15	Abstract
16	In situ X-ray Micro-Tomography (XMT) analyses with a pixel size of 0.325 $\mu$ m were conducted on
17	slag-based blended cements containing 75% of Ground-Granulated Blast-Furnace Slags (GGBS) and
18	25% of Ordinary Portland Cement (OPC), with or without CaCl <sub>2</sub> acceleration. Results show the
19 20	identification of the main cementitious phases and the need to perform data repeatability tests in order to allow their quantification. Investigation of the early hydration during the first 31 h of hydration by
20 21	image subtraction showed (i) the dissolution of OPC/GGBS, (ii) the precipitation of hydrates including
22	C-S-H, (iii) the accelerating effect of CaCl <sub>2</sub> , and (iv) phase-identification based on their specific grey
23	level.

#### 31 I. Introduction

Blended cements with high substitution rates of Ordinary Portland Cement (OPC) by Supplementary Cementitious Materials (SCMs) have the potential to significantly lower CO<sub>2</sub> emissions in the construction industry. Typical SCMs include blast-furnace slag, fly ash, silica fume, natural pozzolans, metakaolin and limestone [1–4]. At high substitution rates (>20-30%), the early strength development of blended cements is, however, reduced compared to plain OPC, because most SCMs have slower hydration rates than clinker phases [5,6]. Accelerating admixtures such as calcium chloride (CaCl<sub>2</sub>) improve the early age reactivity and microstructure development of blended cements [7–10].

39 Cement hydration is a coupled dissolution/precipitation reaction, where clinker ( $C_3S$ ,  $C_2S$ ,  $C_3A$ , C<sub>4</sub>AF) and SCM phases dissolve in a basic medium to precipitate hydrate minerals such as C-S-H, 40 41 portlandite (CH), ettringite and AFm in the pore space. Traditional tools to investigate the hydration 42 reaction include Scanning Electron Microscopy (SEM), X-Ray Diffraction (XRD), solid-state Nuclear 43 Magnetic Resonance spectroscopy (NMR), Thermogravimetric analyses (TGA), isothermal calorimetry 44 and mercury intrusion porosimetry (MIP) [11]. These techniques are suitable for observing, identifying 45 and/or quantifying the evolution of the unreacted phases, hydrates and porosity during hydration. 46 However, at early ages of hydration (i.e., during the first 48 h), the use of conventional tools is limited 47 by sample preparation as (i) early age blended cement pastes have not hardened enough to be cut, 48 polished and resined for SEM observation [12], (ii) the physicochemical reactions progress quickly, 49 which requires a hydration stoppage (usually leading to microstructure alterations) [13], and (iii) carbonation, i.e., reaction between hydrated phases and CO<sub>2</sub>, is a supplementary source of degradation 50 51 of the original matrix [11]. In addition, SCM hydration is sometimes difficult to monitor and to 52 discriminate from that of OPC, as dissolution of both SCM and OPC leads to similar hydration products 53 (e.g., C-S-H), and because most SCMs are amorphous alumino-silicates hardly detectable by common 54 lab devices [3]. In theory, an ideal tool to investigate the early hydration of blended cements would 55 involve (i) an *in situ* analysis, and thus no hydration stoppage, (ii) short acquisition times, and (iii) the 56 possibility of differentiating between the SCM and OPC reactions.

57 Synchrotron X-ray Micro-Tomography (XMT) allows 3D visualization of a given sample using 58 a pixel size of about 1 µm under in situ conditions. This technique has been used to study the microstructure, degree of hydration, permeability, fracturing, and damage of various cements at later 59 60 stages of hydration [12,14–17]. A 3D volume of a sample is reconstructed from thousands of 2D images 61 recorded at various angles [18–21]. The 2D projections, also called radiographs, record the variations in 62 the X-ray linear attenuation coefficients  $\mu$ , which are dependent on the incident X-ray beam energy, and 63 elemental composition and density of the sample components. In cements, Gastaldi et al., 2012 have reported a  $\mu$  value of 1.8 cm<sup>-1</sup> for water, 17.5 cm<sup>-1</sup> for ettringite, 32.0 cm<sup>-1</sup> for C-S-H, 44.8 cm<sup>-1</sup> for 64 65 portlandite, 55.8 cm<sup>-1</sup> for C<sub>3</sub>A, 63.1 cm<sup>-1</sup> for C<sub>2</sub>S, 65.4 cm<sup>-1</sup> for C<sub>3</sub>S, and 102.6 cm<sup>-1</sup> for C<sub>4</sub>AF, for an

incident beam energy of 14 keV [22]. The relatively close  $\mu$  values imply that most of the phases have low grey level contrasts on the XMT images and corresponding histograms. Nevertheless, the porosity, hydration products, and anhydrous phases can be differentiated.

69 Lately, XMT has been used to study the early hydration of various highly reactive cements 70 [12,22–24]. In most studies, the same samples are scanned at fixed time intervals during the first day(s) 71 of hydration, and the resulting XMT images and corresponding grey level histograms are compared to 72 evidence (i) the progressive dissolution of clinker phases, (ii) the precipitation of hydrates, and (iii) the 73 reduction of porosity. For example, Chotard et al., 2003 studied the microstructure development of a 74 calcium aluminate cement between 1 and 24 h of hydration, and showed that the X-ray linear attenuation 75 coefficient varied with the hydration time. Helfen et al., 2005 investigated the formation and development of microcracks and pores in an OPC paste between 8.4 and 16.5 h of hydration. Gastaldi 76 77 et al., 2012 monitored the precipitation and dissolution of cementitious phases from 1 to 12 h on three 78 cement pastes (OPC, calcium sulfoaluminate cement (CSA) and an OPC/CSA mix), and proposed a new 79 method to determine the specific grey levels of various cementitious products in the histograms. Finally, 80 Parisatto et al., 2015 evaluated the influence of the water/cement ratio on two OPC pastes, from 1.75 to 81 71 h of hydration. Most of the time, the microstructural changes were evidenced on histograms because 82 of the complexity and heterogeneity of the materials in the XMT images. Image segmentation was performed in order to quantify the amount of cementitious phases on a Representative Elementary 83 84 Volume (REV), which a priori represents the structural and macroscopic properties of the material 85 [12,14,25–28].

86 From the above-cited literature, XMT appeared ready for common use to monitor early 87 hydration. Therefore, in the present study, XMT was used to investigate more complex and slower 88 reacting materials, i.e. blended cements containing 75% of Ground-Granulated Blast-furnace Slags 89 (GGBS) as SCM and 25% of OPC, with or without CaCl<sub>2</sub> addition as an accelerator. The samples were 90 cast into 300 µm capillaries and scanned during the first 31 h of hydration, resulting in XMT images 91 with a pixel size of 0.325  $\mu$ m. The images were first qualitatively analyzed by morphological and 92 histogram analyses in order to identify the cementitious phases. Then, the REV size was determined in 93 view of phase quantification. Data repeatability tests were carried out in order to evaluate the method 94 error. Early hydration was further investigated by based on histograms and image comparisons of 95 samples scanned at different hydration times. Finally, image subtraction was used to evidence the 96 hydration reactions, such as the dissolution of the anhydrous phases, precipitation of hydrates, as well 97 as their specificities (spatial distributions, specific grey levels in the histograms).

#### 98 II. Materials & Methods

#### 99 2.1. Sample preparation

100 GGBS (produced by ArcelorMittal, and ground/commercialized by Ecocem Materials) and OPC 101 (CEM I 52.5R, Lafarge) were used as raw materials to prepare slag-blended cement pastes composed of 102 75% GGBS and 25% OPC with a water/binder ratio of 0.4 by mass. Powders were mixed and hand-103 stirred for 2 min after addition of water. The mixing water was distilled water for the non-accelerated 104 samples, and a 1 wt.% CaCl<sub>2</sub>.2H<sub>2</sub>O solution (Sigma-Aldrich) for the accelerated samples [29]. After 105 homogenization, the pastes were cast in 300 µm borosilicate capillaries by applying slight underpressure 106 (WJM-Glas, Müller GmbH) 6 hours or 24 hours prior to the measurements. The capillaries were then 107 sealed and stuck into sample holders.

Six samples were prepared to represent the desired compositions and hydration times (Table 1). Two of them were hydrated for 6 h or 24 h without CaCl<sub>2</sub> activation (S75\_6h and S75\_24h) and two replicates (R) were prepared in order to estimate the method error (S75\_6h\_R and S75\_24h\_R). Two samples were accelerated with 1 wt.% of CaCl<sub>2</sub> and hydrated for 6 h or 24 h (S75\_CaCl<sub>2</sub>\_6h and S75\_CaCl<sub>2</sub>\_24h). The 6 capillaries were rescanned about six hours after the initial scan in order to monitor the early hydration. The suffix "rescan+xh" was added to their name, where xh refers to time elapsed after the initial scan.

115

Table 1: I	List of	samples
------------	---------	---------

Name of samples	Hydration time	CaCl <sub>2</sub>	Name of rescans	Hydration time
	of initial scan	activation		of rescan

### 117 2.2. X-ray micro-tomography imaging

118 XMT analyses were carried out at the Swiss Light Source (SLS) of the Paul Scherrer Institut, 119 Switzerland, on the TOMCAT beamline. A beam energy of 21 keV was chosen for imaging all samples, 120 providing a high photon flux that permits fast scans. Transmitted X-ray photons were converted into 121 visible light using a 20  $\mu$ m LuAG:Ce Scintillator, and 1501 projections were taken over an angular range 122 of 180° with an exposure time of 180 ms each. This setting led to a scanning time of about 15 min per 123 sample, and enabled quick mapping of the hydration reaction. Diffraction-limited microscope optics and a PCO.Edge 5.5 camera were used to magnify ( $\times$  20) and capture the radiographs. Images were corrected for the noise of the camera (dark field subtraction) and for inhomogeneities of the beam (divided by flat field). Phase retrieval [30] was also applied prior to the tomography reconstruction [31] using a Paganin algorithm. A distance of 5 mm and a delta/beta ratio of 100 were chosen for the reconstruction. Each reconstruction was of 2560  $\times$  2560  $\times$  2160 voxels with isotropic size of 0.325 µm. This image resolution is about 5 and 1.5 times higher than that reported in other XMT studies on slag-blended cements [16,32–

- 130 36] and OPC pastes [12,14,25,28], respectively.
- 131 2.3. XMT data processing

132 The reconstructed volumes were processed using the Avizo® software on a Dell Precision T3600 133 workstation (64 GB RAM, 6 GB Nvidia graphics card). The 16-bit data sets were first normalized and 134 reduced to 8-bit data sets in order to reduce the amount of data to be processed. During normalization, 135 the grey level ranges were calibrated between initial scans and rescanned images using a linear 136 interpolation procedure, assigning fixed values to the exterior air signal and the GGBS signal maximum 137 peaks. After 8-bit conversion, the calibrated greyscale of the images ranged from 0 to 255. To allow for 138 further image comparison, each image pair was then registered in the same (x,y,z) coordinate system 139 using a rigid-body transformation based on mutual information optimizer. Finally, image subtraction 140 was performed twofold, either by subtracting the initial scan to the rescan image or vice-versa, thus 141 offering the possibility to distinguish the solid phases that disappeared from the ones that formed during 142 the hydration process.

143 Visualization and quantification of the OPC/GGBS dissolution, removal of transitional dense phase in 144 the pore space, and precipitation of portlandite and hydrates\* was performed on subvolumes of  $200 \times$ 145  $200 \times 600 \mu m$  after image subtraction and a simple thresholding method (see section 3.3.1 for details). 146 Note that hydrates\* refers to all hydrate phases except portlandite, e.g. C-S-H, AFm and ettringite for 147 slag based blended cements. The upper and lower thresholding values were chosen manually in order to 148 extract the phase(s) of interest identified based on their morphology, and minimize the contribution of 149 the other phases due to overlapping grey levels.

#### 150 III. Results and Discussion

#### 151 **3.1. Preliminary study of XMT images**

152 *3.1.1. Identification of phases* 

Figure 1 shows a slice of slag-blended cement with the corresponding histogram extracted from the subvolume of  $200 \times 200 \times 600 \,\mu$ m. The cementitious phases were identified by morphological analysis and comparison of histograms with the literature [14,22,37]. Seven main phases were identified:

• porosity in dark grey level (air bubbles, water filled pore network),

- hydrates\* in fairly dark grey level (small interconnected particles in the pore network),
- portlandite in intermediate grey level (zones of irregular shape with a grey level in the GGBS range),
- GGBS in light grey (angular grains of various particle sizes),
- OPC in very light grey level (rounded grains),
- and metallic iron particles in white (local bright spots).

163 In addition, a transitional dense phase was systematically observed in the pore space, except for S75 24h (see further, the blue arrows in Figure 3.a). This phase exhibited an irregular shape and was 164 distributed very heterogeneously in the samples. It had an intensity in the darker range of the grey levels 165 of hydrates\*, and appeared as a grey background in the pore network. Only a high magnification allowed 166 it to be distinguished from hydrates\*. Analysis of the later samples (Figure 3.b) showed that the phase 167 disappeared in all samples after the first few hours of hydration, while the hydrates remained in place. 168 169 After 31 h of hydration, the transitional dense phase was no longer present in the rescanned samples. 170 Therefore, it is unlikely that this phase consisted of solid hydrates. According to its morphology, 171 behavior, and relatively high absorption coefficient, the transitional dense phase was attributed to a 172 mobile pore water enriched in ions or nuclei. As far as we know, no previous study conducted on OPC 173 or slag-based cements has reported this transitional dense phase. It may form according to the following 174 processes: first of all, the high proportion of GGBS (75 wt.%) and its slow dissolution rates compared 175 to clinker phases allows Ca and Si ions to diffuse into the pore space, so they do not necessarily 176 precipitate around slag grains [38]. This makes stronger oversaturation and nucleation in solution 177 possible. Secondly, the resolution here was 5 times higher than that reported in other slag-based cement 178 studies [16,32–36,39]. Therefore, other authors may not have observed it, or may have confused it with 179 hydrates\*.

The histograms derived from image analysis of the subvolumes were composed of four major peaks centered around grey levels of 35 for porosity (peak A), 70 for hydrates and transitional dense phase (peak B), 120 for GGBS and portlandite (peak C), and 150 for OPC (peak D). The respective phases overlap strongly in the histograms. For example, GGBS and CH are strongly convoluted and no thresholding method could differentiate between the two phases. The peak areas in the histogram are proportional to the amounts of corresponding phases in the samples.

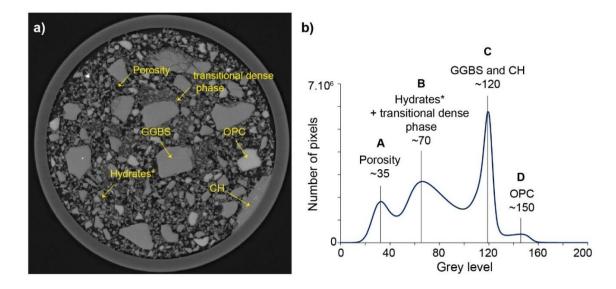

Figure 1: Identification of the cementitious phases in the XMT image of S75\_CaCl<sub>2</sub>\_6h and in the
corresponding histogram.

#### 189 *3.1.2. Determination of the Representative Elementary Volume (REV)*

190 XMT often produces large datasets. In order to reduce the amount of data to be processed and 191 to avoid edge effects, a smaller volume, called Representative Elementary Volume (REV) can be 192 extracted. This volume corresponds to the smallest volume representing the structural and macroscopic 193 properties of a given material. In practice, several techniques allow the REV size to be determined 194 [40,41]. In this study, the methodology of Wan et al., 2014 was applied. This method measures the 195 porosity in cubic volumes of increasing size, starting from a random point in the capillary. The 196 measurement is performed multiple times in order to evaluate the smallest volume at which porosity 197 converges to a constant value. This volume defines the REV.

198 Figure 2.a. shows an example of the REV determination on S75\_6h\_rescan+5h30. The porosity 199 was measured by thresholding the fluid (porosity) from the solid phase in the histogram (grey level value 200 = 50). The cube edge size was increased progressively from 5  $\mu$ m to 220  $\mu$ m from a random point. The 201 procedure was repeated 5 times in different areas of the sample. The porosity converged from an edge 202 size of 100  $\mu$ m onwards, and stabilized around 200  $\mu$ m. This value corresponds to the REV size, which 203 is equal to a cubic volume of about  $8.10^6 \,\mu\text{m}^3$  and a mean porosity of 14% (Figure 2.c, red volume). 204 Note that the REV size is similar to that calculated in previous studies [14,36]. However, it is worth 205 mentioning that REV could not be determined in the initial scans of this sample (Figure 2.b) due to the 206 presence of the transitional dense phase in the pore space, which led to an underestimation of the porosity 207 since its grey level fell into the range of hydrates\* (while it should account for porosity). In the initial 208 scan, no convergence was found for volumes with up to 220 µm edge length; the calculated mean 209 porosities were 3 to 6 times lower (2.5 to 5.0 %) than in the rescan (14%). Even by further increasing 210 the subvolume size to  $200 \times 200 \times 600 \,\mu\text{m}$  a porosity of 3.3 % was calculated, taking almost the whole

186

capillary into account but still avoiding edge effects (Figure 2.c, blue volume). We decided to extract the histograms on subvolumes of  $200 \times 200 \times 600 \mu m$  to compare the initial scan and the rescanned samples in order to avoid artifacts due to the heterogeneous distribution of the transitional dense phase.

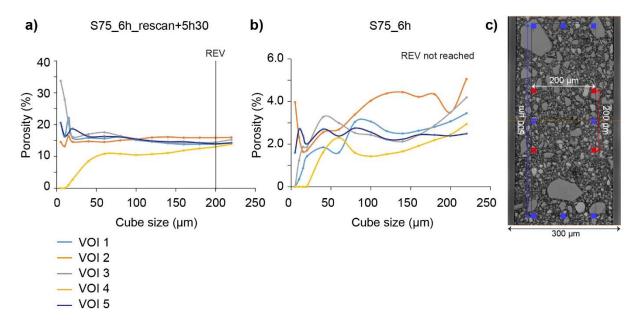

Figure 2: a) Determination of the REV size on S75\_6h\_rescan+5h30, according to the methodology of Wan et al., 2014 (VOI: Volume Of Interest). b) Attempt at REV determination on S75\_6h, which contained a large amount of transitional dense phase in the pore space. c) Representation of the two subvolumes of  $200 \times 200 \times 600 \ \mu m$  (blue) and  $200 \times 200 \times 200 \ \mu m$  (red: REV).

219

214

#### 9 3.1.3. Evaluation of experiment repeatability

220 Repeatability refers to the closeness of the agreement between several tests carried out under similar 221 conditions [42]. In this study, two samples (S75\_6h and S75\_24h) were replicated (S75\_6h\_R and 222 S75 24h R) in order to check the repeatability of the experiment, and because data repeatability is rarely reported in the literature. Figure 3, lines 1 to 4, shows the initial scan and rescanned slices of these 223 224 samples, and their corresponding histograms. Differences in peak height of about 20% for peaks B, C, 225 and D, and of about 80% for peak A were observed between S75 6h and S75 6h R. In S75 24h, the 226 peaks A and B were not distinguishable, while there were two distinct peaks in S75\_24h\_R. In addition, 227 peak C was around 15% higher in S75\_24h than in S75\_24h\_R, but thinner. Surprisingly, this means 228 that two samples prepared in two different capillaries showed substantial differences in the fluid and 229 mineral phase distribution despite the fact that REV was reached. This implies that comparison of 230 histograms and absolute quantifications were limited to variations greater than the measurement error.

Two reasons may explain the lack of data repeatability. First of all, the heterogeneous distribution and variable amount of the transitional dense phase in the pore space may have induced variations in the intensity of peak B. However, this explanation cannot account for the variations of peaks C and D, as

- these peaks are not correlated to the presence of the transitional dense phase. The second reason may
- arise from the small size of the capillaries (300 µm), which may have lowered the paste homogenization
- and prevented the sample preparation to be repeatable. However, glass capillaries of few hundred
- 237 micrometers are regularly used in the literature, resulting in the use of regions of interest smaller or
- similar to the subvolume size  $(200 \times 200 \times 600 \ \mu m)$  used in this study for phase quantifications
- 239 [12,14,22,25]. Therefore, our experimental methodology can be considered in line with that reported in
- the literature. Our results should encourage future studies to control their data repeatability in order to
- allow for quantitative comparisons. In our case, only qualitative analyses were performed.

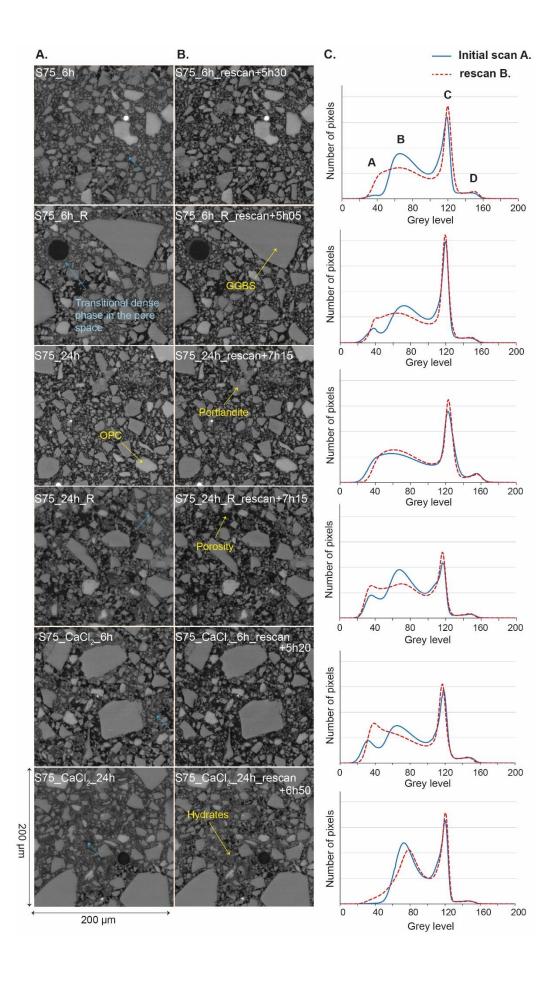

Figure 3: Influence of the hydration time on the XMT images and histograms: a) Initial scan images, b) rescan images, and c) corresponding histograms taken from subvolumes of  $200 \times 200 \times 600$ µm. Note that the replicates S75\_6h\_R and S75\_24h\_R do not show the same histogram shapes than the original samples S75\_6h and S75\_24h, respectively.

# 3.2 Investigation of the early hydration of blended cements from histograms and image comparison

Early hydration of blended cements was investigated by histogram and image comparison of samples scanned at different hydration ages during the first 31 h of hydration. Since no data repeatability was obtained, no phase quantification was attempted.

252 Rescans in time and space are useful to monitor the evolution of a single sample during hydration. 253 Indeed, under this configuration, changes in the histogram peak area and shape result from the evolution 254 of sample mineralogy/chemistry, and not from variations induced by inter-sample variability. Figure 3 255 compares the XMT images of the initial samples (column a), rescanned samples (column b), and 256 corresponding histograms (column c). The first two lines compare the non-accelerated replicates after 6 257 h and 11 h of hydration, the two following lines compare the non-accelerated replicates after 24 h and 258 31 h of hydration, and the last two lines the CaCl<sub>2</sub>-accelerated samples after 6 h and 11 h, and 24 h and 259 31 h of hydration. The initial scans and rescanned images of each sample show little evolution in the 260 grey level distribution and therefore give little information on the hydration reactions. Only the 261 disappearance of the transitional dense phase in the pore space can be identified (blue arrows). Since the transitional dense phase has a grey level in the range of hydrates\* (but, theoretically, should account for 262 263 porosity), its removal decreases the intensity of peak B, and increases the intensity of peak A in the 264 histograms, leading to the apparent contradiction that older samples contain less hydrates. Information 265 about the precipitation of hydrates\* was therefore lost.

Following the dissolution of GGBS/OPC was also difficult, as the XMT images did not show any major changes in particle size during hydration, and no evidence of GGBS/OPC dissolution was observable on the histograms: the intensity of peak C increased during hydration but sharpened, leading to similar peak area, and the intensity of peak D did not show significant variations on either the accelerated or non-accelerated samples. Therefore, image and histogram comparison of rescanned samples did not allow the early hydration to be monitored due to the complex phase assemblage and slow hydration rates of the materials.

#### 273 **3.3. Image subtraction: an alternative method to reveal (blended) cement hydration**

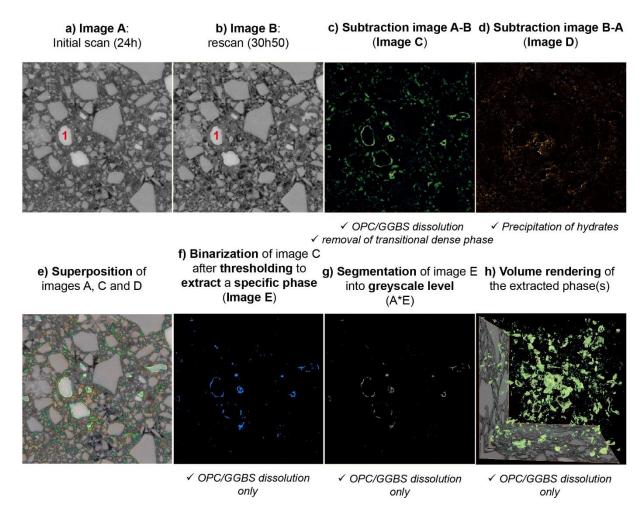

#### 274 *3.3.1. Principle of image subtraction*

275 XMT image subtraction reveals small differences in pairs of nearly identical images [43–46]. In 276 this study, the method was applied to early hydration of un-accelerated and CaCl<sub>2</sub>-accelerated blended cements. In image subtraction, the initial image of a rescanned sample is subtracted from the final image, or vice-versa. The pixel grey level of the subtraction image "A-B" or "B-A" corresponds to the absolute difference of pixel grey levels between the two images. Negative values are set to 0. In theory, the subtraction image of two strictly identical images should be black, but in the case of cements, the hydration reactions lead to some differences. The A-B images show the dissolution of initially present phases whereas B-A show the newly precipitated phases.

283 Figure 4 shows an example of subtraction performed on S75\_24h\_CaCl<sub>2</sub> and on its rescan 6 h 284 50 later (image B). The image of the subtraction "A-B" (Figure 4.c) reveals the dissolution zones of 285 OPC and GGBS, as the difference of pixel grey levels between OPC/GGBS between the initial scans 286 (~150 and 120 respectively), and the resulting porosity (~35) or hydrates (~70) after dissolution or re-287 precipitation was positive. Note that a green color scale was used to enhance the visibility of the changes 288 in the images. The removal of the transitional dense phase in the pore space was also made visible by 289 this operation, as the difference of pixel grey levels between the transitional dense phase ( $\sim$ 70) in the 290 initial scans, and porosity (~35) after its removal was positive. All other chemical transformations 291 leading to null or negative values were set to 0, and appear in black. On the other hand, the B-A 292 subtraction (Figure 4.d.) highlights the precipitation zones of hydrates, as the difference of pixel grey 293 levels between portlandite/hydrates\* in the rescans (~120 and ~70 respectively), and the initial pore space (~35) remained positive. A gold color scale was set in the present case. At the end, the 294 295 superposition of the two subtraction images with the original XMT image reveals a dissolution rim around the OPC grain "1", as well as the precipitation of hydrates\* in its vicinity (Figure 4.e). Further 296 297 information will be extracted in sections 3.3.2 and 3.3.3 by comparing the subtraction images of the un-298 accelerated and CaCl<sub>2</sub>-accelerated systems, at various hydration ages.

299 Segmentation based on simple thresholding was then employed to extract one or more phases 300 from the subtraction images. The thresholding range was set by fitting only the pixel areas of the phase(s) 301 of interest, based on the morphological attribution of section 3.1.1. Either the transitional dense phase 302 in the pore space, GGBS/OPC, or portlandite, and/or other hydrates\* could be separated from the other 303 phases in the subtraction image, depending on the thresholding range used. The quality of the extraction 304 depends on the separation of grey levels, since a large overlap would prevent the appropriate 305 thresholding of the phase of interest: if the thresholding range is too large, the phase of interest will be polluted by other phases and, if it is too small, a part of the phase of interest will not be represented. 306 307 Therefore, a compromise had to be found. In Figure 4.f., only the dissolution of OPC and GGBS was 308 extracted, and the signal of the transitional dense phase was removed. Since the grey levels of OPC 309 edges (~130) and GGBS (~120) overlapped strongly in the histograms, the two phases could not be 310 separated from each other.

311 After thresholding, a binary image was obtained, and its multiplication with the initial XMT 312 image allowed to represent the selected phase(s) in its original grey scale levels (Figure 4.g). Subsequently, the grey scale histogram of the selected phase(s) was extracted. Finally, the extracted 313 phases were represented in 3D (Figure 4.h). In this study, no quantification was performed due to the 314 315 non-repeatability of the experiments and the poor quality of the phase extraction (the signal was systematically polluted by other contributions regardless of the phase extracted). However, this step is 316 317 theoretically possible, and the amount of extracted phase(s) would correspond to the integral of the peak 318 of interest in the histogram of Figure 4.g.

319

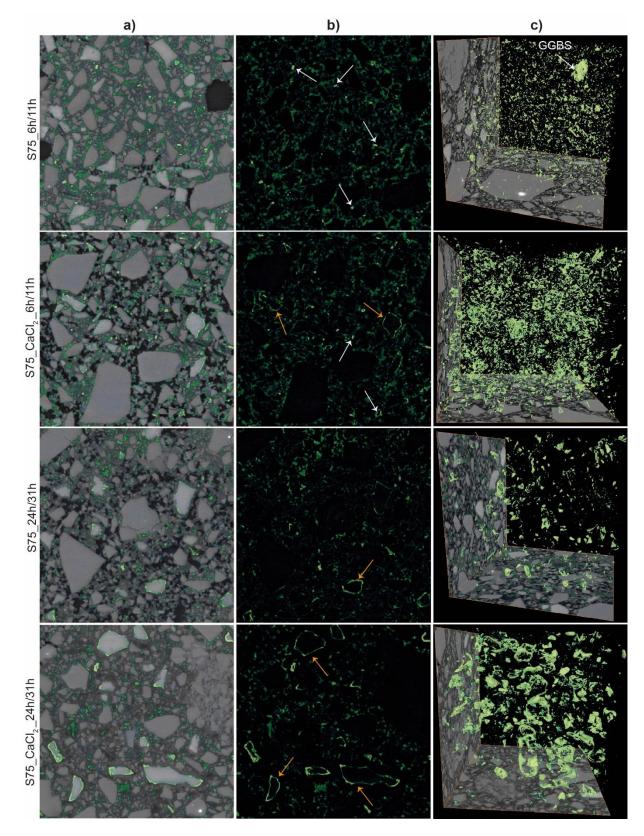

**Figure 4**: Principle of image subtraction performed on S75\_24h\_CaCl<sub>2</sub> and on its rescan 6 h 50 later.

321 3.3.2. "A-B" Image subtraction: GGBS/OPC dissolution, removal of transitional dense phase
 322 in the pore space

Figure 5 represents the A-B subtraction images of the non-accelerated and CaCl<sub>2</sub>-accelerated samples, in the hydration ranges of about 6h/11h and 24h/31h. Column 1 shows the extracted phases overlaid on the original XMT images, column 2 the image subtraction only, and column 3 the volume rendering of the extracted phases (OPC and/or GGBS dissolution, without transitional dense phase inthe pore space).

328 Between 6 h and 11 h of hydration, the subtraction images show mainly removal of the 329 transitional dense phase in the pore space. In the non-accelerated sample (S75\_6h/11h), some small 330 GGBS grains also dissolved. Their dissolution appears as a multitude of small bright spots with a size 331 of about  $1 - 4 \mu m$  in the subtraction image (white arrows in Figure 5). Some bigger GGBS grains (~10 332  $\mu$ m) dissolved more locally, as can be seen in the 3D volume. In presence of CaCl<sub>2</sub> (S75\_CaCl<sub>2</sub>\_6h/11h), 333 less GGBS dissolution was observed, but dissolution rims around the OPC grains were visible (orange 334 arrows in Figure 5). This appears to be in contradiction with a former report on an accelerated slag 335 reaction in presence of CaCl<sub>2</sub> [29]. In that study, the contribution of slag to heat release in isothermal 336 calorimetry appeared after 10 hours of hydration in presence of CaCl<sub>2</sub>, i.e. earlier than the 15 hours of 337 hydration in absence of CaCl<sub>2</sub>. This corresponds to the appearance of AFm phases in XRD. In our study, 338 it is thus possible that, in the accelerated sample, the initial dissolution of GGBS had already taken place 339 during the first 6 hours of hydration (i.e., before the initial scan), so that this initial dissolution was only 340 visible on the non-accelerated sample.

341 Between 24 h and 31 h of hydration, no GGBS dissolution was observed in either the non-342 accelerated or the CaCl<sub>2</sub>-accelerated samples. This supports the idea that the initial GGBS dissolution 343 had already taken place in the accelerated sample, as no dissolution was observed afterwards (until 31 344 h of hydration). In absence of CaCl<sub>2</sub>, only little OPC dissolution was observed in the subtraction images 345 and volume rendering. In presence of CaCl<sub>2</sub>, the OPC dissolution was stronger and affected almost all 346 OPC grains. The comparison of the two volume renderings showed a clear accelerating effect of CaCl<sub>2</sub> 347 on the dissolution of OPC. This is consistent with the fact that CaCl<sub>2</sub> accelerates the dissolution of OPC 348 at early ages [29,47–49].

349

Figure 5: "A-B" image subtractions: a) extracted phases superposed on the original XMT images, b)
subtraction images only (OPC/GGBS dissolution, with transitional dense phase in the pore space), and
c) volume rendering of the extracted phases (OPC/GGBS dissolution, without transitional dense phase

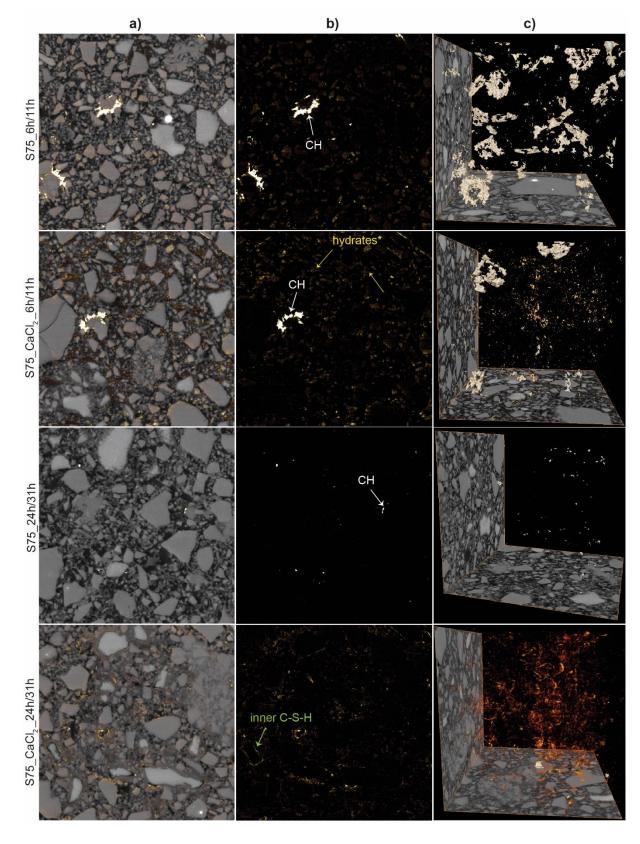

- in the pore space). The arrows were added to highlight dissolution of GGBS (white) and OPC (orange)
   grains.
- 355

#### 3.3.3. "B-A" Image subtraction: precipitation of hydrates

Figure 6 shows the B-A image subtractions of the non-accelerated and CaCl<sub>2</sub>-accelerated samples. This operation enables visualization of the precipitation of portlandite and/or other hydrates in blended cements.

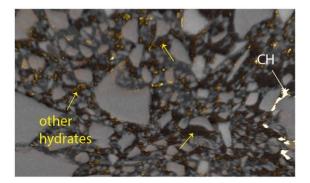

359 Between 6 h and 11 h, only the formation of portlandite is visible in the non-accelerated sample. Numerous CH rims appear in both the subtraction image and the volume rendering of Figure 6 (white 360 arrows). The light orange areas may correspond to the precipitation of other hydrates in the pore 361 362 network, or slight variations in X-ray beam intensity during image acquisition, as some areas fall into 363 the zone of GGBS grains (no precipitation is expected inside GGBS grains). In presence of CaCl<sub>2</sub> 364 (S75\_CaCl<sub>2</sub>\_6h/11h), less portlandite formation was observed but more other hydrates\* precipitated into 365 the pore space (Figure 6, yellow arrows). This is especially visible in the zoom presented in Figure 7. The light orange areas fall almost exclusively within the pore space, which is consistent with faster pore 366 367 space filling by hydrates\* in presence of  $CaCl_2$  as previously reported [47–49]. The higher presence of 368 portlandite in S75\_6h/11h also agrees with the works of Steger, 2019 [50], who showed more portlandite 369 precipitation at early ages in the non-accelerated slag cements at a similar time scale, by *in-situ* XRD.

Between 24 h and 31 h, precipitation of portlandite almost stopped in both the accelerated and non-accelerated samples. However, in the CaCl<sub>2</sub>-accelerated paste, an increased formation of other hydrates\* was observed around the OPC grains. According to the morphology and localization of the phases, they probably correspond to inner product C-S-H, as they fill the volume of dissolved OPC grains (Figure 6, green arrows and volume rendering). In the non-accelerated sample, no hydrate development was observed, except for very small amounts of portlandite.

376

Figure 6: "B-A" image subtractions: a) extracted phases superposed on the original XMT images, b)
 subtraction images only (CH and/or hydrates\* and/or noise), and c) volume rendering of the extracted
 phases (CH and/or C-S-H).

- 381
- 382

Figure 7: Zoom on the precipitation of hydrates\* in the porosity of S75\_CaCl<sub>2</sub>\_6h/11h.

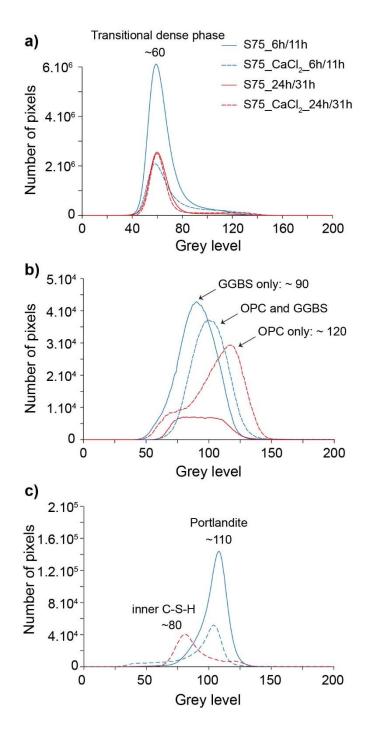

3.3.4. Determination of the specific grey levels of the extracted phases by image subtraction

383

Extraction of the grey level distribution from the histograms after phase segmentation (i.e. Figure 4.g) gave the specific grey levels of the transitional dense phases, i.e., OPC, GGBS, portlandite, and inner C-S-H (Figure 8). The extraction was performed by selecting a specific grey level range of the original images in the subtraction images, which fitted the phase of interest identified base on morphology and comparison with the same spot on the initial scans (see section 3.1.1 and 3.3.1 for

details).

390 The results showed a mean grey level of about  $\sim 60$  for the transitional dense phase,  $\sim 80$  for the 391 inner product C-S-H, ~90 for GGBS, ~110 for portlandite and ~120 for OPC. The grey levels overlapped 392 strongly, spanning  $\pm 20$  to  $\pm 40$  grey level units. Note that the dissolved OPC showed slightly lower grey 393 level (~120) than the average value observed in Figure 1 (~150), probably because of the preferential 394 dissolution of grain edges (Figure 8.b). Edge effects probably associated to partial volume effects / phase 395 contrast decreased the mean grey level of the dissolved OPC compared to the center of the grains. 396 Similarly, in samples where only GGBS was dissolved, the mean grey level of dissolved GGBS is 397 slightly lower (~90) than the average value (~120) determined in section 3.1.1. In systems where OPC 398 and GGBS dissolve, the grey level of the dissolved phases is in between the values for dissolved GGBS 399 (~90) and OPC (~120). Note that in S75\_24h/31h, the signal of OPC is very low due to the difficulty of extracting the OPC phase. 400

401

402 Figure 8: Extraction of the specific grey levels of a) the transitional dense phase in the pore
403 space, b) GGBS and/or OPC, and c) portlandite/inner C-S-H, by combining simple thresholding in the
404 subtraction images with the original image, from (cf. Figures 6 and 7). The number of pixels is not
405 correlated with the amount of a given phase in the samples here, due to the non-repeatability and grey
406 level overlapping.

#### 407 V. Conclusions

408 In this study, XMT was used to highlight the early hydration of both CaCl<sub>2</sub>-accelerated and non-409 accelerated slag-based blended cements with a pixel size of 0.325 µm. Seven cementitious phases were 410 identified in the XMT images and histograms: porosity, OPC, GGBS, portlandite, other hydrates, 411 metallic iron particles and a transitional dense phase in the pore space with a grey level similar to that 412 of the hydrates. For the first time, data repeatability tests were reported for cement pastes cast into glass 413 capillaries of 300 µm. Surprisingly, different capillaries filled with the same paste do not give repeatable 414 results, despite the fact that the REV size was reached, and that sample preparation was similar to what 415 is frequently presented in the literature. This result should encourage future studies to control the data 416 repeatability before conducting quantitative analyses. The early hydration of samples scanned at 417 different hydration times was then qualitatively investigated during the first 31 h of hydration by 418 histogram and image comparisons. These methods gave only limited information on the hydration 419 reaction, due to the complex phase assemblages and slow hydration rates of the materials. Therefore, 420 image subtraction of the same samples was used as an alternative method in order to evidence small 421 differences in the fluid and solid phases. This method allowed to show (i) the dissolution of OPC and 422 GGBS, (ii) the precipitation of portlandite and inner C-S-H, (iii) the accelerating effect of  $CaCl_2$ , (iv) 423 the distribution of dissolved/precipitated phases in 3D, and (v) the specific grey levels of the different phases. More specifically, CaCl<sub>2</sub> was shown to accelerate the dissolution of OPC and increase the 424 425 precipitation of hydrates between 6 h and 11 h of hydration. The effect was even stronger between 24-426 31 h of hydration, with numerous dissolution rims around OPC grains and C-S-H clusters in the pore 427 space. In absence of CaCl<sub>2</sub>, the dissolution/precipitation reactions were slower and were visible only 428 after 24 h of hydration. However, GGBS dissolution was observed between 6-11h of hydration (and 429 suspected before 6 h in the CaCl<sub>2</sub>-accelerated sample), and showed to contribute to the microstructure 430 development of slag-based blended cements at early ages.

#### 431 Author contributions

432 S.B., L.S. and C.P. prepared the samples and performed the XMT analyses under the supervision of 433 A.B. and M.O. A.B. developed the experimental setup. M.O. performed the beamline calibration and 434 data pre-processing. M.P. post-processed the whole dataset and wrote the first draft of the article. C.N. 435 provided the computational equipment, managed data post-processing, and initiated the image 436 subtraction method. M.P., S.B., M.C. and C.P. participated in numerous meetings to discuss the results 437 and all co-authors participated in reviewing and editing the article. M.C. and J.K. led the overall project 438 and acquired funding.

#### 439 **Declaration of interests**

440 The authors declare that they have no known competing financial interests or personal relationships that

441 could have influenced the work reported in this paper.

## 442 Funding

- 443 This work was supported by ArcelorMittal Maizieres Research and the European Commission through
- the Research Fund for Coal and Steel (grant no 749809, 2017) on behalf of the Actislag project.
