High-resolution records of the relative paleointensity of the geomagnetic field have been obtained from five marine cores. Three duplicate records were used to estimate the regional coherency of the data within a single area (Tyrrhenian Sea) while the two others document the field variations in the eastern Mediterranean and the southern Indian Ocean. Careful investigations of distinct rock magnetic parameters have established the downcore uniformity of the sediments in terms of magnetic mineralogy and grain sizes. The time-depth control was provided by oxygen isotopes, and small-scale variations in the deposition rates were constrained by means of tephrochronology. The synthetic curve calculated from the Mediterranean records provides a continuous record of the intensity variations during the last 80,000 years (80 kyr), which correlates well with the sparse volcanic data available for the period 0-40 kyr. The fact that identical behavior is seen in both data sets and that they also compare quite well with results from a core collected in the Pacific Ocean establishes the truly dipolar character of these variations. The dipole field moment is characterized by large-scale changes as shown by the existence of pronounced drops (at 39 and 60 kyr) alternating with periods of higher intensity. The record suggests a periodic nature for these intensity variations; however, the period studied is not sufficiently long to state this conclusively. These results demonstrate the potential of sediments for such studies and constitute a first step towards obtaining a global paleointensity record over a long period of time.

INTRODUCTION

The intensity changes of the geomagnetic field are reasonably well documented for the period covering the last 10,000 years (10 kyr) from a wide number of archeomagnetic studies [Barton *et al.*, 1979; Kovacheva, 1980, 1982; McElhinny and Senanayake, 1982]. Before this epoch, archeological materials are not available, but a few absolute paleointensities have been obtained from volcanic materials. Lava flows provide instantaneous readings of the field at the time of the volcanic eruptions; however, because of the episodic nature of volcanic events, the record obtained from lava flows is extremely spotty. The construction of a composite continuous record is thus severely hindered by the difficulties of obtaining long volcanic sequences and by the large uncertainties in establishing the precise chronology of the successive flows.

Long and continuous sequences with precise chronological control are required to document the time constants involved in the long-term variations of the dipole field. Marine sediments are associated, in principle, with the continuous process of deposition and have the advantage of being able to be precisely dated by oxygen isotopes. However, the use of sediments for paleointensity studies is delicate. The processes accompanying the magnetization of sediments are neither clearly understood

nor very well constrained, since they depend on environmental conditions, lithology (grain size, mineralogy, etc.) and, ultimately, on postdepositional factors. However, the magnetization has been shown to be linearly related to the field intensity, and relative paleofield determinations can be obtained after normalizing properly the contribution of these other factors. The sequences used for paleointensity determinations should have homogeneous and invariable magnetic properties over their full length. Several reliable paleointensity determinations have been derived from sedimentary sequences, including during field reversals [Opdyke *et al.*, 1973; Valet *et al.*, 1988; Laj *et al.*, 1988], and recently, conclusive results have been published which are in good agreement with the archeological data set covering the last 15 kyr [Constable, 1985; Constable and Tauxe, 1987; Tauxe and Valet, 1989].

The aim of the present study is to extend the global record of the geomagnetic field intensity over the last 80 kyr. The approach consists, first, of obtaining duplicate records from the same area in order to determine the reproducibility of the results. Records from different regions can then be compared and evaluated as a group. As a first step this paper summarizes the results obtained from four cores in the Mediterranean Sea.

MEASUREMENTS AND ROCK MAGNETIC PROPERTIES

Natural Remanent Magnetization

Ten cores distributed in the Mediterranean and three cores from the Indian Ocean were initially selected from areas characterized by deposition rates of at least 10 cm per 1000 years in order to provide records with a good temporal resolution. A first sampling was performed using the technique of "U" channels [Tauxe *et al.*, 1983]. The top part of the cores (i.e., the first meter below the seafloor) could not, however, be sampled due to a large water content and/or the presence of coring disturbances.

The measurements (taken at intervals of 1 cm) and stepwise demagnetization of the U channels (at 4, 8 and 16 mT) by alternating fields (AF) were conducted on the pass-through

⁴ Geological Research Division, Scripps Institution of Oceanography, La Jolla, California.

system of the Scripps Paleomagnetic Laboratory. Continuous measurements of the low-field susceptibility (χ) were performed also with the long-core "Bartington" system mounted in line with the magnetometer. At the end of this preliminary investigation, five cores were selected for further detailed studies based on the stability of the directions upon demagnetization and the regularity of the downcore changes in directions, magnetization intensity and low-field susceptibility. The locations, lengths and water depths of these five cores are summarized in Table 1 and Figure 1.

In order to assess the reliability of these sediments for paleointensities, we undertook a detailed investigation of the magnetic properties of the sediment. An average of 60 discrete samples were taken in the five or six first sections (each section being 1.5 m long) of every core by pushing plastic cubes (8 cm³) into the sediment. A total of 1600 specimens were subjected to measurements, including stepwise demagnetization of the natural remanent magnetization (NRM), stepwise acquisition and demagnetization of the anhysteretic remanent magnetization (ARM) and saturation isothermal remanent magnetization (SIRM), measurements of the low-field susceptibility, Curie temperature analyses, X ray analyses, and microscopic studies from magnetic separates.

The measurements of the NRM were done in the shielded room of the Centre des Faibles Radioactivités using a three-axis LETI magnetometer. About 30 pilot specimens per section were selected and completely demagnetized by alternating fields with a minimum of nine steps. The remaining samples were demagnetized in four or six successive steps (usually at 10, 15, 20, 25, 30, and 40 mT). The demagnetization diagrams (Figure 2) are in general of very good quality. Most of them are characterized by a characteristic remanent magnetization decreasing linearly towards the origin with a medium destructive field (MDF) between 15 and 30 mT. Complete removal of the magnetization occurs between 40 and 65 mT. In 20% of the samples a soft secondary component is present and was easily removed after 5 and 10 mT.

Magnetic Mineralogy and Grain Sizes

Stepwise acquisition of isothermal remanent magnetization was performed on 30 pilot samples per section. Complete saturation was observed in fields of 0.25 T, while the MDF was lower than 30 mT. Such characteristics are compatible with the presence of magnetite but do not identify this mineral unambiguously since similar features can be exhibited by iron sulfides. Thermomagnetic analyses were performed on magnetic separates obtained by circulating a slurry within the polar pieces of a Frantz electromagnet. The heating curves in Figure 3a reveal the presence of a single magnetic phase with a

Curie temperature between 550°C and 580°C. The cooling curves are characterized by lower J_s values, probably resulting from the conversion of magnetite into hematite after heating in air. X ray diffraction analyses confirmed the presence of magnetite, which was clearly identified by several peaks at 2.52, 1.49, 2.09, 1.62 and 1.71 Å. No other magnetic mineral was detected (Figure 3b).

Several methods have been suggested for the determination of particle size variations of magnetite. King *et al.* [1982] have constructed a phenomenological model based on a plot of anhysteretic magnetization versus χ . These parameters may be used to determine variations in magnetic grain size and concentration. Changes in the ARM/ χ ratio imply changes in grain size, with higher ratios indicating smaller grain sizes, while changes in ARM and χ with constant ratio correspond to changes in concentration of magnetic material only. It can be seen in Figure 4 that no significant variation of ARM/ χ is observed in any core except for a few peaks characterized by variations exceeding a factor of 3 which yield large and incoherent results in the final NRM/ARM or NRM/ χ ratios. The corresponding samples were therefore ruled out. It must be noticed that this limit is much more stringent than the requirements given so far in the selection procedures for paleointensities [King *et al.*, 1983], where a factor of 10 cutoff limit was proposed.

An alternative method proposed by Petersen *et al.* [1986] is based on a comparison of the MDF values associated with the ARM and the SIRM. The ARM has coercivities higher than SIRM in all records, indicating the dominant role of the monodomain or pseudo-monodomain grains. Microscopic examinations performed on magnetic separates revealed the presence of 0.5-3 μ m magnetite grains with similar size distribution in all samples.

These experiments have shown that magnetite in monodomain or pseudo-monodomain grains is present as the only carrier of remanent magnetization in every core. The downcore variations in the concentration of this mineral have been detected by scrutinizing the variations in the ARM, SIRM and low-field susceptibility (Figure 5). Except for a very limited number of levels close to sandy, ash or sapropel layers the downcore profiles of the three parameters are identical and do not show variations larger than a factor of 2. The similarity between these three distinct parameters involving different families of magnetic grains indicates that the relative distribution of the grain sizes remained constant.

DETERMINATION OF THE RELATIVE PALEOINTENSITY

The ARM, the low-field susceptibility and the SIRM have been used in paleointensity studies in order to normalize the amount of magnetic material [Johnson *et al.*, 1975; Nesbitt, 1966; Kawai and Nakajima, 1973]. The latter two are not strictly related to the monodomain or pseudo-monodomain grains but respond more to the fraction of multidomain grains. Levi and Banerjee [1976] proposed that the ARM is a more adequate parameter because it is mainly sensitive to the grain fraction involved in the NRM, and King *et al.* [1983] have developed an approach based on ARM measurements for selecting sediments adapted to such paleointensity studies. The basic requirements for this type of study are demonstrating the presence of magnetite which is carrying the remanence and the homogeneity of the sediment with respect to grain concentration and grain sizes. The results of the measurements described above have shown that the cores satisfy these conditions and are suitable for relative paleointensity studies. In addition, we have compared the NRM and ARM demagnetization curves. Following a suggestion by Levi and

Banerjee [1976], we assume that the identical demagnetization behaviors of these two parameters provide a good indication that both magnetizations are carried by similar families of grains. In 95% of the cases the slopes of the two curves are similar as well as the MDF values (Figure 6). This test was conclusive.

Based on the constant ratios between the distinct rock magnetic parameters, the ARM, SIRM or χ could equally well be used to normalize the magnetization intensity. The NRM/ARM, NRM/SIRM, and NRM/ χ ratios for the discrete samples have been plotted in Figure 7 together with the NRM/ χ ratio from the continuous measurements. Any level of demagnetization between 10 and 40 mT would have been appropriate. We used the ARM and the NRM intensities after

20 mT for the single samples (and after 16 mT for the U channels) because these values are close to the MDF and at these steps any secondary component of magnetization has been removed. A consequence implicit in the method used here is that the absolute values of the vertical scale are meaningless. The distinct records of the same core have been arbitrarily matched to the same scale as the continuous measurements through the use of a multiplicative factor. As could be expected, the same features are reproduced by every set of measurements, leaving us confident about the reliability of the measurements as well as about the success of the normalization. Differences between the results of normalization with distinct parameters may reflect inhomogeneities within the sediment and suggest an estimate of the limit of confidence in the results on the order of about 0.2 on the artificial scale in Figure 7. i.e. about 20% of maximum field value.

RESULTS

Dating and Time Resolution

Oxygen isotope measurements performed on cores MD 84629 (eastern Mediterranean) and MD 84528 (south Indian Ocean) provided the time scale [Imbrie *et al.*, 1982]. No isotope studies have been performed on the three cores from the Tyrrhenian Sea. However, the cores KET 8251, DED 8707 and DED 8708 were collected in the same area. The two last cores, taken at the same site, duplicate core KET 8004, which has a complete oxygen record and many tephra layers that have been analyzed, dated and correlated with similar layers exposed on land [Paterne, 1985; Paterne *et al.*, 1986]. The sequence of tephra found in KET 8004 was easily identified in the three cores studied; in addition, several marine ash layers occurring over the past 80 kyr were readily correlated with well known (and K-Ar dated) terrestrial deposits [Paterne, 1985; Paterne *et al.*, 1986; Paterne *et al.*, 1988; Tucholka *et al.*, 1987]. Tephrochronology was therefore used to correlate the four records from the Tyrrhenian Sea with very high accuracy (Figure 8a). A total of 6 to 22 stratigraphic levels could be dated with precision for every core, providing a generally satisfactory time-depth control (Figure 8b). In addition, these

correlations are also assessed by the presence of organic-rich levels which are related to the well-known sapropel layers identified in the whole eastern Mediterranean Sea [Ryan, 1972; Cita *et al.*, 1973].

The mean deposition rates calculated from these correlations are generally around 10 cm per thousand years; however, the values obtained within individual intervals between dated horizons sometimes differ significantly. As the number of such levels is relatively large, the time scale of these changes is well constrained. Based on these estimates the final

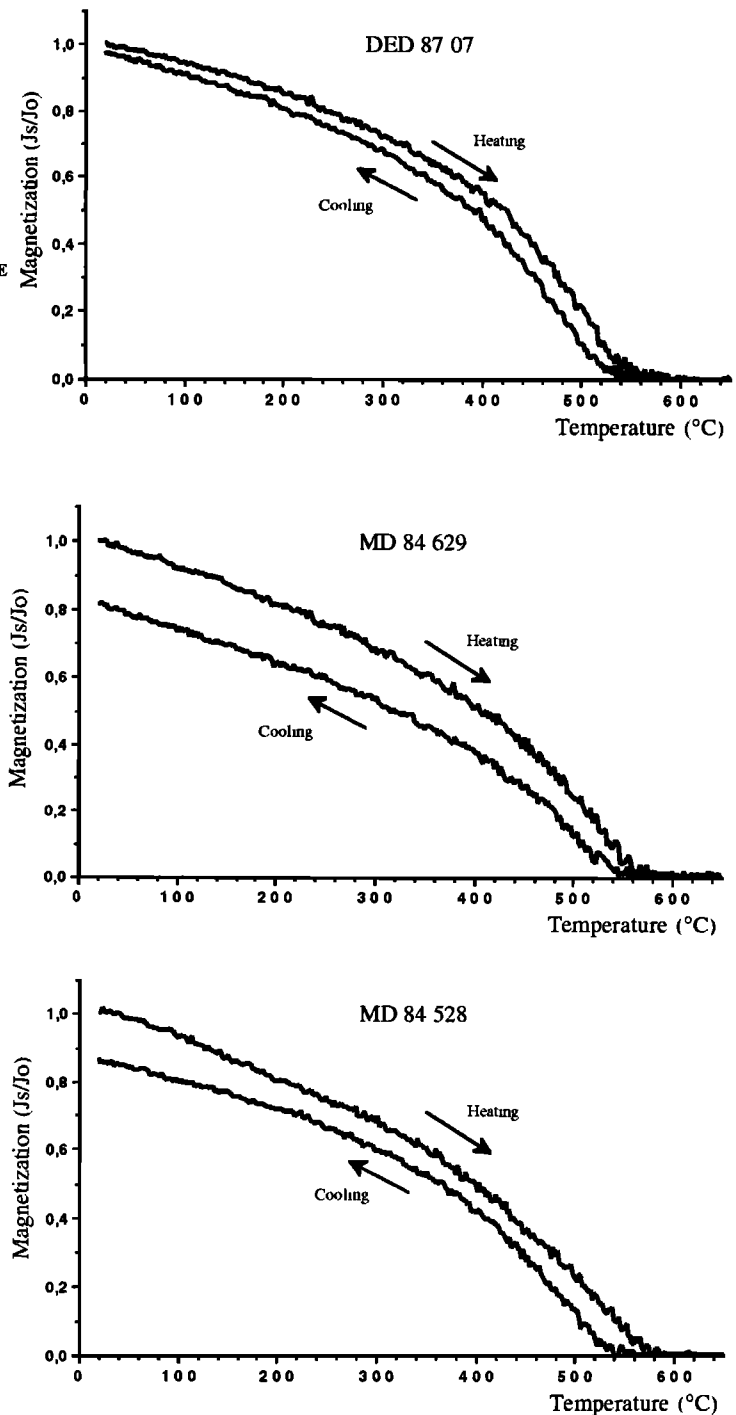

Fig. 3a. Results of thermomagnetic analysis performed under nitrogen atmosphere on samples from cores DED 8707, MD 84629 and MD 84528. The heating and cooling curves are reversible and characterized by the Curie point of magnetite at 580°C.

time versus depth correspondence was established at time increments of 200 years by linear interpolation.

The long-core measurements of the "U" channels, excluding data within 5 cm of the ends of each section, have a temporal resolution of less than 400 years (for a deposition rate of 10 cm per thousand years) [Tauxe and Wu, 1990], which is not significantly different from the 200 years averaged over the size of a single sample.

Reliability of the Records of Geomagnetic Intensity Variations

Before going further into the interpretation of the records of normalized NRM intensity in terms of geomagnetic field behavior we must examine the possible influence of factors other than field intensity.

It must first be shown that the record of intensity is not influenced by changes in the magnetic properties of the sediment. The four measured rock magnetic parameters (NRM, ARM, χ and SIRM) have characteristic relationships as shown in Table 2. The correlation coefficients between parameters characterizing the quantity of the magnetic fraction in the sediments (ARM, χ , SIRM) are high and positive (Student's *t*-test shows $p \ll 0.001$). The NRM intensity shows only a weak correlation with these parameters. The NRM varies by a factor of 10, while the other parameters only change by a factor of 2 or 3. It is thus clear that the first-order variations of the NRM intensity do not depend on changes of the magnetic properties and are therefore mainly related to the variation of the geomagnetic field.

Several authors have reported strong correlations between the evolution of the magnetic properties in ocean sediments

and indices of climatic changes. Some of these paleomagnetic studies [Robinson, 1986; Bloemendal *et al.*, 1988] reveal that glacial periods are characterized by a high magnetic concentration due to low carbonate productivity, while interglacial horizons show low magnetic concentration and high carbonate content following the retreat of the polar front and the re-establishment of coccolith floras. If such effects prevailed for the sediments investigated in this study, the rock magnetic parameters should be correlated with the $\delta^{18}\text{O}$ record. We therefore compared the $\delta^{18}\text{O}$ record with the susceptibility record of core MD 84629. The plots shown in Figure 9 do not demonstrate any convincing evidence for a correlation between χ and the $\delta^{18}\text{O}$ record. However, within the investigated period the amplitude of these fluctuations is low, and as shown above, the paleointensity pattern is not influenced by the rock magnetic parameters used for the normalization.

Relative Paleointensity

As a first step we compared the individual records obtained within the same area (Tyrrhenian Sea). The three paleointensity curves obtained from cores DED 8707, DED 8708 and KET 8251 shown in Figure 10 are virtually identical on all but the shortest time scales. As noted above, the vertical scale is arbitrary and the values of the NRM/ χ ratios differ slightly between cores. This is likely to be a consequence of various local environmental conditions. Indeed, distinct families of magnetic grains yield different ratios between the magnetization intensities and the external field. The coherency of these records from the same area establishes their reliability in terms of geomagnetic behavior. Since the average time

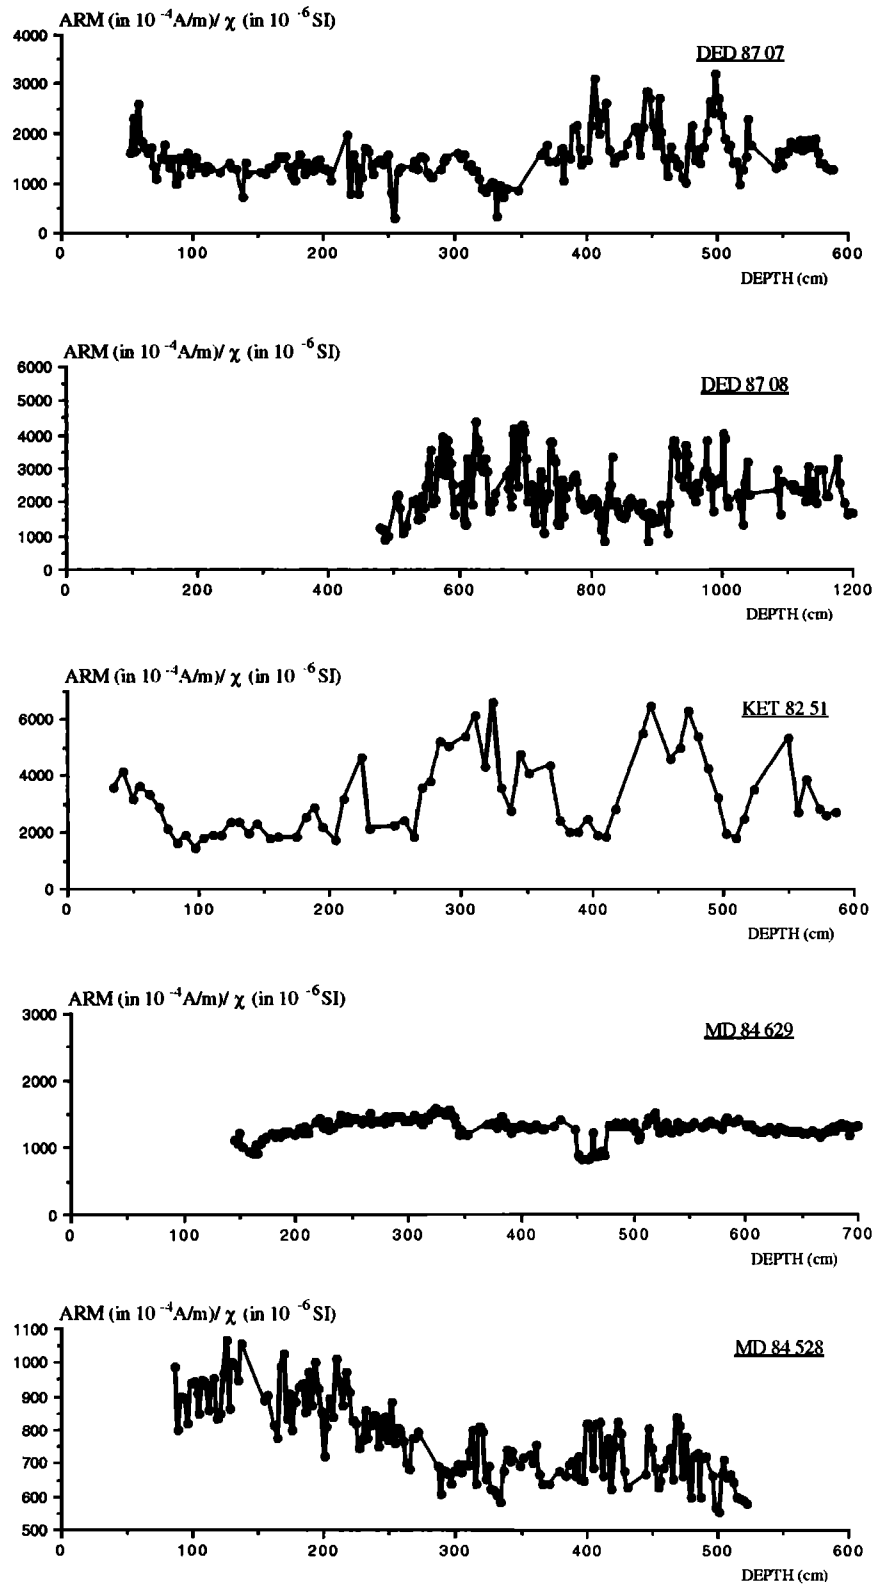

Fig. 4. Downcore evolution of the ARM/ χ ratios showing the absence of significant changes in the grain sizes.

resolution is close to 400 years, the shorter-period nondipole changes are generally filtered from the data.

However, this time span is not long enough to average out completely the effects of the secular variation at a single site. We therefore compared these results with those from the eastern

Mediterranean and the south Indian Ocean (MD 84629 and MD 84528) (Figure 10).

Every core from the Mediterranean Sea depicts similar profiles of the NRM/ χ ratio with two maxima at about 39 kyr and 60 kyr and a broad maximum centered at 52 kyr. Although

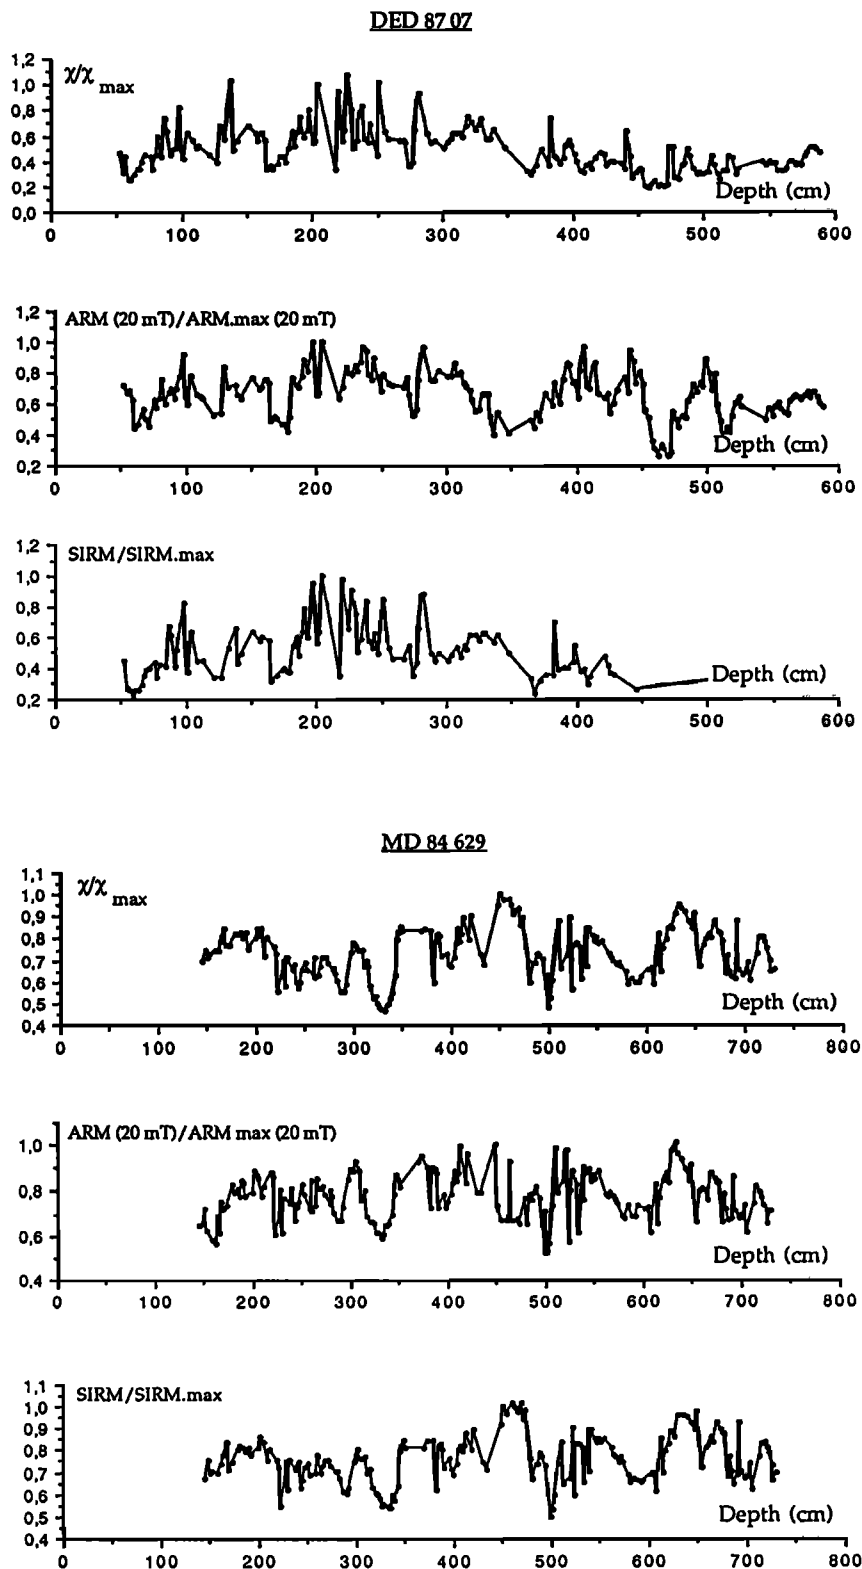

Fig. 5. Downcore variations of three distinct rock magnetic parameters in cores DED 8707 and MD 84629.

the two minima at 39 kyr and 60 kyr are present also in the record from the south Indian Ocean, the rest of the record bears less resemblance to the Mediterranean cores. Such differences may be due to nondipole local effects and/or to rapid variation in the deposition rate. Additional records from this area are thus required to distinguish between these possibilities.

It was thus reasonable to combine the four data sets from the Mediterranean Sea into a global average. To achieve this calculation, the amplitudes of the signals were constrained within the same minimal and maximal values depicted in every core at 39 and 52 kyr. The overall record obtained within successive intervals of 200 years by performing a linear

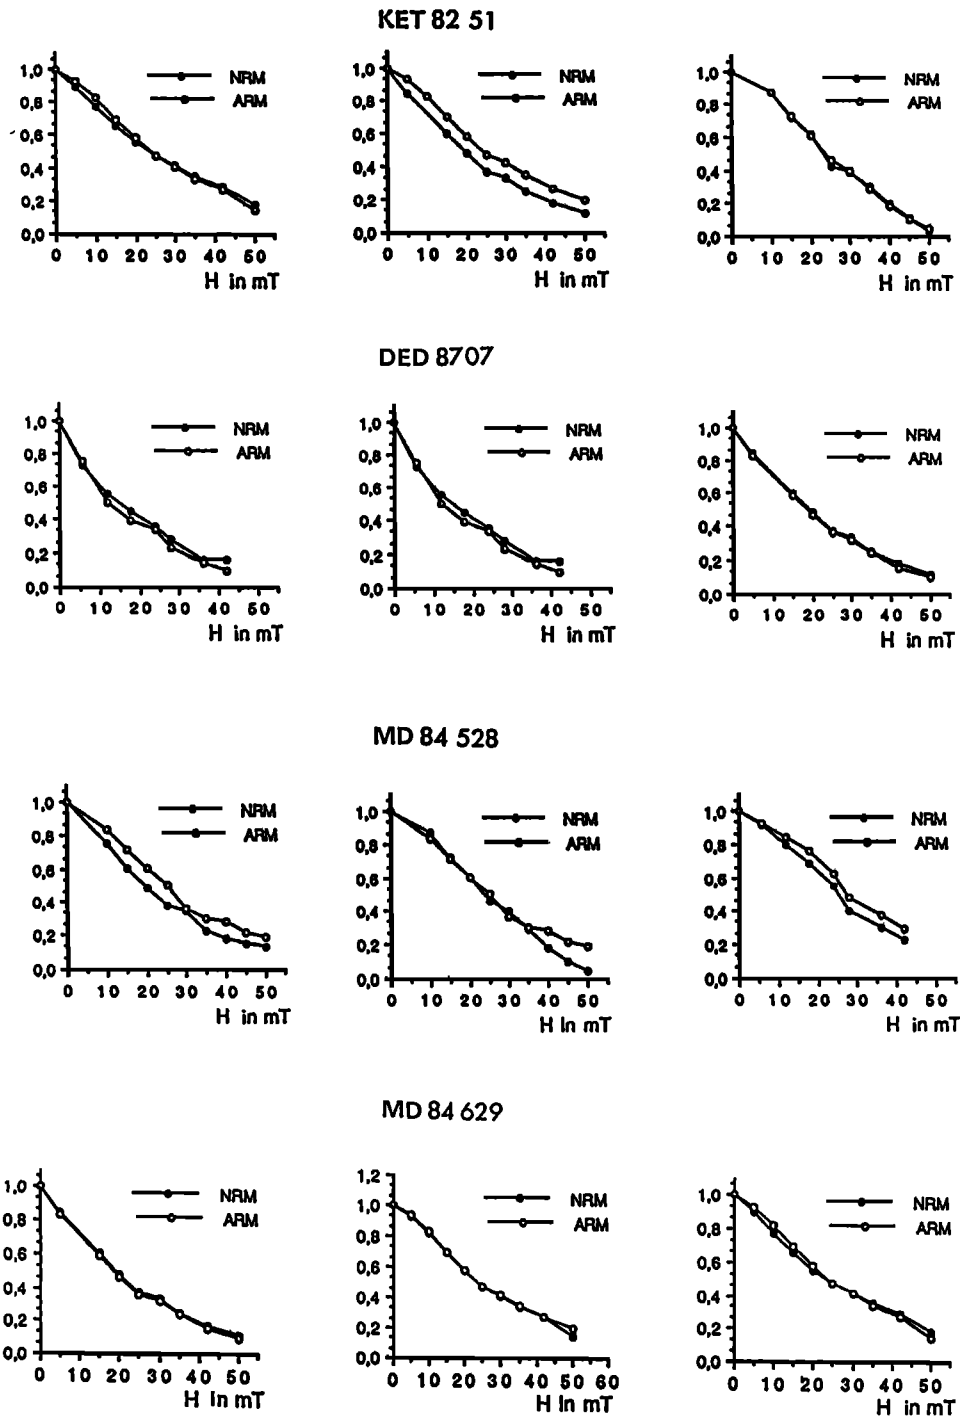

Fig. 6. Comparison between alternating field demagnetization curves of the NRM and the ARM from the same samples. The fact that similar variations are revealed by every parameter rules out the presence of large variations in the distribution of grain sizes. Both magnetizations are characterized by identical coercivities, which suggests that the same families of magnetic grains are involved.

interpolation of the data is shown in Figure 11 together with the envelope representing the mean standard deviation within every interval (characterized by at least three measurements). This curve represents our approximation of the relative paleointensities within the period 0-80 kyr. The envelope corresponds quite well to the main curve and is significantly lower in amplitude than the amplitude of the intensity fluctuations. Some detailed features observed over shorter

periods may, however, be less obvious, and these uncertainties must be kept in mind in the interpretation of the results.

If the paleointensity record obtained from these marine sediments is correct, it should compare with the archeomagnetic and volcanic data sets obtained within the interval 0-50 kyr B.P. [Coe *et al.*, 1978; Barbetti and Flude, 1979; McElhinny and Senanayake, 1982; Salis, 1987; Roperch *et al.*, 1988; Chauvin *et al.*, 1991]. All the drilling

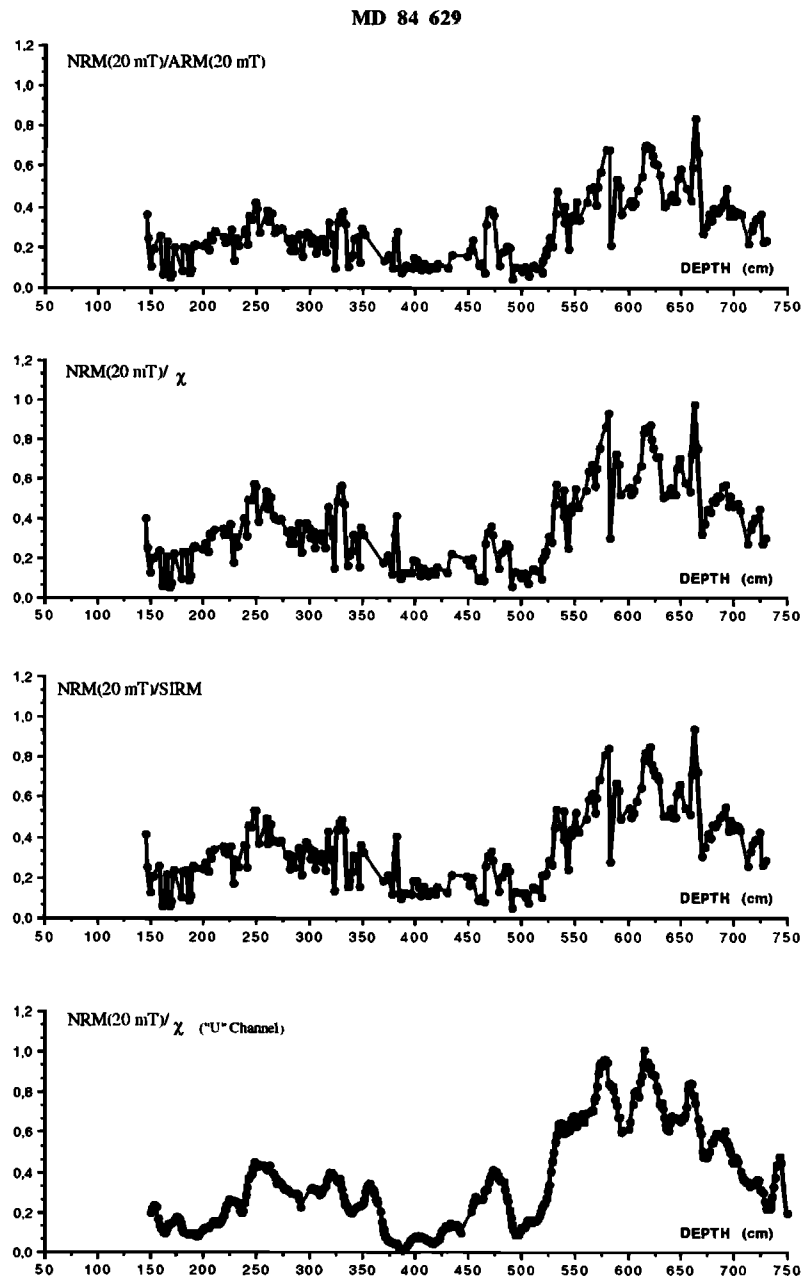

Fig. 7. Ratios of rock magnetic parameters for core MD 84 629. The similarity of the results for the four distinct ratios indicates that every set of measurements can be used as an estimate of relative paleointensity.

sites are located at the same latitude (within a few degrees). It is therefore valid to make direct comparisons between the raw magnetic field intensities deduced from this study and the virtual axial dipole moments calculated from the volcanic data by using an arbitrary scale factor.

The overall agreement between the two data sets plotted in Figure 12a may be somewhat surprising since the volcanic records are very sensitive to the effects of the nondipole fields. Periods with multiple absolute paleointensities show, however, a dispersion which can reach about one fifth of the average field value. This variability is about the same order of magnitude as the present nondipole field intensity. If this explanation is correct, we should then observe a better agreement between both curves after averaging the volcanic records over intervals of 500 years to smooth the influence of

nondipole field variations. It can be seen in Figure 12b that, after smoothing, the curves then superimpose almost perfectly.

DISCUSSION

Unfortunately, the tops of the marine cores were either missing or partly disturbed, so that no record could be obtained for the period covering the last 8 kyr and compared with the archeomagnetic data set compiled by *McElhinny and Senanayake* [1982]. However, the record is in excellent agreement with the rest of the archeomagnetic data set from 40 to 8 kyr and confirms that a general increase of the field intensity prevailed for this period, culminating in a small intensity peak at 9 kyr which has been reported in earlier studies of marine sediments from the Atlantic [*Tauxe and Valet*,

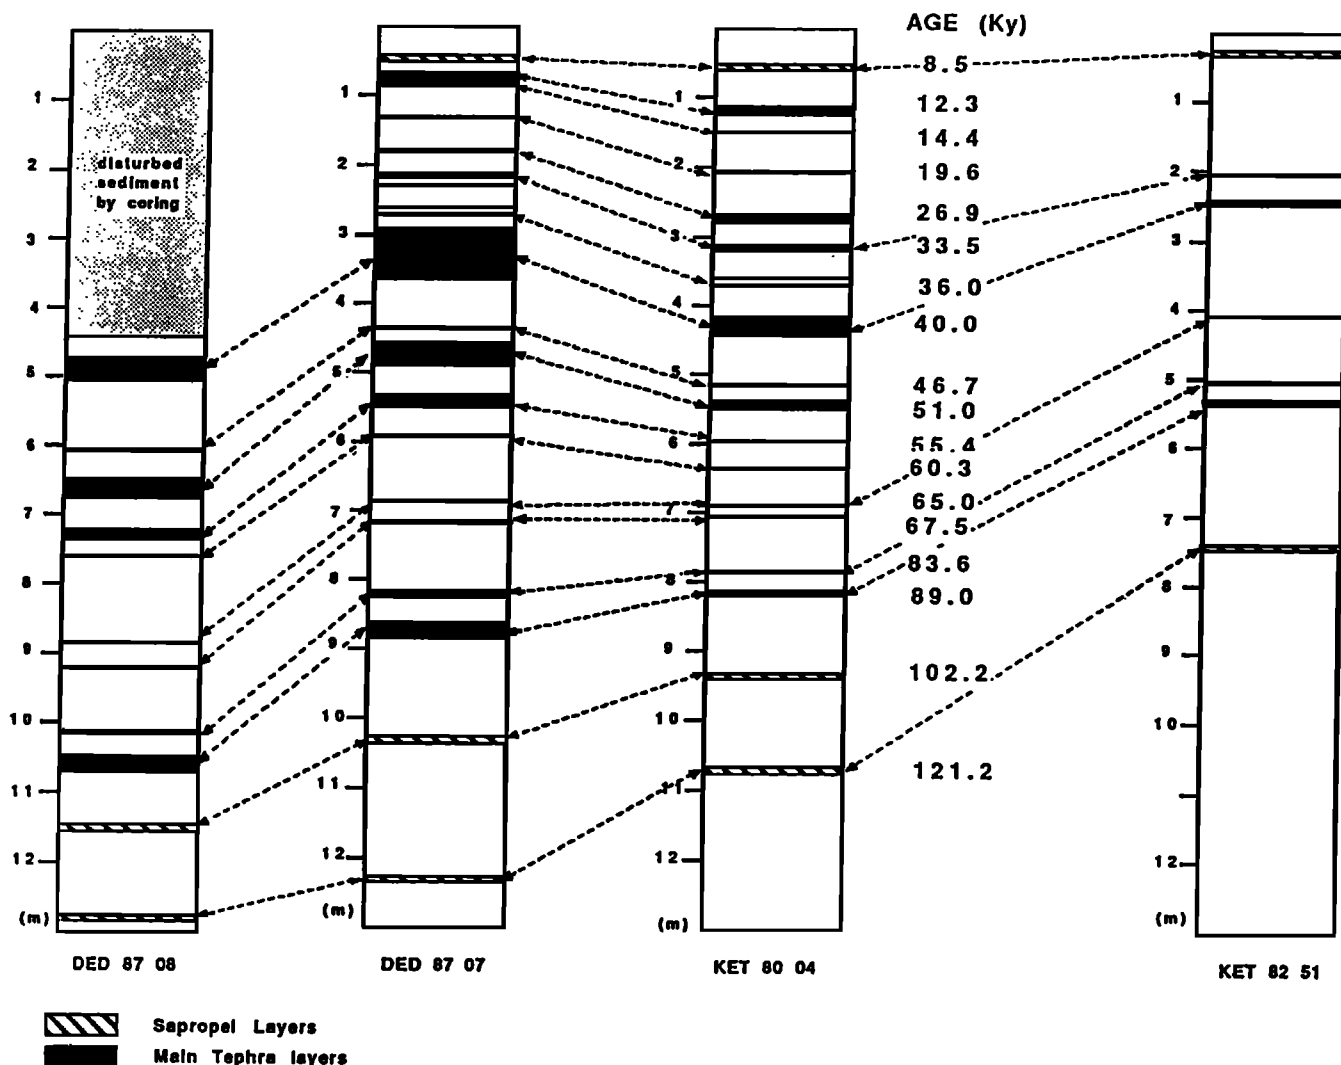

Fig. 8a. Detailed correlations between the four cores from the Tyrrhenian Sea. The absolute time scale is provided by the complete oxygen record of core KET 8004, which was used as a reference [Paterne, 1985; Paterne et al., 1986; Paterne et al., 1988].

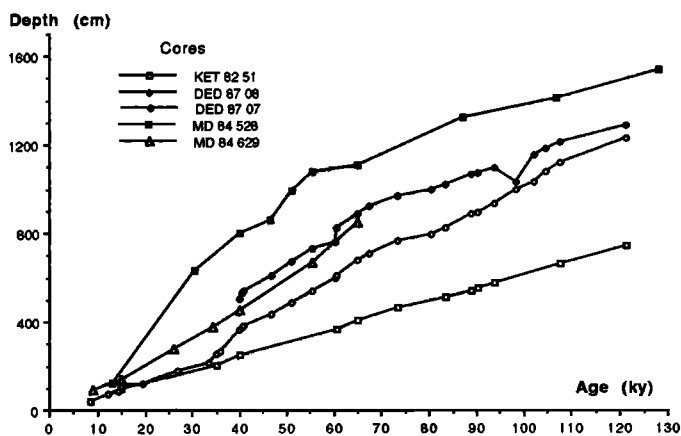

Fig. 8b. Variations in the deposition rates calculated within every successive dated level.

1989] and the Pacific oceans [Constable and Tauxe, 1987]. Such good agreement even on short time scales between remote records obtained from various media constitutes an additional indication of the ability of sediments to retain field intensity variations of relatively high frequency.

The new results obtained in this study indicate that a general field intensity increase has prevailed since 20 kyr B.P. with a minimum value of 28% of the present field. Before this period the paleointensity curve depicts three major oscillations with significant drops occurring at 21, 39 and 60 kyr. On average, the field value was lower by about a factor of 2 than the present intensity for the period 0-80 kyr.

The lowest dipole moment occurred at 39 kyr. Weak intensities and excursions directions were reported in the same time interval in France (Laschamp and Olby flows) [Bonhommet and Babkine, 1967; Chauvin, 1989; Roperch and Bonhommet, 1982; Roperch et al., 1988] and in Iceland (Skalameifell excursion) [Levi et al., 1987; Marshall et al., 1988]. Although the datings of these lava flows agree reasonably well, the error bar inherent in the chronological data does not allow us to establish firmly that they were contemporaneous. No departure of the geomagnetic vector from

the normal direction was observed during this period in the single samples from the marine cores involved in this study, which would mean that the duration of the event was less than 200 years. There is also no evidence for directional changes during this period in the high-resolution sedimentary sequence from Lac du Bouchet [Creer *et al.*, 1986; Creer, 1989; Thouveny *et al.*, 1990]. Discontinuities and/or breaks in the sedimentation could be responsible, but it is difficult to imagine that these phenomena occurred synchronously in different oceans, as well as in lacustrine sediments. Therefore, at least five high-resolution sedimentary records obtained from widely separated areas imply a very short duration of the Laschamp event which, even allowing for possible averaging effects due to postdepositional processes, cannot exceed a few hundred years. An implicit consequence is that the almost complete field reversal recorded at Laschamp and Olby has a duration lower by more than an order of magnitude than durations currently reported for the directional changes associated with reversals. It may thus be difficult to envisage that the Laschamp event was governed by similar processes.

Two regular and successive oscillations with similar amplitudes between 20-40 kyr and 40-60 kyr suggest the presence of sinusoidal variations with periodicities of about 20 kyr. Links between variations in the geomagnetic field and the Earth's orbital parameters have been suggested by several authors [Kent and Opdyke, 1977; Wollin *et al.*, 1978; Negi and Tiwari, 1984]. Although the time constants observed in this study appear to be similar in magnitude to those involved in the precession of the Earth's orbit, the present record is far too short to establish the validity of a periodic cycle. The record begins at about 10 kyr, and the oldest part, between 60 and 80 kyr, is marked by a somewhat higher noise level.

Three independent paleointensity records have been obtained from the Pacific Ocean which cover long periods. Kent and Opdyke [1977] performed a statistical analysis of the NRM/ARM record from core RC10-167, located in the North Pacific, and found a dominant 43-kyr period during the last 700 kyr. Tauxe and Wu (1990) performed a new analysis of this record by taking into account the changes in the sedimentation rates (the previous time scale was based solely on the Brunhes-Matuyama boundary) combined with two other cores (ERDC 113p and 89p comprised between 0 and 372 kyr) from the Ontong Java plateau [Constable and Tauxe, 1987], in the western equatorial Pacific. These authors found that a dominant frequency of around 33 kyr (which is the same peak as detected by Kent and Opdyke taking into account the rescaling effects) prevailed for the last 350 kyr. However, this analysis has been performed over a very long period from records with a much lower resolution than that of the present study. A synthesis of

the results from the North Pacific has been obtained by combining the results from box cores [Constable and Tauxe, 1987] and the record from piston cores [Tauxe and Wu, 1990]. The result is in good agreement with the stacked record in Figure 12c. Within small phase shifts related to the uncertainties in the datings, identical variations are observed within the same time intervals. Only the oscillation between 20 and 30 kyr is not obvious in the Pacific record ERDC 113p. This may be due to changes in the deposition rate, discontinuity between piston cores and box cores, and also a consequence of the very different average time resolution (by a factor of 8) between both records.

Based on these results it seems therefore that different periodicities could have prevailed at distinct epochs. There is a priori no apparent reason for suspecting stationary features of the geomagnetic field. However, the present data set is restricted to a limited number of cores, and a thorough investigation, from many regions, is now necessary to extend the analysis further back in time on a more global scale.

CONCLUSION

Relative paleointensity estimates of the geomagnetic field variations have been made from five marine cores distributed in the Tyrrhenian Sea, the eastern Mediterranean and the south Indian Ocean. Oxygen isotopes and tephrochronology provided independent time frameworks for the last 80 kyr. There is excellent agreement between the records when plotted on the same time scale, and features as short as 2 or 3 kyr could be resolved with good precision. Little discrepancies found between the synthetic curve from Mediterranean records and the single record from the south Indian Ocean demonstrate the importance of acquiring distinct records from the same area in order to isolate the true dipolar field variations. The overall curve compares quite well with the global archeomagnetic data before 10 kyr B.P. and provides an excellent fit to the sparse absolute paleointensities obtained from lava flows within the period 0-40 kyr. Two well-marked minima at which the geomagnetic field intensity fell to 22 and 28 percent of the present value occurred at 39 and 60 kyr, respectively. Interestingly, the low field values at 39 kyr coincide with the period recording anomalous directions at Laschamp, but no directional change is apparent in the records. Although some evidence of a periodic cycle of 20 kyr could be deduced from

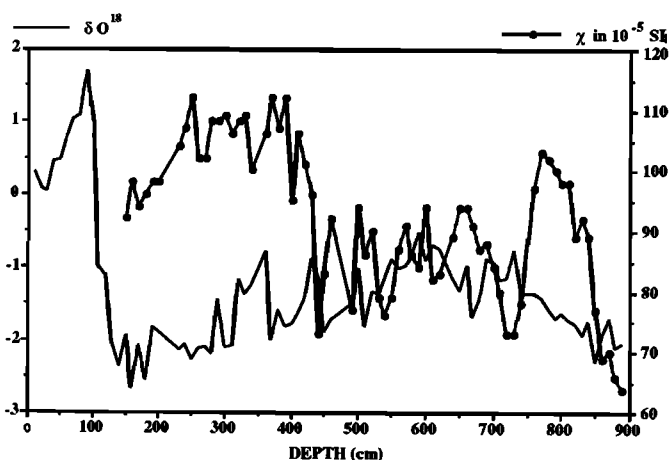

Fig. 9. Comparison between the $\delta^{18}O$ and the low-field susceptibility records of core MD 84629. Some correlations could be present, but the amplitude of the variations does not account for major and long-term changes.

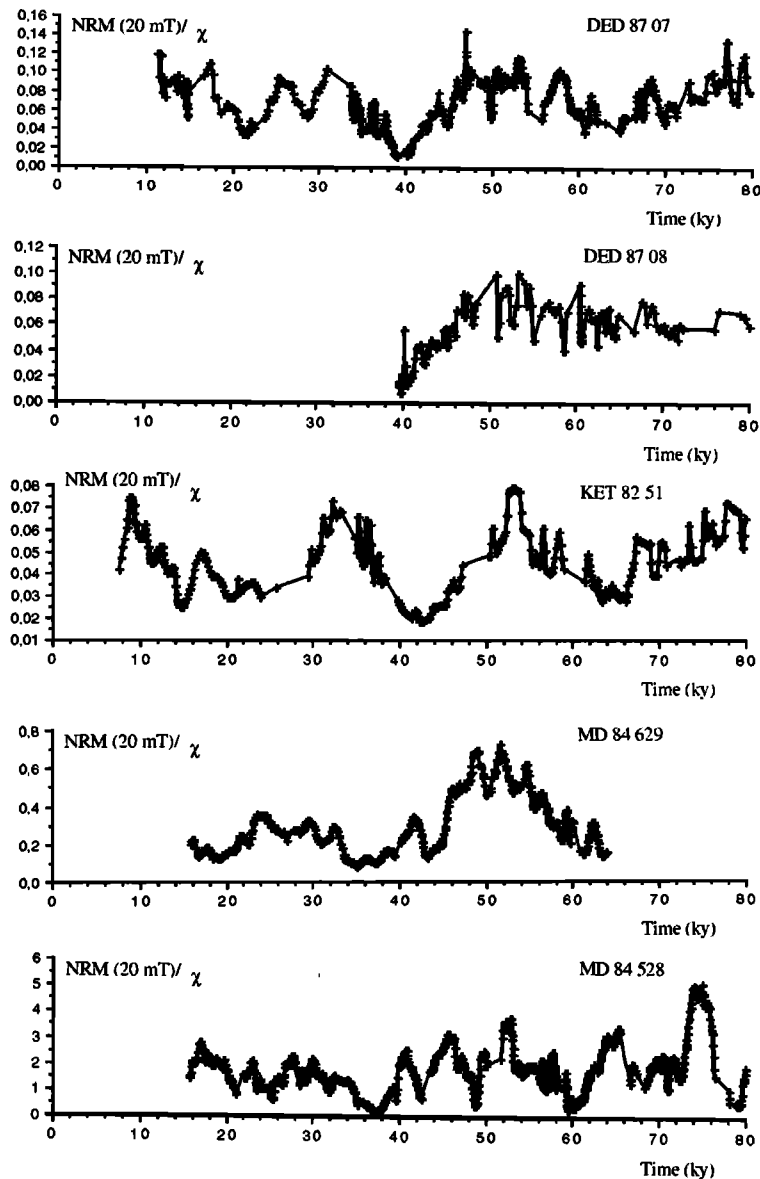

Fig. 10. Evolution of the NRM (20 mT)/ χ ratio plotted as a function of time. The vertical scales are arbitrary.

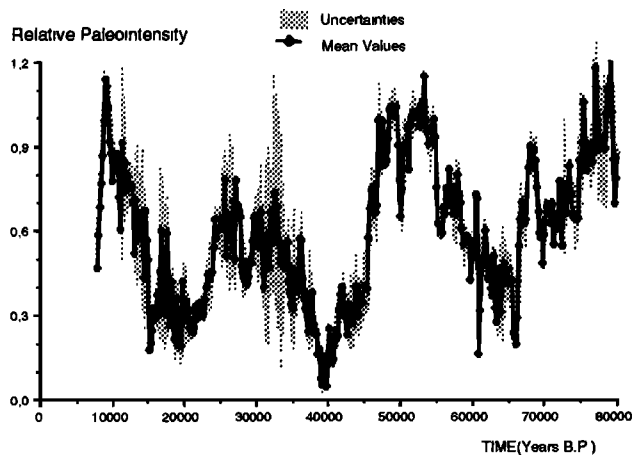

Fig. 11. Stacked record of the NRM(20mT)/ χ data calculated from the four scaled Mediterranean cores (DED 8707, DED 8708, KET 8251 and MD 84629). The envelope of the curve is delimited by the standard deviation from the mean of the measurements (within intervals of 200 years). This curve represents our best approximation of the relative field paleointensity.

these data, the records are too short for establishing conclusive correlations with parameters linked to the Earth's orbit.

The present results also compare quite well with a paleointensity record from the western equatorial Pacific. This correlation can be envisaged as a first step towards the construction of a global paleointensity record of the dipole field. Indeed, the remarkable coherence between normalized intensity records from geographically distinct areas with different paleoenvironmental conditions demonstrates the potential of sediments as reliable recorders of relative variations of the geomagnetic field intensity.

Acknowledgments. The authors are pleased to acknowledge C. Laj, L. Hagee, R. Weeks for critical readings of the manuscript. D.C. Clark and J. Tessier provided technical assistance. A. Mazaud and C. Jehanno provided generous assistance in various stages of this work. The marine cores used for this study were collected during cruises of the French oceanographic vessel Marion Dufresne (Terre Australes et Antartiques Françaises). This is CNRS-INSU DBT-Messages Sédimentaires contribution 313 and CFR contribution 1173.

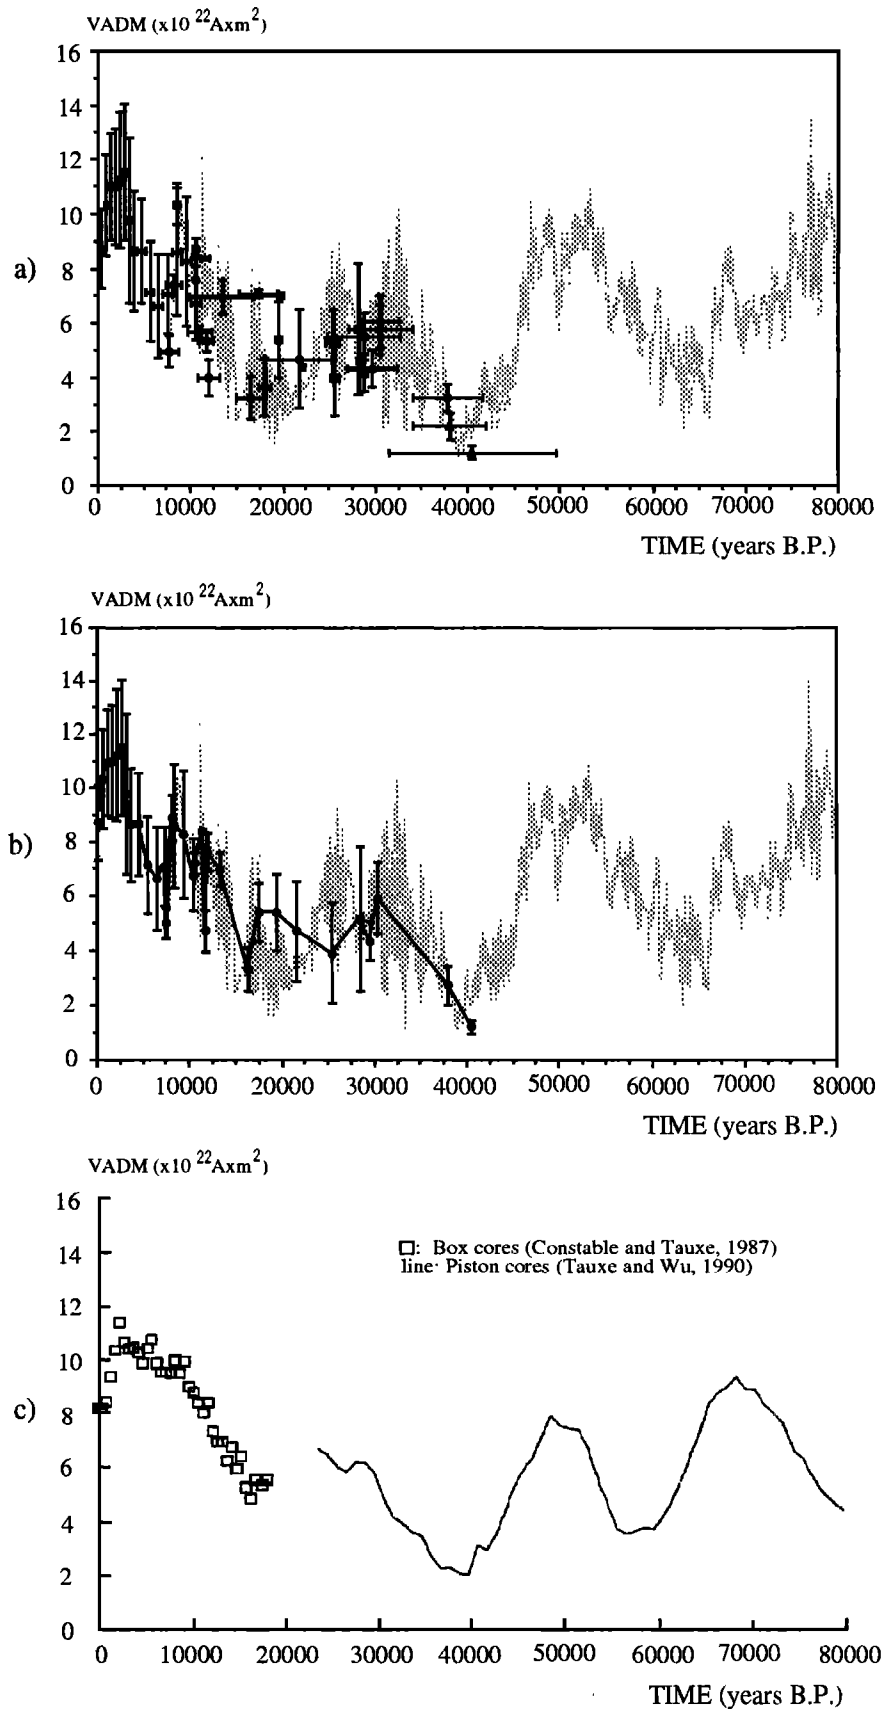

Fig. 12. (a) Comparison between the sedimentary records and the (archeomagnetic and) volcanic data sets available for the period 0–40 kyr. small square: *Coe et al.* [1978]; large square: *Barbetti and Flude* [1979]; small circle: *McElhinny and Senanayake* [1982]; large circle: *Salis* [1987]; small triangle: *Roperch et al.* [1988]; large triangle: *Chauvin et al.* [1991]. (b) The volcanic data averaged within intervals of 500 years. (c) Stack record obtained from piston cores ERDC113p in the eastern equatorial Pacific [*Tauxe and Wu*, 1990] and box cores in the North Pacific [*Constable and Tauxe*, 1987]
