13

Abstract

Only 6% of known species have a conservation status. Methods that assess conservation 14 statuses are often based on individual counts and are thus too laborious to be generalized 15 to all species. Population genomics methods that infer past variations in population size 16 are easy to use but limited to the relatively distant past. Here we propose a population ge-17 nomics approach that tests for recent population decline and may be used to assess species 18 conservation statuses. More specifically, we study Maximal Recombination Free (MRF) 19 blocks, that are segments of a sequence alignment inherited from a common ancestor with-20 out recombination. MRF blocks are relatively longer in small than in large populations. 21 We use the distribution of MRF block lengths rescaled by their mean to test for recent 22 population decline. However, because MRF blocks are difficult to detect, we also consider 23 Maximal Linkage Disequilibrium (MLD) blocks, which are runs of single nucleotide poly-24 morphisms compatible with a single tree. We develop a new method capable of inferring 25 a very recent decline (e.g. with a detection power of 50% for populations which size was 26 halved to N, 0.05 $\times N$ generations ago) from rescaled MLD block lengths. Our framework 27 could serve as a basis for quantitative tools to assess conservation status in a wide range 28 of species. 29

1 Introduction

The severe and rapid changes imposed by human activities upon living organisms are 31 suspected to be a major factor leading to short-term mass extinctions (Barnosky et al., 32 2011). The most comprehensive list of endangered species is the Red List of the International 33 Union for Conservation of Nature (IUCN) (Rodrigues et al., 2006). Criteria used in the 34 list to assess the species conservation status are based on geographical range, population 35 trends, threats to habitat and ecology. Despite being very robust and reliable, these 36 criteria are hard to establish for many species. To quantify the ongoing crisis for a wider 37 range of organisms, there is a crucial need to develop quantitative measures of extinction 38 risk to efficiently monitor species in real time and at a global scale. Previous attempts 39 were developed to estimate quantitatively extinction rates, including by two of the present 40 authors, based on occurrence data (Régnier et al., 2015; Ceballos et al., 2017; Sánchez-41 Bayo and Wyckhuys, 2019) or genetic data (from museum specimen Díez-del Molino et al. 42 (2018); van der Valk et al. (2019)). The genetic methods measure the genetic diversity 43 at different time to estimate the population size at these times and conclude on a general 44 trend. The limitation of these methods is the difficulty to obtain time series data. 45

A handful of genomes sampled in a population at a single time point can help infer 46 the past demography of this population (Gutenkunst et al., 2009; Li and Durbin, 2011; 47 Excoffier et al., 2013; Harris and Nielsen, 2013; Sheehan et al., 2013; Schiffels and Durbin, 48 2014; Lapierre et al., 2017; Ringbauer et al., 2017; Terhorst et al., 2017; Beichman et al., 49 2018). In standard population genetic inferences, the periods when variations of population 50 size can be estimated are of the order of N_e generations back in time. N_e denotes the so-51 called effective population size (Wright, 1931). Recent methods such as MSMC (Schiffels 52 and Durbin, 2014) can provide inferences on more recent past but hardly scale up to large 53 datasets of complete genomes because of their computational load. With the development 54 of next generation sequencing, complete genomes from multiple individuals of the same 55 species are now released routinely (Gibbs et al., 2015; Alonso-Blanco et al., 2016). Actual 56 methods can not be applied to test for recent decline of populations, the models and 57 methods we present in this manuscript specifically target very recent past when considering 58 small populations and are meant to be applied to datasets of arbitrary size. 59

Methods using whole genome sequences to infer demography use different measures of genomic polymorphism. One of these measures is the so-called Site Frequency Spectrum,

or SFS (Fu, 1995). The SFS, that is the genome wide distribution of the frequencies of 62 polymorphic alleles in a sample of the population, is strongly distorted by the demographic 63 history of the species (Adams and Hudson, 2004; Marth et al., 2004). SFS-based methods 64 (e.g. Gutenkunst et al. (2009)) can handle arbitrarily large numbers of loci and genomes 65 but disregard correlations between sites caused by genetic linkage. Using genetic linkage 66 information may help overcoming the SFS-based methods limitations (e.g. difficulty to 67 discriminate between different scenarios Lapierre et al. (2017) and to infer recent demog-68 raphy). 69

Recombination is the process by which two DNA sequences are intermixed to create a new sequence that combines segments of different ancestries. When two homologous regions of the genome are inherited from the same ancestor without having undergone recombination, they are said IBD: *Identical By Descent*. The probability distribution and the length of IBD regions passed through generations have been studied (Stam, 1980; Chapman and Thompson, 2003; Stefanov, 2000).

Recombination patterns are also characterized by Linkage Disequilibrium (LD). LD 76 arises when individuals of a finite population share chunks of DNA inherited from a com-77 mon ancestor (IBD blocks). Specifically, two variants located at two distinct sites are 78 in linkage disequilibrium (LD) when their joint frequency differs from what is expected 79 under independence. More specifically, LD is defined as the covariance $f_{A_1B_1} - f_{A_1}f_{B_1}$, 80 where f_{A_1} is the frequency of allele 1 at locus A (Lewontin and ichi Kojima, 1960). When 81 $f_{A_1} \times f_{B_1} = f_{A_1B_1}$, the two variants are said in complete linkage equilibrium. On average, 82 LD decreases exponentially with genetic distance due to recombination. The pattern of 83 LD is distorted by demography (Hill and Robertson, 1968) and thus can be used to infer 84 the past demography of a population (Hollenbeck et al., 2016; Patin et al., 2014). 85

Importantly, despite the fact that breakpoints between IBD blocks are usually not 86 observable when comparing two homologous regions, "long enough" IBD blocks can be 87 retrieved by applying one of several recent methods to a pair of sequences (Purcell et al., 88 2007; Gusev et al., 2009; Browning and Browning, 2010). These methods are based on 89 detecting long identical shared segments (Gusev et al., 2009) or shared regions that harbor 90 multiple rare variants (Purcell et al., 2007; Browning and Browning, 2010). If two individ-91 uals share the same rare variant, they may also share the surrounding chromosomal region, 92 particularly because rarer variants are more likely to be relatively recent. Most methods 93 take sequencing errors into account, allowing IBD blocks to not be totally identical. The 94

accuracy of IBD block detection depends on the algorithm used (Browning and Browning,
2013).

Some demographic inference methods are based on the distribution of lengths of inferred pairwise IBD blocks in a population. Palamara et al. (2012) have calculated the distribution of expected lengths of pairwise IBD blocks for a given parameterized demographic model. Browning and Browning (2015) have calculated the expected time to the most recent common ancestor (TMRCA) of an IBD block as a function of its length. Then they use the empirical density of IBD block lengths to estimate the distribution of TMRCA and thus the variations of effective population size through time.

Other methods use the length of identical shared segments of chromosome within a 104 diploid individual (Hayes et al., 2003). Two identical shared segments may be inherited 105 from a common ancestor without recombination event (and then be IBD) or may not be 106 IBD as there are invisible recombination events that may have occurred within it. The 107 probability that the two haplotypes of an individual share identical alleles for a given 108 number of adjacent positions can be predicted (Hayes et al., 2003; MacLeod et al., 2009). 109 Tools have been developed to apply these methods to infer demographic inference from 110 genomic data (MacLeod et al., 2013; Harris and Nielsen, 2013). 111

Yet another approach to infer demographic history from IBD blocks is to reconstruct 112 the genome-wide distribution of the TMRCA between two haploid genomes. In PSMC, 113 Li and Durbin (2011) devised a Hidden Markov Model that infers the TMRCA from the 114 positions of heterozygous sites along a pair of sequences and then estimate a step-wise 115 demographic pattern. MSMC, the extension of PSMC (Schiffels and Durbin, 2014), ana-116 lyzes the heterozygosity pattern from multiple individuals and uses first coalescence events 117 between any two haploid genomes of the sample. These methods are computationally 118 intensive (as of today, MSMC cannot infer the demographic history of more than 8 indi-119 viduals) and pool the diversity on windows of 100 bp, that are assumed to form a single 120 locus with two states, heterozygous or homozygous. 121

Importantly, the previous methods infer stepwise changes of the "effective population size" $(N_e(t))$ that are estimated from the density of coalescence events. This motivated Mazet et al. (2015, 2016); Chikhi et al. (2018); Rodríguez et al. (2018) to propose to replace $N_e(t)$ by the more explicit *Inverse Instantaneous Coalescence Rate*. IICR only matches the instantaneous population size when the population is panmictic. It is nonetheless always possible to find a population model with constant size but spatial structure that corresponds to any IICR of a size-changing population for the TMRCA of 2 sequences (Chikhi et al., 2018). For larger samples, the joint distribution of coalescence events $[T_2, T_3, \cdots]$ can be used, in theory, to disentangle structure from demography (Grusea et al., 2019).

Existing methods for demographic inference using recombination information often use 131 the whole genome of few individuals (less than 10) or use a smaller part of the genome. 132 These methods only consider the joint history of two individuals (e.g. the pairwise IBD 133 length distribution or the time of the first coalescence event between any two haploid 134 genomes) which algorithmic complexity increases drastically with the number of individuals 135 (e.g. detection of pairwise IBD blocks is quadratic) and generates a computational load 136 limiting in most cases the application of the methods to a larger number of individuals. On 137 the other hand, with few individuals, demographic inferences are unable to detect recent 138 changes of population size. 139

Following the idea of Tiret and Hospital (2017), we decided to study the IBD concept 140 extended to a multilocus segment and a larger number of individuals (n > 2). Some studies 141 have been conducted on the amount of genetic material shared IBD with n > 2, consider-142 ing closely related individuals (Donnelly, 1983; Ball and Stefanov, 2005). We extend the 143 concept at a population level while relaxing the need for *identical* sequence (without mu-144 tation), which is why we decided to define a new term. We call 'MRF blocks' homologous 145 segments that are entirely inherited from the same ancestor without recombination; these 146 segments may or may not harbour different alleles, because of mutations. An MRF block 147 is a segment of an alignment of haploid genomes that share the same coalescent tree. A 148 recombination event along the sequence cuts the genome alignment into two MRF blocks, 149 one on each side of the recombination point. By definition there is no recombination 150 within MRF blocks so that all variants located within an MRF block are necessarily in 151 complete linkage disequilibrium. The reciprocal is not true, as variants in complete LD do 152 not necessarily belong to the same MRF block. MRF blocks carry the information of any 153 recombination event that happened among the sampled individuals. As for IBD blocks, 154 MRF blocks are usually not observable. 155

¹⁵⁶ **Outline** We have developed a new test to detect very recent population declines of en-¹⁵⁷ dangered species. We first consider the full length distribution of MRF blocks in a sample of haploid genomes $(n \ge 2)$. Second, as MRF blocks are not directly observable from sequence alignments, we devised a simple and efficient algorithm to chop an alignment of $n \ge 4$ haploid genomes in Maximal Linkage Disequilibrium (MLD) blocks, that are segments which variants are in complete LD. From the length distributions of MRF blocks or MLD blocks, we devised a summary statistic to test whether a population has been declining in the very recent past. Our method is not limited by the number of genomes in the sample.

165 2 Model and Methods

In the absence of recombination, ancestral relationships between genomes can be repre-166 sented in the form of a genealogical tree. Individual haploid genomes at present time are 167 the leaves of the tree, the MRCA of these individuals is the root. The fusion of two lin-168 eages into one (a common ancestor) is named coalescence event (Kingman, 1982), hence 169 the name of "coalescent tree". The sum of all branch lengths that separates two genomes 170 up to their common ancestor is the time of divergence between them, usually expressed in 171 generations. In the Wright-Fisher model with constant population size N, branch lengths 172 measured in number of generations scale like N. In particular, if we define T as the total 173 length of the coalescent tree, the expectation of T is proportional to N. Large popula-174 tions generate coalescent trees with deep nodes, whereas small populations have shallow 175 coalescent trees. 176

In the presence of recombination, two loci of an alignment have the same coalescent 177 tree only if no recombination event happened since their MRCA. We name MRF block, 178 a maximal interval along the alignment of sites sharing the same coalescent tree. MRF 179 blocks are consequently separated by recombination points, corresponding to recombination 180 events. It is standard to assume that conditional on the total length T of the coalescent 181 tree of a site, the length L of its MRF block is exponentially distributed with rate ρT , 182 where ρ is the recombination rate (expressed in a arbitrary unit proportional to Morgan). 183 Then for a fixed ρ , T and L are negatively correlated: recombination is more likely to 184 occur in deep trees, which thus are carried by shorter blocks. As mentioned above, as T185 is proportional to N, MRF blocks are also shorter in larger populations. More accurately, 186 because the law of T/N does not depend on N, neither does the law of NL (for n = 2187 it alludes to results of Carmi et al. (2014)). In other words, if population 1 has size N_1 188

and population 2 has size N_2 , the distribution of MRF block lengths in population 2 can be deduced from that in population 1 by a scaling factor N_1/N_2 , both populations having identical demography otherwise. For example if $N_2 = 2N_1$, the MRF blocks in population 2 are twice smaller than those of population 1.

Note that for a given N the lengths $(L_1, L_2, ...)$ of successive adjacent blocks have the 193 same distribution, but they are not independent, because the coalescent trees of adjacent 194 MRF blocks are not. The dependencies between these trees is encoded in the so-called 195 Ancestral Recombination Graph (ARG) (Griffiths and Marjoram, 1997). Because these 196 dependencies have a complex structure (Wiuf and Hein, 1999), a popular way of approxi-197 mating them is the Sequentially Markovian Coalescent (SMC) (McVean and Cardin, 2005; 198 Marjoram and Wall, 2006). This approximation neglects coalescences between lineages 199 with no overlapping ancestral material and assumes Markovian dependencies of coalescent 200 trees along the sequence: the genealogy of an MRF block only depends on the genealogy 201 of the adjacent ones. 202

Although genealogies of different MRF blocks are not independent, they are asymptotically independent as the distance between them increases.

Throughout this article, we use msprime to generate MRF blocks directly from the ARG (Kelleher et al., 2016) but very similar results were obtained with a local SMC implementation. We assume constant recombination and mutation rate along the genome. We simulated the alignment of n = 10 haploid genomes at present time.

Demographic scenario. We consider a single change of population size (Fig 1a). Here N_t represents the population size at time t, t = 0 is the present time and positive values represent the past. We denote by κ the ratio of the two sizes: $\kappa = N_{\infty}/N_0$, and by τ the time at which the population size changes in coalescent units of N_0 generations. If $\kappa = 1$, $N_{\infty} = N_0$: there is no change. If $\kappa = 10, N_{\infty} = 10N_0$: the population size has been divided by 10, τN_0 generations in the past.

215 **3 MRF blocks**

216 **3.1** Distribution of block lengths

Impact of population decline on tree length. For declining populations ($\kappa > 1$), the 217 coalescent trees have two distinct time scales: a first one for the shallow part of the tree 218 $(t < \tau)$, expressed in N₀ generations, and a second one for the deep part of the tree $(t > \tau)$ 219 that is expressed in κN_0 generations. When the declining population tree is compared to a 220 standard coalescent tree (constant population size), it has shorter external branches if the 221 reference time scale is expressed in κN_0 generations or longer internal ones if the reference 222 time scale is expressed in N_0 generations. When it is compared to a reference tree with 223 population size chosen so as to have the same T_{MRCA} , its external branches are too short 224 and its internal branches are too long. Similarly, the distribution of the total length T of 225 the tree is overdispersed when compared to the length of the standard coalescent tree with 226 the same mean. 227

Impact of population decline on lengths of MRF blocks. For a declining population, 228 the distribution of the length L of MRF blocks will depend not only on ρ and N_0 but also 229 on κ and τ . As the tree relative branch lengths are distorted and the distribution of T 230 is overdispersed, so is the distribution of L. In a declining population, the distribution 231 of L can be seen as a mixture of the two distributions that correspond to the two pop-232 ulation sizes, N_0 and κN_0 . The strength of the decline (κ) tunes the difference between 233 the distributions; the date of decline (τ) tunes in what proportion the two distributions 234 are mixed. When $\tau \to 0$ (practically, $\tau < 10^{-4}$ times N₀ generations for a sample size 235 $n \in [10, 100]$), the distribution of L is indistinguishable from that of block lengths in a 236 population with constant size equal to κN_0 . At the opposite, for $\tau \to \infty$ (practically, 237 $\tau > 10$ times N_0 generations for a sample size $n \in [10, 100]$, the distribution of L is indis-238 tinguishable from that of block lengths in a population with constant size equal to N_0 . As 239 a result for $\tau \in [10^{-4}, 10]$, the distribution of L has an excess of MRF blocks smaller than 240 the N_0 reference and an excess of MRF blocks longer than the N_∞ reference (Fig 1b). The 241 small blocks correspond to the trees which total length T is mostly driven by the distant 242 N_{∞} time scale and the long ones to the trees which total length T is mostly driven by the 243 recent N_0 time scale. 244

As mentioned in the previous section, in a population with constant size N, the distribution of L, briefly denoted L_N , scales like 1/N, in the sense that the distribution of $\tilde{L} := NL_N$ does not depend on N. In particular, the distribution of L' := L/E[L] does not

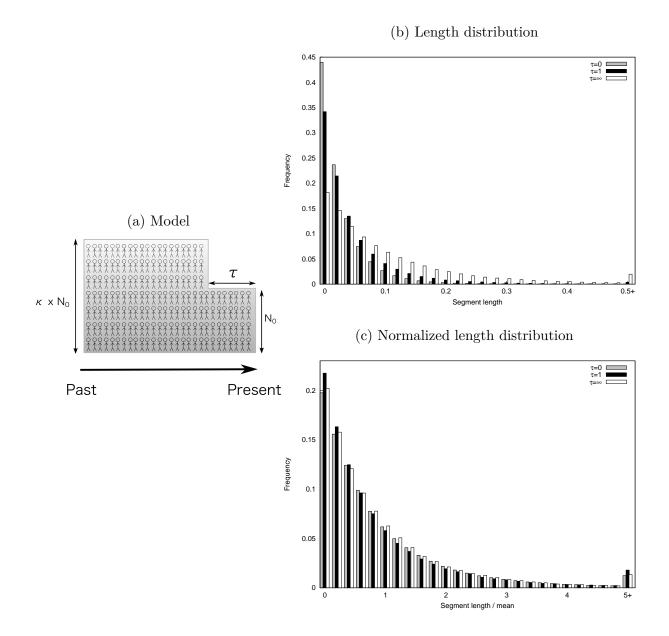

Figure 1: Impact of the demography on the distribution of MRF block lengths. (a) The demography considered here is a sudden size change tuned by 3 parameters : N_0 , the actual population size, τ the date of decline (in backward time) and κ the strength of decline. Time is expressed in N_0 generations. (b) Distribution of L for $\rho = 1$, $\kappa = 3$ with $\tau = \{0, 1, \infty\}$. When $\tau = 0$ (grey) or $\tau = \infty$ (white), population size is constant. (c) Distribution of L' = L/E[L] under the same values of $\rho = 1$, κ and τ . In case of a decline, the distribution is overdispersed, with an excess of both short and long normalized MRF blocks.

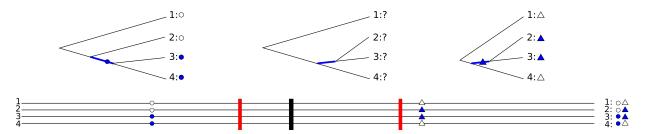

Figure 2: Detection of recombination in three MRF blocks. The four lines represent four haploid genomes, circles and triangles are mutation events, red lines are the true recombination events delimiting MRF blocks and above each MRF block is represented its true tree. Mutation events occur on certain lineages as represented on the trees. The first recombination event generates an incompatibility between the blue branches of the first two MRF blocks, but as no mutation occurs on the second MRF block, this recombination event cannot be detected. The second recombination event does not change the topology of the tree and thus this second event cannot be detected either. However, the first and the third MRF blocks carry mutations that are not compatible; thus a minimum of one recombination event can be inferred between the two mutations, as indicated by a vertical thick black line arbitrarily placed in the middle.

depend on N in a population with constant size and follows the law of $\tilde{L}/E[\tilde{L}]$. However, the distribution of L' is distorted when there is a size change. For a declining population, the distribution of L' is overdispersed, it has an excess of small blocks (*i.e.* less than 0.2)

and an excess of long blocks (*i.e.* more than 5), as can be seen on Fig 1c. (i.e. more than 5)

Note that we always have E[L'] = 1, but here E[L] has

$$\frac{1}{N_{\infty}}E[\tilde{L}] = E[L_{N_{\infty}}] < E[L] < E[L_{N_0}] = \frac{1}{N_0}E[\tilde{L}].$$

As the block distribution of L_N is a mixture of the one of L_{N_0} and $L_{N_{\infty}}$, E[L] is bounded by $E[L_{N_{\infty}}]$ and $E[L_{N_0}]$ that depend on the population size.

255 4 MLD blocks

256 4.1 Definition

All recombination events are not directly visible in a genome alignment. First, adjacent MRF blocks may have coalescent trees sharing the same topology and the same branch lengths, so that mutations occurring on either tree show exactly the same pattern on either block. Second, adjacent MRF blocks may have coalescent trees sharing the same topology but not the same branch lengths, so that mutations occurring on either tree display the same bipartitions (compare the second and third tree in Figure 2). Third, even if two adjacent MRF blocks have trees with different toplogy, it is possible that branches distinguishing these topologies do not carry mutations (see the second block in Figure 2). Importantly, recombination events that happen between the two oldest lineages do not impact the topology of the tree, so are never detectable because they do not impact the

²⁶⁷ possible bipartitions.

A possibility used in the literature to detect breakpoints between MRF blocks is to detect the changes in the density of polymorphic sites along the sequence due to the change of coalescent tree (like in PSMC, Li and Durbin (2011)).

Here we used instead the incompatibilities between bipartitions displayed by polymorphic sites to place the minimal number of recombination events on the alignment. Two bipartitions are said incompatible when they are not compatible with a common tree.

In what follows, we will assume that the mutation rate μ is constant through time and along the genome.

276 4.1.1 The four-gamete test

From now on, we assume that each site can be hit at most once by a mutation, so that 277 a polymorphic site is always bi-allelic, an assumption known as the "infinitely-many sites 278 model". The four-gamete test (Hudson and Kaplan, 1985) serves to detect incompatibilities 279 between bipartitions displayed by two polymorphic sites. For any two biallelic sites (A/a 280 and B/b) there are at most four gamete haplotypes in the population (A-B A-b a-B and a-281 b). Under the infinitely-many sites model, the four possible haplotypes cannot be observed 282 in a sample if the two sites share the same genealogy. Then if the four possible haplotypes 283 are observed in the sample, a recombination event must have occurred between them – 284 but not necessarily the other way round. This property can be used to compute a lower 285 bound for the number of recombination events in a genome alignment (Hudson and Kaplan, 286 1985) or even to estimate the recombination rate (Hey and Wakeley, 1997). We used it to 287 compute and place the minimal number of breakpoints in a genome alignment. 288

Two polymorphic sites are said *incompatible* if the four possible haplotypes are present in the sample. When a sequence of adjacent polymorphic sites contains no pairwise incompatibility, we speak of a sequence of compatible sites. Note that a sequence of compatible sites are in complete linkage disequilibrium. We thus define an MLD block, for *Maximal*

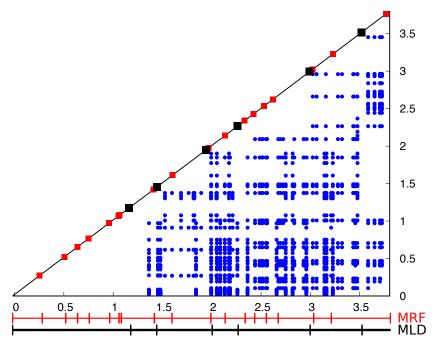

Figure 3: The incompatibility matrix and the chopping algorithm. X and Y-axis are positions on the genome alignment. Blue dots represent a pair (x,y) of incompatible sites. The red squares are the true positions of recombination events (MRF breakpoints) and the black squares are MLD breakpoints inferred by the chopping algorithm.

²⁹³ Linkage Disequilibrium block, as any maximal sequence of compatible sites.

We now explain how to extend this notion originally designed for haploid genomes (or phased diploid genomes) to an unphased diploid genome, that is, a diploid sequence lacking the linkage information. For an unphased diploid genome, the two original haplotypes can be determined if the diploid genome is homozygous at at least one the two sites:

- When the genome is homozygous at both loci (A/A-B/B), both haplotypes must be A-B.
- When the genome is homozygous at one locus and heterozygous at the second one (A/A-B/b), the haplotypes must be A-B and A-b.

The four-gamete test can then be extended to a sample of unphased diploid genomes by saying that two sites are incompatible in this sample if they are incompatible in the subsample of haplotypes that have been inferred thanks to the previous remark. When the haplotype is ambiguous, the sites are considered compatible and do not bring more information about a recombination event.

307 4.1.2 The chopping algorithm

We used the four-gamete test to detect incompatibilities in the genome alignment and to chop it into MLD blocks (Fig 3). To avoid computing the full matrix of pairwise incompatibilities between all polymorphic sites of the genome, we only compute the incompatibilities for sequences of P adjacent polymorphic sites (by default P = 150). Each pair of incompatible sites (i, j) defines an interval that contains at least one MLD breakpoint. To place the MLD breakpoint, we seek the shortest interval that is sufficient to explain the incompatibilities.

Algorithm: We retrieve all intervals and sort them in increasing order of site positions along the genome (first by i the first site position and when equal, by j the second site position). As we scan two times the list of intervals, the algorithm complexity is linear with the number of polymorphic sites:

1. Discarding and shortening. For this step, we scan the list in reverse order, from 319 the last (N) to the first interval. (The algorithm can be done in the forward order, 320 the distribution will be slightly different but it will not affect the study.) Each 321 interval containing another entire interval is discarded: for two intervals (i_N, j_N) 322 and (i_{N-1}, j_{N-1}) , if $i_N \leq i_{N-1} \leq j_{N-1} \leq j_N$, then (i_N, j_N) is discarded. When two 323 intervals overlap, they are replaced by their intersection (the two original ones are 324 discarded): for the two intervals (i_N, j_N) and (i_{N-1}, j_{N-1}) , if $i_{N-1} \leq i_N \leq j_{N-1} \leq j_N$, 325 both are replaced by a new interval (i_N, j_{N-1}) , that is then compared to (i_{N-2}, j_{N-2}) ... 326

2. **Positioning.** From the final list of disjoint intervals, we place an MLD breakpoint at the middle of each interval.

³²⁹ MLD breakpoints partition the genome alignment into MLD blocks.

4.2 Length distribution

The distribution of the length L_c of a typical MLD block does not only depend on the distribution of L (MRF block length) but also on the fraction p of recombination events that are detected. This fraction increases with the ratio μ/ρ , as illustrated in Figure 4a. When many mutations occur in two different MRF blocks ($\mu \gg \rho$), the probability that they occur on incompatible branches of their respective coalescent trees increases and so

(a) Factors impacting the power of detection

(b) MLD block lengths

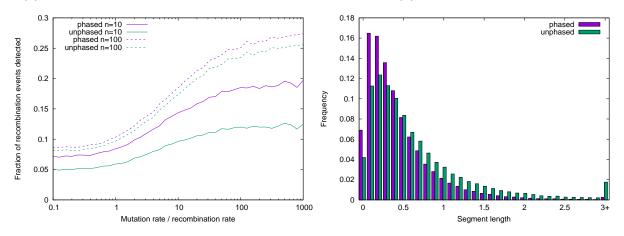

Figure 4: Detection of recombination events and its impact on MLD block length (L_c) distribution under a constant population. (a) Fraction of recombination events that are detected as a function of μ/ρ for different sample sizes (n = 100, dashed lines and n = 10 plain lines) and for phased (purple) or unphased (green) diploid genomes. (b) Distribution of MLD block lengths for phased (purple) and unphased (green) diploid genomes in a population of constant size $(\mu = 10, \rho = 1, n = 10)$.

does the detection efficiency, up to a point of saturation due to cases when these MRF blocks share the same tree topology. The number of sampled individuals also impacts the efficiency of detection (Fig 4a): the larger the sample size, the higher the probability to observe incompatible mutations. The four-gamete test for unphased diploid genomes has obviously less power to detect recombination than for phased genomes (Fig 4a).

The lower the power to detect recombination, the longer the MLD blocks. In particular, 341 phased genomes have smaller MLD blocks than unphased ones (Fig 4b). Furthermore 342 increasing the sample size results in more detectable recombination points and thus smaller 343 MLD blocks. In Figure 4b, the average block length, in our arbitrary unit for n = 10 phased 344 haploid genomes is $\bar{L}_c = 0.497 \ (\mu = 10, \rho = 1)$. Considering smaller sample size will result 345 in larger MLD blocks (e.g. $\bar{L}_c = 1.32$ for n = 5). This implies that the total number of 346 blocks can be limiting for small sample size, and that these long blocks will be harder to 347 detect in scaffolds of partial genomes. In (very) large samples, MLD blocks are shorter: 348 $\bar{L}_c = 0.132$ for n = 600 (ten times smaller than for n = 5) and $\bar{L}_c = 0.103$ for n = 6,000. 349 On a side note, the theoretical pitfall of having too small "undetectable" blocks can always 350

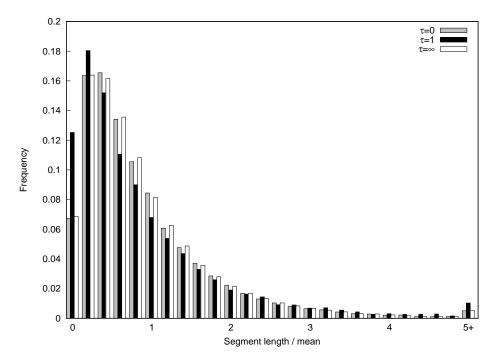

Figure 5: Distribution of L'_c for a population of constant size (white, $N = N_0 = 1$ and grey, $N = \kappa N_0 = 3$) and for a declining population (black for $\tau = 1$) with $\rho = 1$, $\mu = 10$ and n = 10.

³⁵¹ be overcome by subsampling.

Here, we consider the block lengths normalized by the average length $L'_c = L_c/\overline{L_c}$. Similarly to the MRF blocks, the distribution of L'_c does not depend on the value of N but does depend on the demographic scenario (Fig 5). However, it still depends on our ability to detect recombination and so on the ratio μ/ρ and n the number of sampled individuals. To compare distributions, it is then important that they have the same ratio μ/ρ and the same n.

Similar to what we have observed for MRF blocks, a declining population exhibits both an excess of small blocks ($L'_c < 0.2$) and large blocks ($L'_c > 5$) (Fig 5). The shape of the distribution of L'_c (Fig 5) differs from the one for L' (Fig 1c): MLD blocks are longer than MRF blocks. Indeed, they contain a variable number of MRF blocks and below a certain size, MRF blocks are not detectable as recombination points at the edges of an MRF block can be detected only when mutations have occurred inside the block. MLD blocks are always longer than MRF blocks.

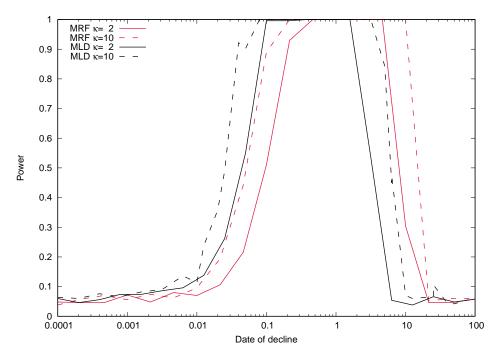

Figure 6: Power to detect population decline. The test based on MRF blocks (f) is pictured in red, whereas the one based on MLD blocks (f_c) is represented in black. We assess the power of the two tests for $\kappa = 2$ (plain line) and $\kappa = 10$ (dashed line) with $\tau \in [0.0001, 100]$.

5 Statistical tests for population decline

366 **5.1 Test**

To test for population decline, we use the excess of small and large blocks that we observe 367 when comparing samples from a declining vs a constant population size. More specifically, 368 we compute the fraction of blocks which normalized length is either smaller than 0.2 or 369 larger than 5, both in the case of MRF blocks $(f = f_{L'<0.2} + f_{L'>5})$ and of MLD blocks 370 $(f_c = f_{L'_c < 0.2} + f_{L'_c > 5})$. To set an empirical threshold value under H_0 , we simulate 10,000 371 genomes of 10^5 MRF blocks under a constant population size for 10 haploid genomes 372 and compute both $f^{5\%}$ and $f^{5\%}_c$ as upper limits for one-tailed tests: $f^{5\%} = 0.214236$ 373 and $f_c^{5\%} = 0.075824$. As the threshold is empirical, simulations need to be redone for 374 a change in sampled size or in null model. Time needed for simulations depends on the 375 algorithm/software used and the specific features of the model. 376

377 5.2 Power

To assess the power of this test, we simulated 1,000 replicates under population decline (H_1 with various τ and κ) and report the fraction of runs where $f^{H_1} > f^{5\%}$ for MRF blocks or $f_c^{H_1} > f_c^{5\%}$ for MLD blocks. When the power is 1, the decline was significant in all runs. When the power is 5%, the decline is not detectable, the test can not differentiate H_0 and H_1 .

Without surprise, results show that the power of the test to detect population decline 383 depends on both the decline strength (κ) and the date of decline (τ) (Fig 6). For both 384 tests based either on MRF or on MLD blocks, the power outreaches the 5% risk only for 385 a range of τ . The type I error of the test is 5% as expected. For both tests, the range 386 of detection is wider when the decline is stronger (compare dashed to solid lines in Fig 387 6). The surprise is that the test based on MLD blocks (f_c) detects more recent declines 388 than the test based on MRF blocks (f). Therefore, we recommend using the f_c test when 389 searching for very recent decline even if MRF blocks are known (which is generally not the 390 case). 391

³⁹² 6 Application to data: the case of the western lowland ³⁹³ Gorillas

6.1 Handling the low quality of real genomes

Genomic data sets often include sequencing errors and regions that are not genotyped. Consequently, the f_c test cannot be run as is on these data sets. We present some modifications to our test to handle the poor quality of data. We show in this section that adjustments can be made to get the information from the L'_c distribution.

399 Simulations with lower quality

Difficulties in applying the f_c test to real data sets can stem from the low quality of DNA sequences. We replicated in the simulated genomes the two main issues, namely the interruptions of DNA tracts and the absence of genotyping for some SNPs in some individuals.

⁴⁰⁴ DNA tract interruptions truncate MLD blocks and make their detection difficult. The

number, size and location of these interruptions will have an effect on the detection of MLD blocks and thus will alter the L'_c distribution. To handle the effect of interruptions, we placed the interruptions at the same positions in our simulated chromosome as in the real chromosome.

As for the partial genotyping issue, we artificially lowered the genotyping quality in the simulated chromosomes. We used the empirical distribution of missing individuals (e.g. chr1 of *Gorilla gorilla*, Fig 7) to pick random positions in the simulated chromosome and erase the genotypes of some individuals.

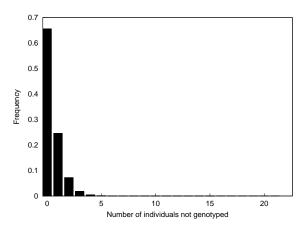

Figure 7: Distribution of the number of individuals not genotyped per SNP on chromosome 1 of the Gorillas dataset (Prado-Martinez et al., 2013).

413 Mutation rate and recombination rate

To cope properly with the issue of genotyping, we simulated chromosomes with the same number of mutations and the same MLD length mean as in the studied data set. We use the Watterson estimator (Watterson, 1975) for the mutation rate and fixed the recombination rate so that simulated and real chromosomes had the same average length of MLD block.

6.2 Application to Chr1 of Gorilla gorilla gorilla

We applied this methodology on chromosome 1 of twenty-three unrelated western lowland Gorillas (*Gorilla gorilla gorilla*) from the Great Ape Genome Project (Prado-Martinez et al., 2013). The chromosomes have 247,249,719 base pairs. The 23.1% of sites that are considered "low coverage"(Prado-Martinez et al., 2013) divide the chromosome alignment into 6,277,293 uninterrupted stretches. The 5,388,083 interruptions due to a single site
were not considered as *interruptions*. To speed up simulations, we considered stretches
longer than 499 sites, as smaller stretches often carry no entire MLD block. We chopped
chromosome 1 using a window of 150 polymorphic sites, into 7,082 MLD blocks with an
average length of 307.897 bp.

⁴²⁸ **Distribution of** L'_c

The distribution of L'_c for our sample of gorilla sequences has an excess of small and long MLD blocks compared to the L'_c distribution of a constant population with the same characteristics (same number of mutations and same average length of MLD blocks) (Fig 8). The excess of small blocks is even larger than what we see in simulated declines (see above). The truncation of long MLD blocks due to the inclusion of low quality of genotyping can potentially inflate this excess.

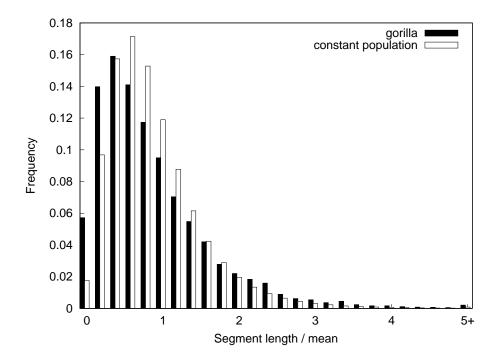

Figure 8: Distribution of L'_c for a population of constant size (white, mutation rate= 0.000375, recombination rate= 0.012) and for the chromosome 1 of the gorillas (black)

With the low quality of genotyping and the chosen mutation and recombination rates, the threshold value $f_c^{5\%}$ is 0.041627. As we measure $f_c^{gor} = 0.0631178$ for the gorillas, the test significantly rejects H_0 . However, it is possible that other designs of similar tests (tweaking the lower or upper bounds) may be more relevant to analyze demography from low quality chromosome alignments.

However, and this may be even more important, misspecifications of the model can also
make the test significant. Among all, we have chosen to explore the impact of recovery
after the decline and of spatial structure.

443 **7** Misspecification of H_1

To appreciate how the f_c test, that was specifically designed to detect population decline, is sensitive to other violations of H_0 , we explored their sensitivity to a scenario of bottleneck (decline followed by recovery) and to a scenario with structure but no demography.

447 7.1 Bottleneck

In the bottleneck scenario, we model a population that experienced a sudden strong decline 448 $(\kappa = 10)$ at time $\tau = 1$ in the past and recovered to its original size after a duration of 449 $x \in [0,1]$. If x = 0, there is no population decline. If x = 1, the population has not 450 recovered and the bottleneck scenario is identical to our original H_1 . When the bottleneck 451 lasts long enough (x > 0.02), it is detected by the f_c test (Fig 9b). On the contrary, when 452 the bottleneck is too short (x < 0.02), the distribution of L'_c is similar to the one under H_0 453 (Fig 9a). This shows that even if the population has recovered, the signal of decline will 454 be observable in the excess of short and long MLD blocks. 455

456 7.2 Island-mainland structure

Structured populations generate signals of population size change, even when the popula-457 tion is stationary (Mazet et al., 2015). For example if the size of the sample is n = 2, for 458 any population model with spatial structure, there exists a model without structure but 459 specifically designed variations of population size which has the same distributions of coa-460 lescence times (Mazet et al., 2016). We consider here a larger sample size (n = 10, as in the461 other scenarios). We assume that genomes are sampled from an island with population size 462 N and the island receives migrants with individual rate m from the mainland, which has 463 population size 10N. The shape of the distribution of L'_c is impacted by the migration rate 464

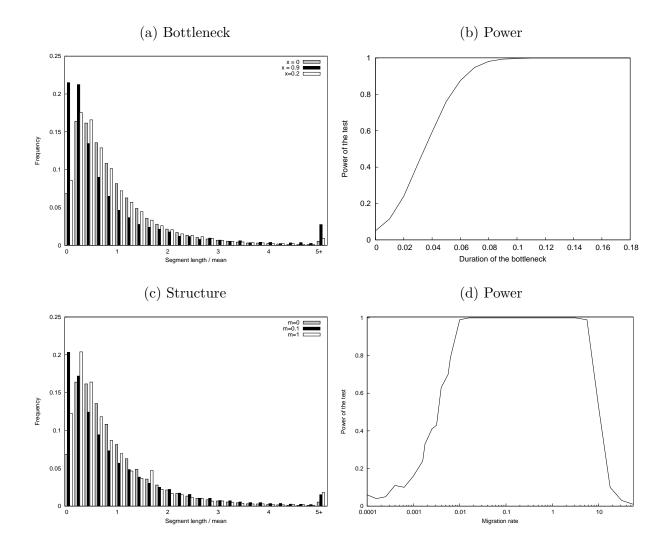

Figure 9: Distribution of L'_c and power of the f_c test under two alternative scenarios. (a) In the bottleneck scenario, the population size is constant equal to N except during the period [1 - x, 1] (measured in units of N generations backwards from the present) during which it equals N/10, with $x = \{0, 0.2, 0.9\}$ (x = 1 corresponds to decline without recovery). (b) Power of the f_c test on the bottleneck population as a function of the duration of the bottleneck, $x \in [0, 0.18]$. (c) In the island-mainland scenario, the population size is constant equal to N (island) and receives migrants at individual rate $m = \{0, 0.1, 1\}$ from a population of size 10N (mainland). (d) Power of f_c test as a function of m, the migration rate from the mainland to the island.

and the ratio of population sizes between the island and the mainland (data not shown). 465 When the migration rate gets too small (m < 0.001) or too large (m > 10), the distribution 466 of L'_c is the same as under H_0 (Fig 9c). For intermediate values (*i.e.* 0.001 < m < 10), 467 an a excess of short and long blocks will be observed (Fig 9d). However, the shape of the 468 distribution of L'_c is visually different from the one of a declining population, that is, the 469 excess of small blocks is higher than under a declining scenario. For a value of m = 0.1, 470 the proportion of blocks between 0 and 0.1 times the mean is significantly higher than the 471 proportion of blocks between 0.1 and 0.2 times the mean, which is not observed for the 472 distribution of block lengths under decline. This suggests that the distribution could be 473 used to differentiate between the effects of demography and structure. 474

475 8 Discussion

We have explored the impact of demography, more specifically recent population decline, 476 on the pattern of recombination in a sample of n genomes, where $n \gg 2$. We have shown 477 that the distribution of the distances between recombination breakpoints (MRF block 478 lengths) is strongly affected by the demography. More specifically, a decline will result in 479 an overdispersion of the distribution, that is, a relative excess of short and long blocks. 480 As most recombination breakpoints are difficult, and sometimes impossible, to detect in a 481 sequence alignment, we have proposed to restrict ourselves to the ones that can be detected 482 using the four-gamete test. These detectable breakpoints delineate blocks in full linkage 483 disequilibrium that we named MLD blocks. 484

Although different from the distribution of MRF blocks, the distribution of MLD block lengths is also overdispersed when the population has been declining recently. Using simple tests based on an excess of small and long blocks (f and f_c), one can detect declines for a wide range of different dates and strengths.

Surprisingly, the f_c test based on MLD blocks has more power for very recent declines ($\tau \approx 0.01$) than the f test based on MRF blocks. The past demography of the population impacts the distribution of the length L of MRF blocks but also the fraction p of MRF breakpoints that also correspond to MLD breakpoints. When recombination occurs at distant times when only $k \ll n$ ancestor lineages are present (*i.e.* the most ancient times of the tree), it rarely produces incompatibilities detectable with the four-gamete test (never when k = 2). For a declining population, these ancient lineages have longer branches

than the ones of a constant population scenario, so that recombination events occur more 496 frequently in these lineages. This results in a smaller p for declining populations and thus 497 in more numerous (ancient, small) MRF blocks per MLD block. The relative abundance of 498 long recent MLD blocks becomes thus more important in the distribution. This effect fades 499 away for distant declines. In summary, the effect of recent declines on the L_c distribution 500 is the result of both a change in the L distribution and a change in the fraction p of 501 breakpoints detected, which can explain the difference in power between the f and the f_c 502 tests. 503

We also show that using the f_c statistic, the decline can still be detected even if the population has recently recovered its original size (bottleneck scenario). Finally, we showed that local sampling of a small deme with constant size also leads to rejection of H_0 for f_c but that the distribution of block lengths seems distorted in a way that can help distinguish the two scenarios. We leave this for future work.

One interesting advantage of using the f and f_c tests are their efficiency in computing 509 time, such that they can scale up to a very large sample of long genomes. For example, the 510 chopping of the entire human chromosome 1 (1.636.975 SNPs) for a sample of 10 unphased 511 genomes takes 16 seconds on a laptop (with an Intel Core i7 processor running macOS High 512 Sierra). This very short computing time is an interesting asset of this test compared to 513 other methods based on variations (e.g. in SNP density) induced by recombination events 514 (Li and Durbin, 2011; Palamara et al., 2012; MacLeod et al., 2013; Harris and Nielsen, 515 2013; Browning and Browning, 2015). The main choice that influences the computation 516 time of the chopping algorithm is the number of sites considered for the chopping window. 517 An increase in the chopping window size will increase the number of sites to test for 518 incompatibility. 519

In the theoretical assessment of the f_c test, we have made the assumption that the recombination rate is constant along the genome and that entire genomes are aligned. Let us discuss the limits of these assumptions.

First, the recombination rate is known to vary along the genome, especially in regions of high recombination known as recombination hot-spots. It could be possible to integrate these variations via the knowledge of the recombination map. Indeed, if the recombination rate is twice higher in a given region of the genome, MRF blocks will be twice smaller, so ⁵²⁷ we can correct this distortion by multiplying all MRF block lengths by 2.

Another issue of the test based on MLD block lengths is the need of whole genome data. For normalisation of the MLD block distribution, the average length of a block is needed. If the whole distribution of MLD block is not available, it can compromise the estimate of the average length, and so can compromise the test based on the normalised distribution. The test requires genome data with good SNP quality for all the individuals.

The f_c test is a genome-wide approach that can detect population decline that started 533 even very recently, down to orders of $\tau = 0.01 N_0$, where N_0 is the current (effective) 534 population size. This corresponds to very recent times, in particular when considering en-535 dangered populations. For example, there are approximately 600 mature mountain Gorilla 536 individuals alive (IUCN Red List of 31 July 2018). Assuming that the current effective 537 population size is a third of the mature individuals, $N_0 \approx 200$, the f_c test will detect 538 decline as recent as 0.01 * 200 = 2 generations ago. Great apes populations (Bonobos, 539 Chimpanzees, Orangutans) have been sequenced (Prado-Martinez et al., 2013) and are 540 actively re-sequenced (Gordon et al., 2016). The coverage used to sequence the data cur-541 rently available is not high enough to apply our test. To infer MLD blocks, the sequenced 542 DNA tracts need to be uninterrupted. Using these whole-genome data in higher quality, 543 we will be able to confirm their decline thanks to the f_c test. 544

Giant pandas have a 'vulnerable' conservation status in the Red List. Recently they 545 have seen their population increased (around 500 mature individuals, from IUCN website 546 2019). Applying the f_c test on some genomes of theirs (Zhao et al., 2013) sequenced in 547 higher quality, will give some precise information on their demography. As the test is 548 influenced by duration and strength of a bottleneck, the strength and the date of the 549 increase in the population size impact the result of the test. Applying the f_c test to 550 mammals with approximately known demography will be interesting to verify the method. 551 However, the real asset of this test is its possible application to a much wider range of 552 organisms. Whole-genome data start to become more and more common for non-model, 553 non-vertebrate organisms like honeybee (Wallberg et al., 2014), as well as organisms with 554 no conservation status such as mimicry butterflies (Zhang et al., 2017). 555

The chopping algorithm detects incompatibilities among trees along the genome. All the sites in a MLD block are compatible with one topology. We developed the algorithm to detect a recent change in population size. However, its use is not limited to population
demography. Conflicting genealogies are also present in phylogenetic inference (Maddison,
1997). This algorithm could be used to partition the genome according to compatible trees
before estimating the trees.

Recombination and mutation events leave a joint imprint on genomes which depends notably on the demography of the population. Their frequency and locations carry information about the past history of this population (decline, bottleneck, structure...). Using MLD breakpoints to chop genomes gives insights into this history and may be used to gain further information on other aspects impacting the frequency of recombination events through time and along the genome (e.g. hitch-hiking due to selection).
