and epifluorescence micrographs of cells from strain PNA19-9 from Toaroto beach
1107 (Punaauia, Tahiti island). (A–C) Live specimens: (A) specimen with an oval shape; (B) rounded
1108 specimen; (C) lateral view with focus on the undulated cingulum. (D–I) Epifluorescence
1109 micrographs: (D) apical view; (E) antapical view; (F) detail of the surface of 2^{'''} plate (G) lateral
1110 view showing the undulation of the cingulum; (H) Right ventral view; (I) detail of the apical pore
1111 complex (APC) and 2' plate. Scale bars: 10 μm in A–H, 5 μm in I.

1112

1113 **Fig. 4.** Scanning electron micrographs of field specimens from the bloom of Toaroto beach (Tahiti
1114 island). (A) Apical view; (B) antapical view; (C) apical view of a smaller and less pointed
1115 specimen; (D) antapical view of a small and round specimen; (E) ventral view, note the undulated
1116 cingulum; (F) ventro-apical view; (G) ventro-antapical view; (H) left lateral view showing the
1117 undulated cingulum and apical pore complex; (I) right lateral view. Scale bars: 10 μm .

1118

1119 **Fig. 5.** Scanning electron micrographs of field specimens from the bloom of Toaroto beach (Tahiti
1120 island). (A) Detail of apical plate series and apical pore; (B) detail of the second apical (2') plate
1121 and Po plate; (C) detail of the ventral area, with the ventral opening (Vo) and list of the Sda plate
1122 (black arrowhead) visible; (D) antapical view of the sulcal area; (E) ventral view of the sulcus; (F)
1123 detail of the sulcal plates; (G) sulcal plates on a broken specimen, note the ventral opening within
1124 the Ssa plate; (H-I) Thecal pores of two sizes, note that the internal structure is visible within larger
1125 pores; (J) internal view of thecal plates, with smaller thecal pores better visible. Scale bars: 2 μm in
1126 A, B, C, D, E and G, 1 μm in F, and 500 nm in H, I and J.

1127

1128 **Fig. 6.** Maximum Likelihood phylogenetic tree inferred from LSU rDNA D8–D10 sequences of
1129 various *Ostreopsis* strains and field specimens. Sequences from the present study are in bold face on
1130 a gray background. *Coolia* sp. is used as an outgroup. Black vertical bars show distinct *Ostreopsis*
1131 clades. Numbers at nodes represent bootstrap support values from Maximum Likelihood (ML) and
1132 posterior probabilities from Bayesian Inference (BI). Bootstraps values below 65 and posterior
1133 probabilities below 0.70 are indicated with '-'.
1134

1135 **Fig. 7.** Maximum Likelihood phylogenetic tree inferred from LSU rDNA D1–D3 sequences of
1136 various *Ostreopsis* strains and field specimens. Sequences from the present study are in bold face on
1137 a gray background. *Coolia monotis* is used as an outgroup. Black vertical bars show distinct
1138 *Ostreopsis* clades. Numbers at nodes represent bootstrap support values from Maximum Likelihood
1139 (ML) and posterior probabilities from Bayesian Inference (BI). Bootstraps values below 65 and
1140 posterior probabilities below 0.70 are indicated with '-'.
1141

1142 **Fig. 8.** Maximum Likelihood phylogenetic tree inferred from ITS–5.8S rDNA sequences of various
1143 *Ostreopsis* strains and field specimens. *Ostreopsis mascarenensis* and *Ostreopsis* sp. 4 are used as
1144 outgroup. Sequence from the present study are by bold face on a gray background. Black vertical
1145 bars show distinct *Ostreopsis* clade. Numbers at nodes represent bootstrap support values from
1146 Maximum Likelihood (ML) and posterior probabilities from Bayesian Inference (BI). Bootstraps
1147 values below 65 are indicated with ‘-’.

1148

1149 **Fig. 9.** Toxicity of *Ostreopsis* sp. 6 (strain PNA19-1) as assessed by means of the CBA-N2a. Dose-
1150 response curves of Neuro-2a cells when exposed to increasing concentrations of (A) standard of
1151 PITX and (B) cell extract of strain PNA19-1. Data represent the mean \pm SD of each concentration
1152 run in triplicate in three independent experiments ($n = 3$), in the absence (O^- condition, dotted lines)
1153 vs. presence of 200 μ M Ouabain (O^+ conditions, plain lines). The EC_{50} values obtained in O^- and O^+
1154 conditions were estimated at $1,074 \pm 23$ and 156 ± 17 $pg. mL^{-1}$ for PITX, and 564 ± 19 and $137 \pm$
1155 13 cell equiv. mL^{-1} for strain PNA19-1.

1156

1157 **Fig. 10.** Toxin contents and profiles of the eight *Ostreopsis* strains isolated from the Toaroto bloom
1158 analyzed by LC-MS/MS.

1159
