22 Abstract

23
24
25
26 During the mid-to-late Pliocene (ca. 4–3 Ma), several hominin species were present in central
27 Sahel, eastern and southern Africa. Potential discovery of hominin remains from this period is limited
28 by the availability of exposed Pliocene deposits and the ability to investigate them. As a result, most
29 discoveries have been made in the Afar region of Ethiopia and in the Lake Turkana basin, thus unveiling
30 only a portion of Pliocene hominins' probable geographical presence. In this study we provide a
31 continental view of geographic areas potentially accessible to these hominins. To do so, we simulate the
32 climatic envelope suitable for mid-to-late Pliocene hominin presence, using the earth system model
33 IPSL-CM5A and the Maxent habitat suitability algorithm. The latter indicates high habitat suitability
34 for these hominin species in semi-arid regions where annual thermal amplitude and mean annual
35 precipitation are moderate, mostly corresponding to tropical xerophytic shrublands. Our habitat model
36 estimates geographically continuous, suitable climatic conditions for hominins between central Sahel
37 and northeastern Africa, but not between eastern and southern Africa. This discontinuity suggests that
38 southern African and eastern African hominins were separated by an environmental barrier that could
39 only be crossed during particularly favourable periods or by undertaking long-range dispersal over
40 climatically hostile habitats. During simulated periods of climate changes driven by orbital precession
41 this climatic barrier is not present. The Turkana basin, the Laetoli region, and a large part of southern
42 Africa remain suitable for all precession angles, suggesting that these areas may have functioned as
43 refugia. The constant presence of these stable areas combined with the periodic establishment of
44 corridors for dispersion can potentially explain hominin diversity in eastern Africa.

51 1. Introduction

52

53 The mid-to-late Pliocene, ca. 4–3 million years ago (Ma), was a period of global warmth with
54 atmospheric CO₂ concentrations around 400 ppm, smaller ice sheets, reduced desert areas compared to
55 the present, a global temperature 2–3°C warmer than the preindustrial period (e.g. Salzmann et al.; 2013;
56 Haywood et al., 2020). Oxygen isotope ratios of benthic foraminifera and continental ice records show
57 that this period was climatically stable, with the exception of short-lived cold episodes around 3.6 Ma
58 and 3.3 Ma (De Schepper et al., 2014; Lisiecki and Raymo, 2005). During this period, several hominin
59 species appear to have coexisted and fossil occurrences occur in three distinct geographic areas: central
60 Sahel (*Australopithecus bahrelghazali*: Brunet et al., 1995, 1996; Lebatard et al., 2008), eastern Africa
61 (*Au. anamensis*, *Au. afarensis*: Haile-Selassie et al., 2019; *Kenyanthropus platyops*: Leakey et al. 2001;
62 *Au. deyiremeda*: Haile-Selassie et al., 2015) and southern Africa (*Au. prometheus*: Clarke and Kuman,
63 2019; *Au. africanus*: Dart, 1925; Herries et al., 2013). These hominins thrived in C₃-C₄ mosaic habitats
64 (Behrensmeyer and Reed, 2013), close to freshwater sources in the form of rivers (Curran and Haile-
65 Selassie, 2016), springs and oases (Barboni et al., 2019), or lakes (paleo-lake Turkana: Feibel, 2011;
66 Boës et al., 2019; paleo-lake Chad: Schuster et al., 2009; Lee-Thorp et al., 2012). They may have used
67 technology, since the oldest recovered retouched pebble assemblage discovered near Lake Turkana is
68 dated ca. 3.3–3.2 Ma (Harmand et al., 2015).

69 While their exploited microhabitats appear to have been mostly dominated by the presence of freshwater
70 and some locally sustained trees, several authors propose that they could have coped with a variety of
71 environments (within which similar microhabitats could occur), thus leading to the idea that the genus
72 *Australopithecus* could have been eurytopic (Bonnefille et al., 2004; Behrensmeyer and Reed, 2013).
73 Our ability, however, to observe and investigate hominin remains from this period is limited by the
74 availability of exposed Pliocene deposits. As a result, most discoveries have been made in the Afar
75 region of Ethiopia and the Lake Turkana Basin, thus representing only a portion of the probable Pliocene
76 hominin geographic distribution. Here, we aim to provide a continental view of the geographic areas
77 potentially accessible to these hominin populations. Reconstructing the presence of freshwater sources
78 at reduced geographic scales is speculative for chronological intervals that have a resolution of hundreds

79 of thousands of years and regions for which detailed paleotopography is unknown. However, sources of
80 perennial freshwater and associated gallery vegetation can occur anywhere total annual precipitation
81 exceeds 200–300 mm and topographic depressions or river channels exist (Quade et al., 2018). This is
82 the case during the mid-Holocene and the Last Interglacial when surface drainage was reactivated in the
83 Sahara (e.g. Coulthard et al., 2013; Skonieczny et al., 2015), as well as in areas where precipitation is
84 lower than that threshold, but sustained by groundwater (e.g. present-day Ounianga lakes in northeastern
85 Chad: Kröpelin et al., 2008). C₃-C₄ mosaic habitats, similar to those occupied by hominins, are
86 ubiquitous in African savannah environments (Marston et al., 2018) for which woody cover depends on
87 the frequency and intensity of single rainfall events (Good and Caylor, 2011), which are not known for
88 past periods. Although there is a link between large-scale climate and hominid microhabitats, i.e.,
89 perennial freshwater sources enable the development of mosaic habitats, we cannot mechanically
90 calculate this.

91 We address these issues from a statistical point of view by employing climate envelope modeling
92 methods to determine which large-scale climate variables are most appropriate for explaining known
93 hominin occurrences between 4 Ma and 3 Ma and inferring their potential distributions. To do so, we
94 employ a set of mid-to-late Pliocene climatic variables simulated with the earth system model IPSL-
95 CM5A (Dufresne et al., 2013) to create a climatic envelope model that best matches the distribution of
96 mid-to-late Pliocene hominin occurrences using the *kuenm* R package (Cobos et al., 2019), which uses
97 the Maxent algorithm (Phillips et al., 2006, 2017). Via this approach, we 1) evaluate the capacity of
98 these methods to diagnose the appropriate areas for which we possess data; 2) map potentially suitable
99 areas currently free of paleontological remains and 3) employ a series of insolation sensitivity
100 experiments to investigate potential dispersal between our targeted geographic regions and potential
101 refuge areas.

104

105

106

107

108 2. Methods

109 2.1 Climate model description and setup

110

111 We use the earth system model IPSL-CM5A to simulate late Pliocene climate. Atmospheric
112 resolution of the model is 3.75° in longitude by 1.9° in latitude, with 39 vertical levels. Mean grid
113 spacing of the ocean model is approximately 2° , while latitudinal resolution is refined to 0.5° near the
114 equator and 1° in the Mediterranean Sea. This model has been widely used for the study of future and
115 past climates (e.g. Dufresne et al., 2013; Kageyama et al., 2013; Contoux et al., 2012, 2015). The
116 boundary conditions used to force the model follow the Pliocene Model Intercomparison Project phase
117 1 (PlioMIP1) guidelines described by Haywood et al. (2010). They have been adapted to the IPSL-
118 CM5A model with a modified topography, smaller ice sheets, and atmospheric concentration of CO₂
119 fixed at 405 ppm (Contoux et al., 2012). The climate model uses PlioMIP boundary conditions
120 designed to simulate the climate of the mid-Piacenzian (Contoux et al., 2012). Given that benthic
121 isotope ratios show that climate variability was low from 4–2.8 Ma except for two cold outbursts at
122 3.6 and 3.3 Ma (Lisiecki and Raymo, 2005; Tan et al., 2017), we extrapolate that this simulation is
123 valid for the period between 4–3 Ma, which mostly corresponds to the Piacenzian. There exists a
124 multitude of possible orbital configurations for any period that spans several hundred thousand years,
125 but we can only use one set of orbital parameters per simulation since we conduct equilibrium climate
126 simulations rather than transient ones. Because the primary goal of the PlioMIP simulation was to
127 compare the climate of the mid-Piacenzian to the preindustrial, the choice made by the PlioMIP
128 community was to use the present-day orbital configuration. This present-day configuration is one for
129 which eccentricity is small. In other words, climate variability linked to precession, which is the main
130 mode of climate variability during the Pliocene, is also small. Thus, we use it as a proxy for Pliocene
131 ‘mean’ climate. This simulation (Pliocene ‘mean’ climate) has been extensively studied and compared
132 to other climate models in the framework of PlioMIP1 (e.g. Haywood et al., 2010; Zhang et al., 2013).
133 We also conducted four additional Pliocene experiments in order to capture an envelope of maximum
134 climate variability during our target period. We do so using modified orbital parameters corresponding

135 to the period of highest eccentricity (see appendix 1) with four different precession angles (one per
136 simulation), corresponding to the Earth at perihelion at the Northern Hemisphere summer solstice
137 (PlioMax June) and autumn equinox (PlioMax September), and the two opposites, at aphelion at
138 Northern Hemisphere summer solstice (PlioMin June) and autumn equinox (PlioMin September).
139 Orbital parameters were calculated using the Analyseries software (Paillard et al., 1996).
140 Climatological means were calculated from the last 50 years of each simulation. Bias correction of the
141 climate model output was obtained by using the climatic anomalies (temperature difference and
142 percent change for precipitation, e.g. Hély et al., 2009) superimposed on Climate Research Unit
143 climate observations at 0.5° by 0.5° (New et al., 2002). This is possible since the biases of a climate
144 model are supposed to be stationary through different time periods (Krinner and Flanner, 2018). Our
145 simulated climatic fields are thus downscaled from a resolution of 1.9° by 3.75° to 0.5° by 0.5°.

146

147 2.2 Vegetation model description and setup

148

149 We employed the BIOME4 model (Kaplan et al., 2003) to calculate vegetation in equilibrium with
150 the Pliocene mean climate and the four orbital Pliocene climates. To do so, we calculated climate
151 anomalies between each Pliocene experiment and the preindustrial control experiment (temperature
152 difference and percentage of change for precipitation and clouds, e.g. Hély et al., 2009) interpolated at
153 0.5°x0.5°. The anomalies were then added to the 0.5°x0.5° gridded data from the Climate Research Unit
154 (New et al., 2002). The model BIOME4 calculates vegetation types in equilibrium with climate model
155 outputs (monthly mean precipitation, air surface temperature, cloud cover and absolute annual minimum
156 air surface temperature). Atmospheric CO₂ concentration was fixed at 405 ppm (PlioMIP value) and
157 soil characteristics kept at present-day values.

158 Biomes are assigned according to which plant functional types (PFT) are dominant, as well as the
159 productivity and leaf area index (LAI) of each PFT. For example, when the productivity on one grid cell
160 is dominated by the the tropical raingreen tree PFT, followed by the C₄ tropical grass and the woody
161 desert PFT, the grid cell will be associated with tropical xerophytic shrubland biome if the LAI of the

162 tropical raingreen tree PFT is < 4 and to the tropical savannah biome if the LAI of tropical raingreen
163 tree PFT is > 4 .

164

165 2.3 Hominin occurrence data

166

167 Predictive architectures used to estimate ecological niches or climatic envelopes rely, in part, upon
168 the geographic coordinates (longitude and latitude) of locations where the target population has been
169 observed. In this study, the occurrence data are the locations where fossil hominins dated from ca. 4–3
170 Ma have been recovered. This choice was made for several reasons. First, our climate model is
171 representative of Piacenzian climate (ca. 3.6—2.8 Ma). This corresponds to the chronological interval
172 to which *Au. afarensis* has been dated. Climatic envelope modeling is performed typically at the
173 species level. However, the diversity of *Australopithecus* species is poorly constrained as some
174 species, and even genera, are controversial (*Au. bahrelghazali*, *Au. prometheus*, *K. platyops*). The
175 intra-specific and inter-specific variability of *Australopithecus* species is also poorly understood, such
176 that with the recent discovery of the first complete cranium of *Au. anamensis* (Haile-Selassie et al.,
177 2019) remains previously assigned to *Au. afarensis* were reclassified as *Au. anamensis*. Given the
178 taxonomic uncertainty of many *Australopithecus* remains, and considering that the genus provides a
179 working framework, we chose to simulate the climatic envelope suitable for the ensemble of Pliocene
180 *Australopithecus* species, as well as *Kenyanthropus*. This approach is justified by the review of
181 *Australopithecus* paleoenvironments carried out by Behrensmeyer and Reed (2013) demonstrating that
182 these hominins are all associated with similar environments, thus suggesting that their climatic
183 envelopes were likely similar. We excluded the more primitive *Ardipithecus*, which is older than 4
184 Ma, as well as *Australopithecus* species that are clearly Pleistocene in age (*Au. garhi* and *Au. sediba*)
185 since climatic deterioration due to the Northern Hemisphere Glaciation was already well established
186 by that time (e.g. Tan et al., 2018).

187 In order to have independent training and test data sets and to limit spatial auto-correlation, we
188 eliminated multiple occurrences such that a grid cell (0.5° by 0.5°) only contained a single occurrence
189 point (see below). As a result, we have only 18 occurrence points (Table 1) despite the fact that more

190 than 18 paleontological sites exist. Most of these localities are tightly clustered, especially in the
 191 Awash Valley and the Turkana Basin.

192
 193 Table 1. Hominin occurrence points used in this study. The sites of Assa Issie (*Au. anamensis*), Aramis
 194 (*Ardipithecus* and *Au. anamensis*), Maka and Belohdelie (*Au. afarensis*) and Bouri (*Au. garhi*) all fall in
 195 the grid cell ‘Middle Awash’ because of their geographic proximity.

2.4 Maxent climate envelope model and kuenm R package descriptions and set-up

202 We use the term “climatic envelope modelling” to describe our approach. This term expresses the
 203 idea that “a multivariate space of climatic variables best matching the observed species’ distribution is
 204 being estimated” (Araujo and Peterson, 2012). It does not imply a direct link with Hutchinson’s theory
 205 of ecological niches, as is the case with the term “ecological niche modeling”. In this study, we assume
 206 that aspects of climate determine, at least in part, species distributions, and we do not interpret the
 207 resulting predictions within a strict ecological niche framework. The output from the Maxent model is
 208 termed habitat suitability index. This term of habitat should not be interpreted in the sense of
 209 microhabitat because the climatic data that we provide Maxent are at a large scale of 0.5° (i.e. roughly
 210 2500 km²). The term habitat suitability index should be understood as a measure of how suitable the
 211 large-scale environment was to the targeted African Pliocene hominins.

212 To model the climatic envelope, we use the Maxent algorithm (Phillips et al., 2006, 2017; Phillips
 and Dudik, 2008), which has shown to perform well compared to other correlative predictive

213 architectures, especially when relying on limited occurrences datasets (e.g. Phillips et al., 2006; Elith et
214 al., 2006; Hernandez et al., 2006). Maxent requires the geographic location of sites where the target
215 species have been observed (i.e., fossil localities) and geographically continuous environmental
216 variables over the region of interest, which are derived from the climate model described above.
217 Maxent is based on the maximum entropy principle such that the estimated probability distribution is
218 constrained by climatic characteristic associated with the known occurrence localities while it avoids
219 assumptions not supported by the data. Maxent is not a classical presence-absence modeling method,
220 but rather a presence-background method as real absences are not known and cannot be taken into
221 account during the sampling of environmental variables (Guisan et al., 2017). This approach to
222 background sampling makes Maxent suitable for making distributional predictions based on
223 paleontological data. Maxent will compare the probability distribution associated with presence
224 occurrences with the one associated with background points randomly sampled in the environment. The
225 area over which this comparison will be done (i.e. the calibration area) has a great influence on model
226 performance. Its size should be neither too small or too large (e.g. VanDerWal et al., 2009), and should
227 be biologically meaningful to ensure that the background points represent the environmental conditions
228 accessible to the species (Anderson and Raza, 2010; Barve et al., 2011). The calibration area
229 encompassing all occurrences points and used in Maxent models can be found in Appendix 1. Maxent,
230 however, is known to be sensitive to model settings (e.g. parameterization, number of variables) that
231 affect model complexity (Warren and Seifert, 2011; Peterson et al., 2018). The more complex a model
232 is, the more likely it will be overfitted. The more overfitted a model is, the more it will struggle to
233 extrapolate suitable habitats outside areas where occurrences are already known (Peterson et al., 2007).

234 In order to address this sensitivity and select the optimal parameterization, we employed the
235 *kuenm* R package (Cobos et al., 2019) to produce and evaluate candidate models, as well as to perform
236 final evaluations of the best models. We performed model calibration by testing the performance of
237 2210 candidate models. We produced these models using 26 distinct variable sets, made up of all unique
238 combinations of two or more of the five climatic and vegetation variables from the Pliocene ‘mean’
239 climate simulation described below. The candidate models also employed one of 17 regularization
240 multipliers (0.1–1 at intervals of 0.1, 2–6 at intervals of 1, as well as 8 and 10), and five feature classes

241 or feature class combinations (q, qp, lp, lq, lqp; l=linear, q=quadratic, p=product). We based our
242 evaluations of the candidate models' performance by first evaluating significance and predictive power
243 using partial ROC (500 iterations, and 50% of data for bootstrapping; Peterson et al., 2008) and omission
244 rate metrics. We then evaluated model complexity using the Akaike Information Criterion for small
245 sample sizes (AICc) (Warren and Seifert, 2011). We retained model parameterizations that resulted in
246 statistically significant models, resulted in omission rates lower than 5%, and Δ AICc values less than
247 two. The parameters of these retained models were used to create final models with 10 replicates by
248 bootstrapping. The complete *kuenm* R script that used the Pliocene 'mean' climate model is provided as
249 an Rmarkdown document in Appendix 2. The final model was projected onto the sets of environmental
250 conditions for each of the four precession angle configurations. During the process of model projection,
251 we allowed free extrapolation given the response curves (i.e., response curves not truncated for at least
252 two variables) observed during model calibration. In order to consider, the risks associated with strict
253 extrapolation and to prevent misinterpretation of transferred areas with non-analogous conditions, we
254 employed the mobility-oriented parity (MOP) metric (Owens et al., 2013). Following the approach
255 suggested by Pearson et al. (2006) for small sample sizes, the simulated climatic envelope represents
256 "regions that have similar environmental conditions to where the species is known to occur, and not as
257 predicting actual limits to the range of a species", given that absence of proof is not the proof of absence
258 (see Discussion). The lower threshold for hominin presence was set to the value of the lowest habitat
259 suitability index (fixed sensitivity; Peterson et al., 2011: p.119) score amongst the occurrence points.

260 The five variables used for predicting the envelope model are representative of mean climate
261 and seasonality: Warmest Month Temperature (WMT), Coldest Month Temperature (CMT),
262 Temperature Difference between the warmest and the coldest months (DT), Mean Annual Precipitation
263 (MAP), and Driest Month Precipitation (DMP). Mean Annual Temperature (MAT), Wettest Month
264 Precipitation (WMP), Precipitation Difference between the wettest and the driest months (DP) and Net
265 Primary Productivity (NPP) were excluded from the final analysis, following the recommendations of,
266 e.g. Merow et al., (2013), because they contributed only marginally to the definition of the climatic
267 envelope and were highly correlated to the employed variables. The candidate models used to build the

268 final model do not necessarily include all of the five selected variables as model overfitting increases
269 with the number of employed environmental variables (Guisan et al., 2017).

270 Given the chronological uncertainty associated with hominin fossil contexts and the temporal
271 span of the targeted period, we cannot associate specific fossils or groups of fossils with a particular
272 orbital configuration. The most conservative choice is to use the least extreme orbital
273 configuration—Pliocene ‘mean’ climate—to estimate a climatic envelope. With this configuration,
274 eccentricity is small thereby favoring lower seasonality and lower climatic variability linked to
275 precession. To detect suitable areas that remained stable across the four precession configurations (i.e.
276 refugia), we thresholded the final model and each projection by reclassifying as non-suitable (i.e. 0) all
277 grid cells with suitability scores lower than the lowest value amongst the occurrence points. Next,
278 suitability scores were grouped into three equal categories (low-, mid- and high-suitability areas) to
279 facilitate the reading of the models’ geographic projections and prevent direct interpretations of
280 suitability values. Finally, a binary model was computed by reclassifying all suitable grid cells as one
281 and non-suitable cells as zero. We then compared the four obtained binary predictions with the main
282 Pliocene ‘mean’ climate model to reveal temporally stable areas of suitability.

283

284 2.5 Temporal and spatial sampling sensitivity tests

285

286 In order to test the sensitivity of our climatic envelope model to the chosen temporal window with
287 respect to occurrence sampling, we replicated the approach described above by removing the oldest and
288 most recent Australipithecus taxa from the dataset (i.e. *A. anamensis*, *A. africanus*, *A. prometheus*). The
289 localities, Lomekwi, Kanapoi, Makapansgat, Sterkfontein and Taung, are removed from model
290 computation, resulting in the loss of all South African occurrences. The map of habitat suitability
291 corresponding to this sensitivity test is available in Appendix 1. As recommended for small occurrence
292 datasets (Pearson et al., 2006; Shcheglovitova and Anderson, 2013), we used a delete-one jackknife
293 approach (or leave one out approach) to evaluate the influence of individual occurrence on predictive
294 variability. We removed one locality from the dataset, computed the model with $n - 1$ localities in
295 *kuenm* and repeated this process until every locality have been removed once (i.e. n separate models

296 for n observed localities). The n projections of these n models, as well as a consensus of all
297 projections, are available in Appendix 1.

298

299 **3. Results**

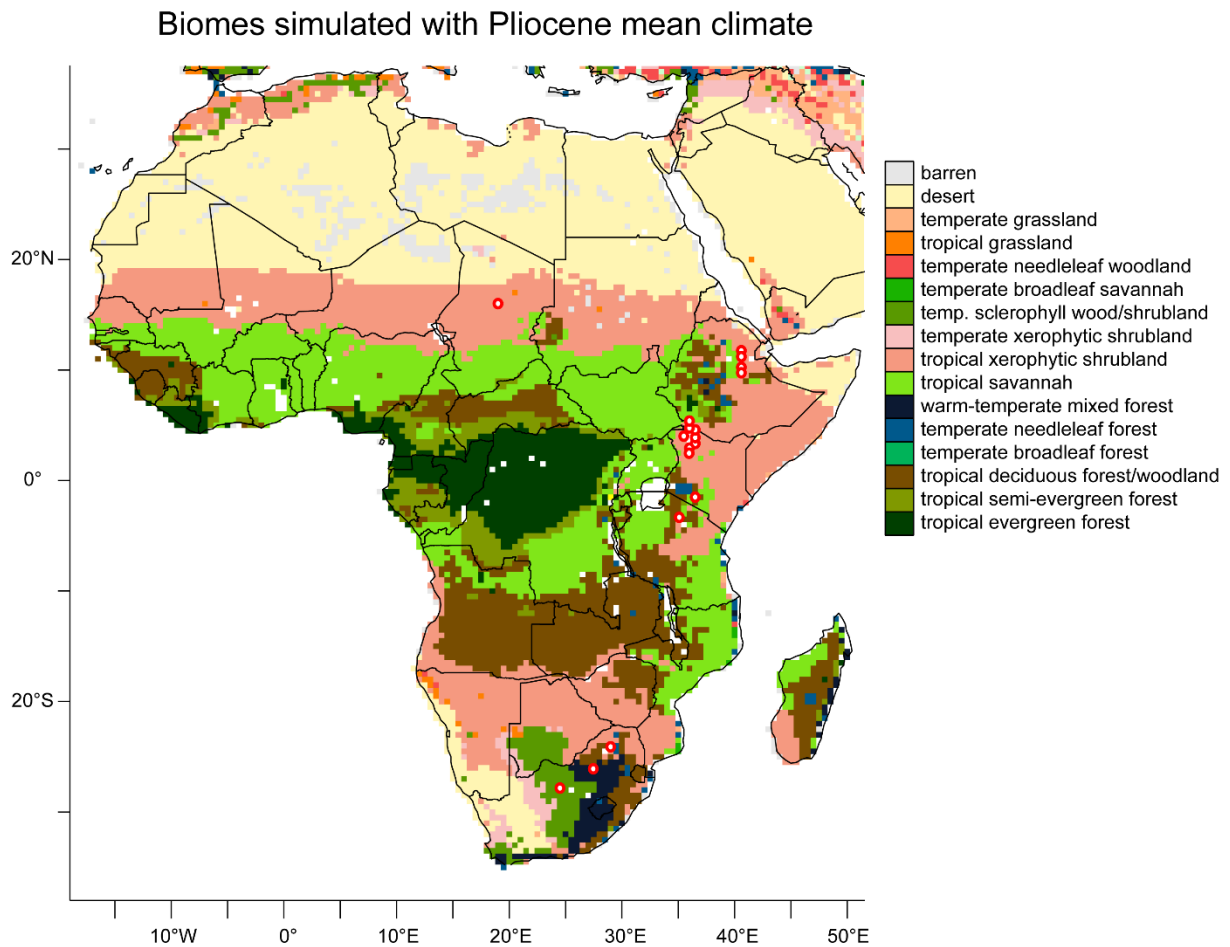

300

301 **3.1 Climate model validation**

302

303 First, we assess the validity of the climate model at hominin sites by comparing
304 paleoenvironmental reconstructions to the biome simulated with the BIOME4 model using IPSL-
305 CM5A climate variables (see Supplementary Material). Vegetation reconstructions at hominin sites
306 describe a seasonal, dry mosaic of woodland, shrubland and grassland (Behrensmeier and Reed, 2013
307 and references therein), with small-scale more mesic environments sustained by local water resources
308 (e.g. microhabitats sustained by rivers, lakes and springs; see Barboni et al., 2019). The BIOME4
309 model indicates tropical xerophytic shrubland, tropical savannah, or tropical deciduous woodland at 16
310 of the 18 hominin localities (Fig. 1, see also Methods). In the BIOME4 model, productivity is higher
311 in tropical deciduous woodland (Kantis locality) than in tropical savannah (Usno and Laetoli
312 localities), and in tropical savannah than in tropical xerophytic shrubland (e.g. Awash Valley, Koro-
313 Toro locality), but the same plant functional types are present in these three biomes. These biomes
314 describe a mix of tropical raingreen trees, C₄ tropical grass, and woody desert plant functional types
315 (C₃ and C₄) that correspond to a warm, seasonally dry climate, which is in good agreement with the

316 mosaic of woodland, bushland and grassland inferred from vegetation reconstructions, although local-
317 scale water sources are invisible to the model.

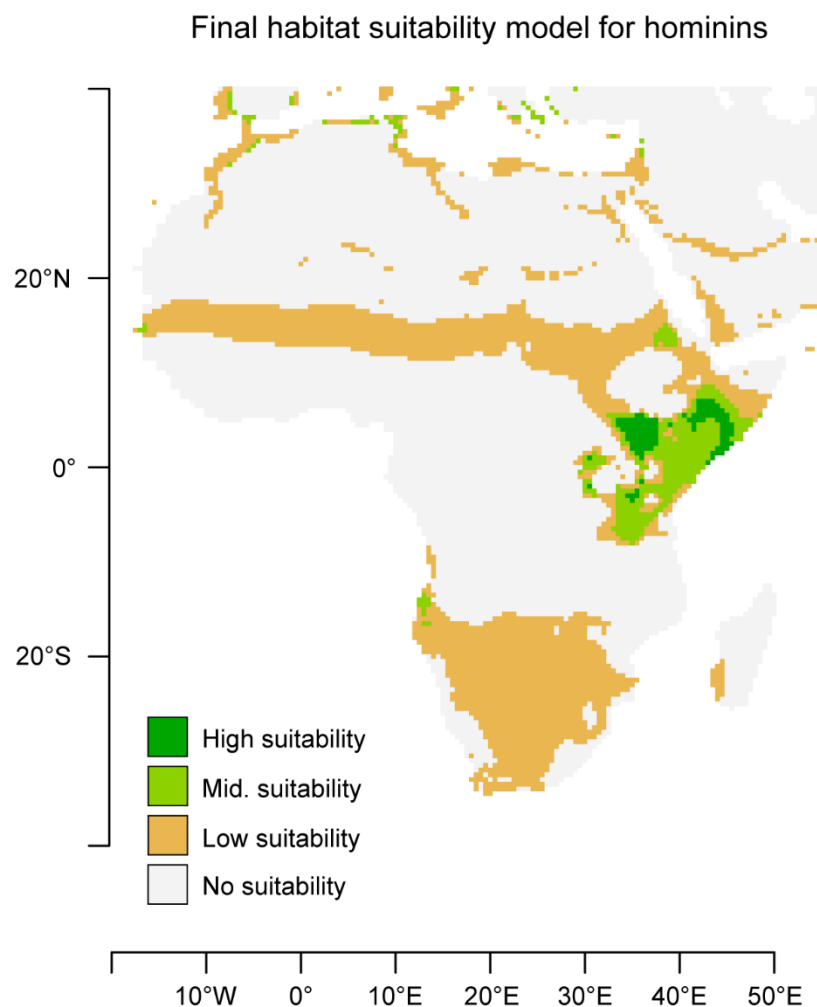

318
319
320 Figure 1. Vegetation simulated with BIOME4 for the Pliocene mean climate. Red circles are the 18
321 hominin occurrence points.
322

323 3.2 Hominin climatic envelope estimations and robustness

324 At a regional scale, the highest habitat suitability areas reconstructed by the climatic envelope
325 model are located in tropical eastern Africa, except over eastern Somalia and western Ethiopia (Fig.
326 2). The Turkana Basin, areas west of Lake Victoria, as well as a region covering southern Somalia,
327 eastern Kenya and northern Tanzania (including Laetoli and coastal regions, hereafter called the SKT
328 region), and finally western Eritrea, northern Somalia-Djibouti and eastern Ethiopia (including the
329 Awash valley) are the most climatically suitable regions for *Australopithecus*. Three other regions
330 show reasonable habitat suitability indices. The first is a latitudinal corridor at ca. 15°N, covering
331 Africa from the Atlantic coast to the Red Sea, at roughly the latitude of Lake Chad. This Sahelian

332 corridor suggests a probable continuity of environmental conditions between the Awash valley and the
333 Lake Chad region, with the potential for population dispersals within this corridor. The second area of
334 interest is located in South Africa, southwestern Angola, Botswana, non-coastal Namibia, southern
335 Mozambique, and southeastern Zimbabwe. This area is not connected to eastern Africa in our model,
336 suggesting that population dispersals to or from this southern African area would not have been
337 possible under mean Pliocene climate conditions. The last area is located on the African
338 Mediterranean coast, including the locality of Ain Boucherit, where no Pliocene hominins have been
339 recovered to date, but where stone artefacts and cut-marked bones dating to ca. 2.4 Ma are
340 documented (Sahnouni et al., 2018). Our geographic coverage also includes southern regions of
341 Eurasia (e.g. Yemen, Israel, Jordan, parts of southern Europe) for which habitat suitability attains
342 values suggesting that mid-to-late Pliocene hominins could have survived in these regions if they had
343 been accessible. After *kuenm* calibration process, the final model meeting significance and complexity
344 requirements (of 2210 candidate models) is based on two of the five available variables: the
345 temperature difference between the warmest and the coldest month (DT) and mean annual
346 precipitation (MAP). All hominin occurrences are located in regions where annual precipitation is
347 below 800 mm/yr with a marked dry season and limited annual thermal amplitude (up to 15°C; Fig. 3)
348 inside semi-arid zones (BS in the Köppen-Geiger classification, Peel et al., 2007).

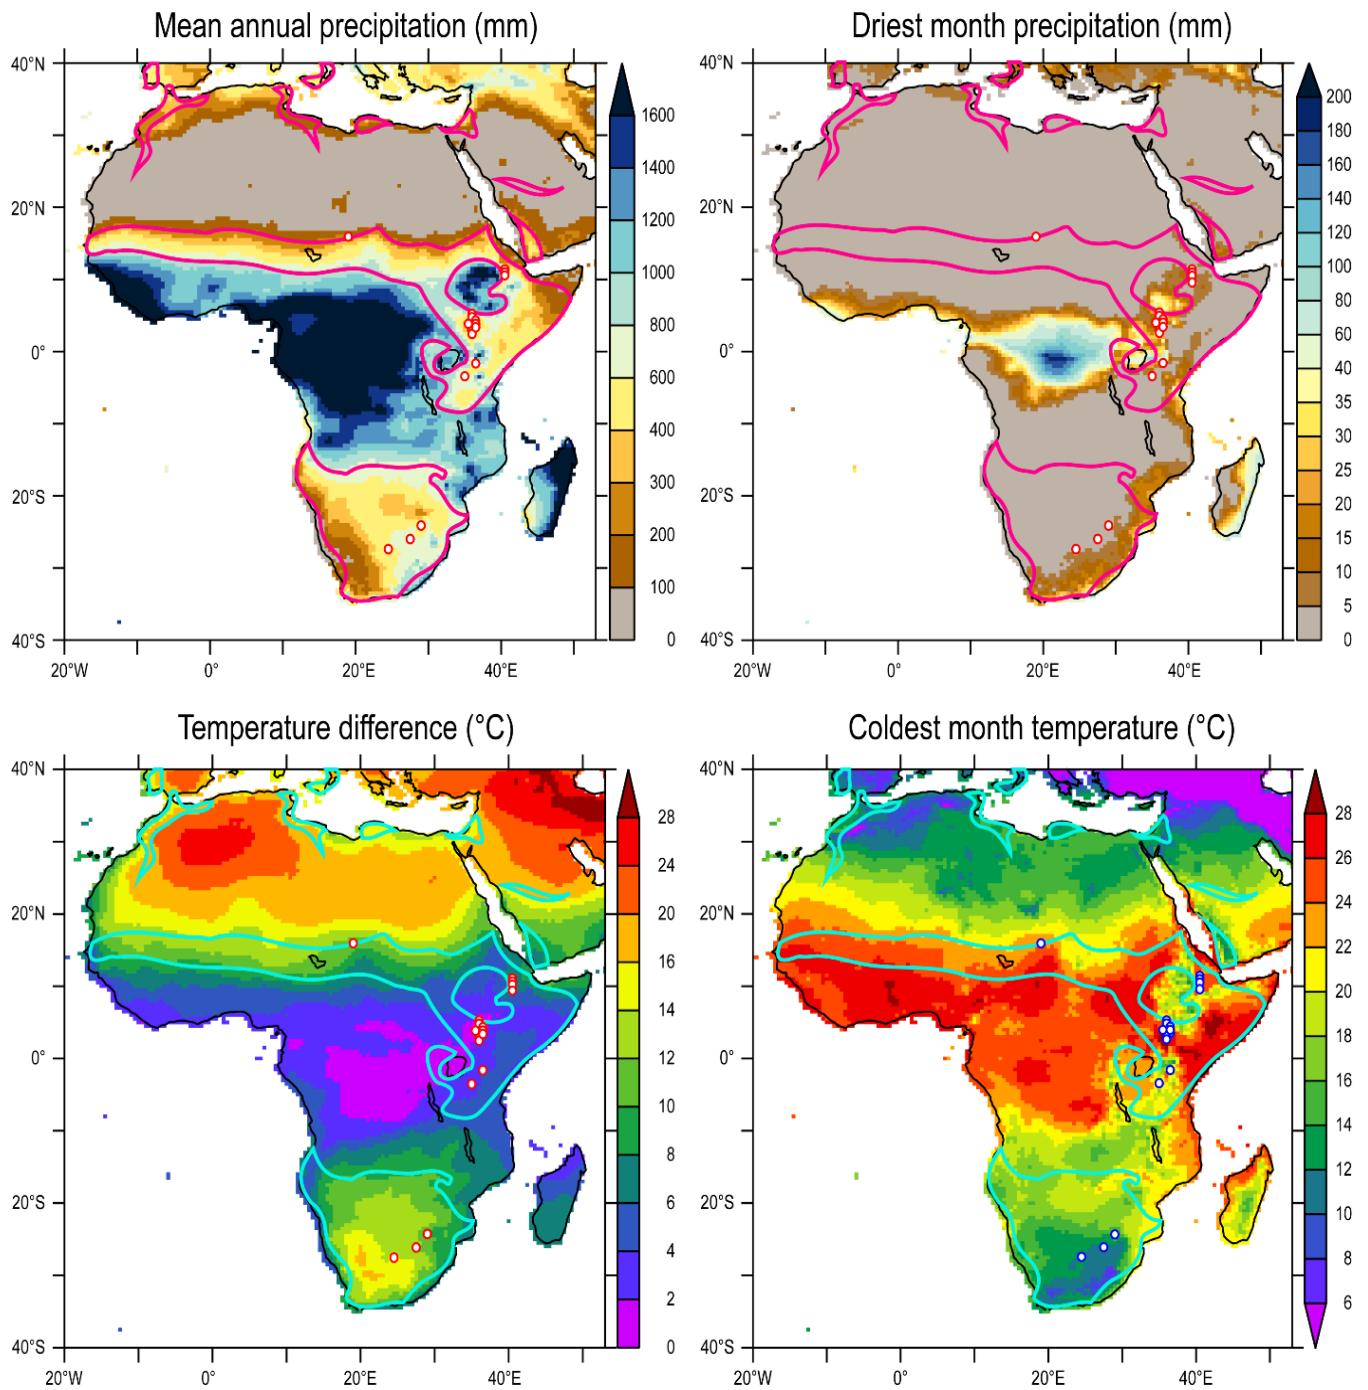

349 Sensitivity tests on the occurrence data (i.e., leave one out approach) reveal that habitat
350 suitability in the Sahelian corridor is not governed by a single locality, not even Koro-Toro located in
351 central Sahel, while the suitable area in northern Africa is a result of climatic similarities to occurrence
352 points located in eastern Africa (e.g. the Middle Awash) or in southern Africa (e.g. Taung; see Suppl.
353 Fig. 1). The Allia Bay locality in Kenya has the strongest influence on suitability scores in the
354 Sahelian corridor, but even its removal is insufficient to make this pattern disappear. The consensus
355 map (see Suppl. Fig. 1), which combines all the sensitivity tests, demonstrates the robustness of the
356 depicted pattern for hominins in Pliocene ‘mean’ climate (Fig. 2) by preserving the three main areas of
357 suitable habitats (i.e. eastern, southern Africa, and the Sahelian corridor).

358
359 Figure 2. Habitat suitability index for hominins under the Pliocene mean climate scenario. All values
360 above the lowest presence threshold are shown (see Methods). Low suitability regroups cells with
361 habitat suitability values ranging from 0.08–0.36; middle suitability range from 0.36–0.63; and high
362 suitability is assigned to cells with values over 0.63. The final *kuenm* model is based on the DT and
363 MAP variables.
364

365 The sensitivity test conducted via temporal sampling (i.e. the removal of youngest and oldest
366 species; see Suppl. Fig. 2) demonstrates the robustness of the climate envelope modeled with all
367 selected occurrences (Fig. 2). We performed this test without the three localities from South Africa
368 and nevertheless the same areas remain suitable for hominins. The main differences between this
369 sensitivity test and the main model are the absolute suitability values in suitable areas. In southern
370 Africa, the eastern coast depicts middle and high suitability in the sensitivity test while in the main
371 model these areas are associated with low suitability scores. In northern Africa and the European
372 Mediterranean coast, suitability values are higher in the test, while conversely the areas of middle and
373 high suitability in eastern Africa are more geographically limited than in the main model.

374 Our results show that eastern and southern Africa were not connected, with respect to
375 suitability, under Pliocene mean conditions. However, we know that *Australopithecus* was present
376 both in eastern and southern Africa, indicating that either: 1) climate variability allowed them to cross
377 this environmental barrier; or 2) they were able to reach/occupy both regions because their niche was
378 in fact broader or because they attempted long-range dispersal across climatically unsuitable areas. In
379 an effort to evaluate the first hypothesis, we further examined potential geographic variability of
380 suitable areas for mid-to-late Pliocene hominins caused by orbital precession changes.

382

383 Figure 3. Mean annual precipitation (MAP), driest month precipitation (DMP), temperature difference
 384 between the coldest and warmest months (DT), and coldest month temperature for the Pliocene
 385 (CMT). Areas suitable for hominins from figure 2 are outlined. MAP and DT are the variables
 386 composing the “best” parameter setting selected after model calibration.

387

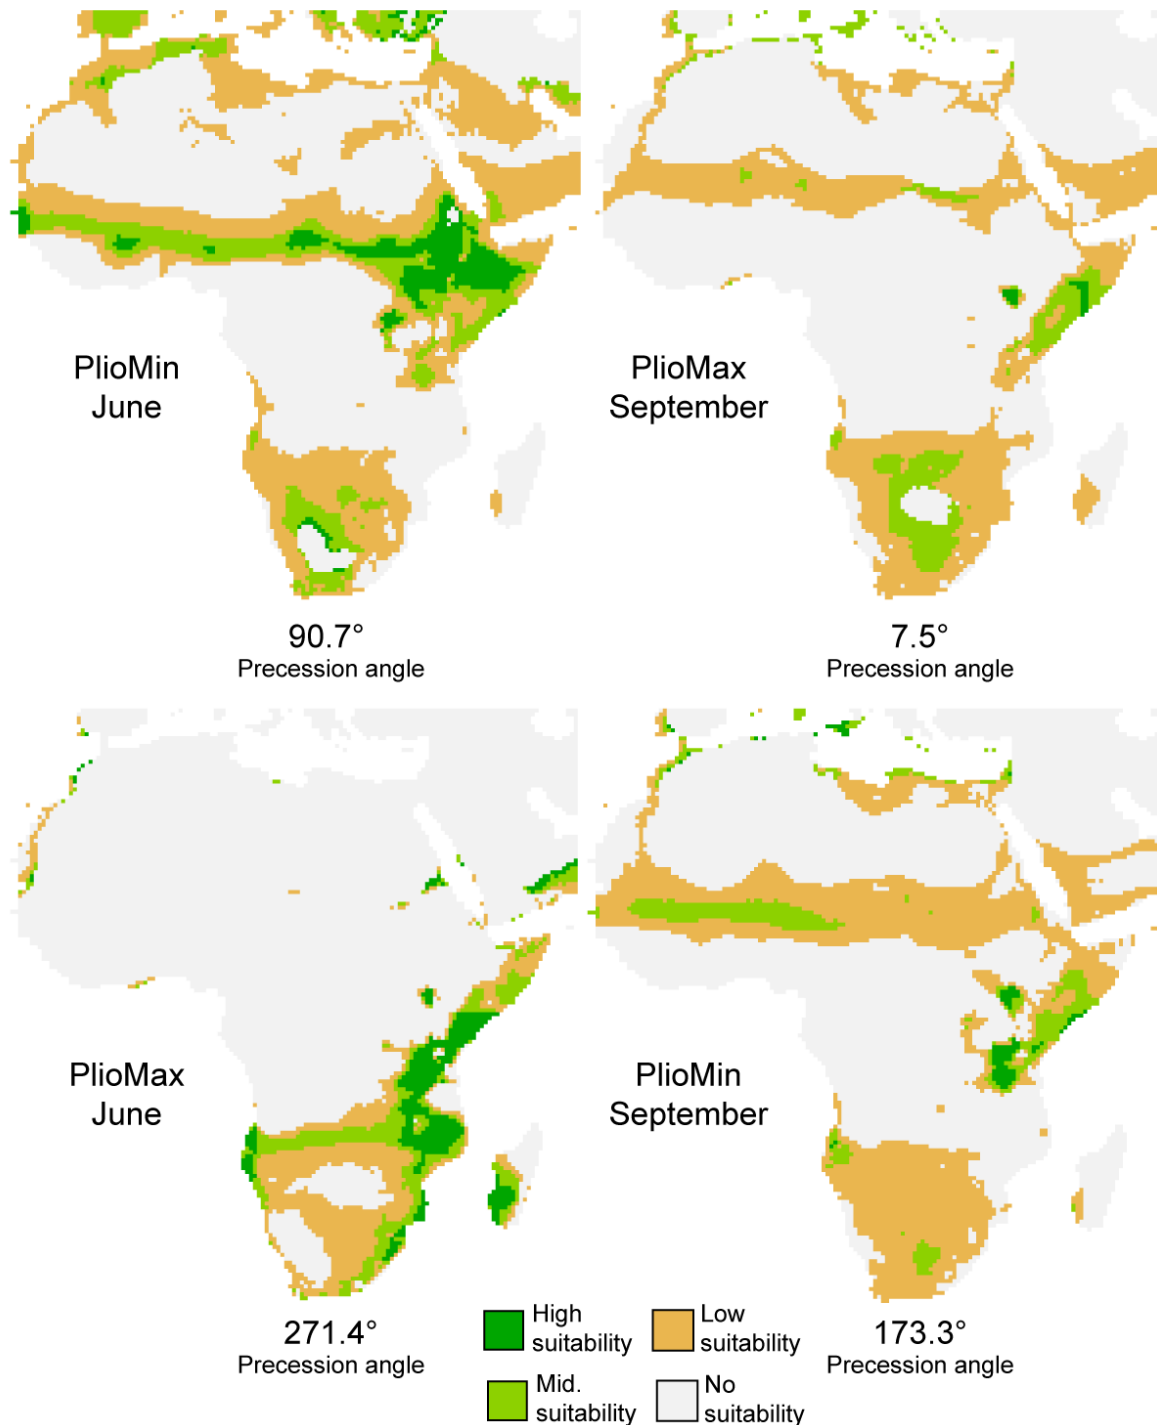

388

389

390

391 3.3 Orbitally driven climate variability and potential dispersals

392 We projected the climatic envelope estimated from Pliocene mean climate conditions onto four
393 Pliocene climate scenarios simulated with summer and autumn insolation maxima and minima (Figure
394 4, Suppl. Fig. 3-6). This provides examples of the potential ability of Pliocene hominins to disperse

395 Figure 4: Projections of the final model computed with the Pliocene mean configuration onto four
396 orbital precession configurations (see Methods). PlioMax June with a precession angle of 271° is the
397 most distant configuration from Pliocene ‘mean’ climate (i.e. 100.04°), whereas PlioMin June is the
398 closest (90.74°).

399 geographically during specific climate scenarios driven by orbital precession variability—dispersals
400 that would not necessitate them changing the environmental conditions they exploited.

401 During periods of boreal summer or autumn insolation maxima (PlioMax June simulation and
402 PlioMax September simulation, respectively), the Afar region and a large portion of eastern Africa are
403 unsuitable, except for the Turkana region and the SKT region (including the Laetoli and coastal
404 regions) (Fig. 4). During these periods, the tropical rain belt is located further north. The Sahelian
405 band of suitability is shifted north of Koro-Toro (Suppl. Fig. 5) into the present-day Sahara for
406 PlioMax September, and it is totally absent for PlioMax June. There remains a large unsuitable area
407 between Laetoli (the southernmost eastern African site) and Makapansgat (the northernmost southern
408 African site) for three of the configurations. However, in the PlioMax June projection (i.e. boreal
409 summer maxima), a continuous zone of middle and high climatic suitability between eastern and
410 southern Africa emerges (Fig. 4, bottom left), which would have allowed hominin dispersal to/from
411 the south. Variations in precession angle could therefore be a potential factor controlling the
412 emergence of corridors permitting the dispersion of ancient hominins between eastern and southern
413 Africa along the Kingdon line (Kingdon, 2003; Joordens et al., 2019). During periods of boreal
414 summer insolation minima (Fig. 4, top left, PlioMin June), the habitat suitability indices becomes high
415 in the northern part of the African rift, particularly in the Ethiopian highlands, down to the Baringo
416 locality and also extend down to Laetoli through the SKT region. Suitability in the Sahelian band
417 increases strongly and shifts southward following the tropical rain belt. Three areas remain above the
418 lowest presence threshold for all orbital configurations and can therefore be considered true core areas
419 or refugia (Fig. 5)—the Turkana Basin, the SKT region, and a vast portion of southern Africa. To the
420 contrary, the Sahelian band and the Awash Valley remain suitable in some, but not all, of the four
421 climate scenarios.

422

423 Figure 5: Refuge areas. Consensus map based on the final climatic envelope's suitable areas estimated
 424 with Pliocene 'mean' climate (Fig. 2), as well as with the four orbital precession configurations (Fig.
 425 4).

426

427 **4. Discussion**

428

429 **4.1 Australopithecus in semi-arid climate**

430 From the late Miocene onwards, early hominins were not found in sites sampling densely forested

431 environments nor shadowless plains, but instead are known from more or less wooded, mosaic habitats

432 (see Sponheimer 2013). The earliest known hominin, *Sahelanthropus tchadensis*, lived in a Sahelian-

433 like mosaic landscape close to lake settings (Vignaud et al., 2002; Le Fur et al., 2009; Blondel et al.,

434 2010; Novello et al., 2017). The early Pliocene hominins *Ardipithecus ramidus* and *Ardipithecus*

435 *kadabba* are also thought to have lived in an open, wooded savannah biome (Levin et al., 2008; White

436 et al., 1994, 2009; Cerling et al., 2011), within which they occupied localized forested micro-habitats

437 sustained by springs (WoldeGabriel et al., 2009; Barboni et al., 2019). However not all early hominids
438 are associated with savannahs, *Orrorrin* lived in an open deciduous forest, punctuated by very wet
439 areas (Bamford et al., 2013; Senut, 2020).

440 By the late Pliocene, *Australopithecus* occupied open landscape environments. Pliocene hominin
441 localities of the Lower Awash Valley and the Turkana Basin had mammal communities corresponding
442 to a climate for which precipitation was low (inferior to 800–1000 mm/yr) and temperature seasonality
443 was pronounced (Robinson et al., 2017). Our model suggests that these populations occupied regions
444 characterized by a semi-arid climate (dry and seasonal with moderate thermal amplitude) and
445 environments that would have been more or less wooded depending on surface and sub-surface water
446 availability. Blumenthal et al. (2017) postulate that variable climatic conditions in the Turkana Basin,
447 within the range of present-day environments, were already present at 4.2 Ma, suggesting that the
448 region's hominins were already occupying (semi-)arid areas with soil temperatures of approximately
449 30–35°C (Passey et al., 2010). Sponheimer (2013) also states that the australopithecine masticatory
450 apparatus was adapted to abrasive food already by 4 Ma, implying that they could rely on (although
451 perhaps only seasonally) xerophytic tubers which are found in arid environments and can contain up to
452 70% water. A re-examination of Turkana *Au. anamensis* has shown that C₄ biomass composed up to
453 30% of their diet, suggesting increased foraging in open landscapes already by 4 Ma (Quinn, 2019).
454 An increased proportion of C₄ foods in the hominin diet occurs at 3.8 Ma (Uno et al., 2016), and *Au.*
455 *bahrelghazali* was also dependent of C₄-derived resources (Lee-Thorp et al., 2012). At Hadar, *Au.*
456 *afarensis* was a mixed C₃/C₄ feeder and coped with ecological changes via "... a highly varied intake
457 of C₄ foods" (Wynn et al., 2016). Recent dental analyses of *Au. africanus* also reveal that this species
458 faced seasonal dietary stress (Joannes-Boyau et al., 2019). Finally, our results show that the climate
459 envelope of mid-to-late Pliocene hominins largely overlaps with semi-arid climates, but also includes
460 more temperate climates. This agrees with Behrensmeyer and Reed (2013) who consider that
461 *Australopithecus* could survive "considerable seasonal temperature" variations, thus suggesting that
462 they possessed enhanced thermoregulatory capacities (Lieberman, 2015). This is a step towards the
463 genus *Homo*, which appears to have been adapted to even more arid climates (DiMaggio et al., 2015;
464 Robinson et al., 2017).

466 Dispersal events during the Pliocene are thought to have strongly influenced the
467 paleobiogeography of *Australopithecus* (Foley et al., 2013). Our results support this hypothesis by
468 indicating that australopithecines in Chad, eastern Africa and South Africa faced similar climatic
469 conditions. However, dispersal between eastern Africa and southern Africa appears to have been
470 possible only during periods of extreme summer insolation (PlioMax June), when the Lake Malawi
471 basin would have been dry enough to create continuous semi-arid environments (Fig. 4 and Suppl.
472 Figure 5). To the contrary, *Au. bahrelghazali*, *Au. afarensis*, and *K. platyops* could have dispersed
473 between the Turkana Basin, Laetoli and the SKT region, the Awash Valley and central Sahel—with
474 the Turkana basin and the SKT region remaining suitable during periods of extreme insolation forcing.
475 Isolation of some regions (e.g., the Turkana Basin and SKT regions serving as refugia), induced by
476 climate and vegetation changes driven by orbital forcing, would have isolated animal populations
477 (including hominids) and reduced gene flow, thus fostering allopatric speciation by vicariance. This
478 would explain the highest levels of species diversity in eastern Africa in that distinct species could
479 develop during periods when the two regions were not connected, and later disperse during periods
480 when they were environmentally linked. Comparing the habitat suitability map to the vegetation model
481 (Figs. 1 and 2), it is evident that areas of suitability correspond primarily to those where the simulated
482 biome is tropical xerophytic shrubland (represented in pink in Fig. 1), although the two maps are not
483 strictly superimposable. This environment is typically present along woodland margins (fringe
484 environments), corresponding to the hypothesis that *Australopithecus* was an edge (or ecotonal)
485 adapted genus (Sussman and Hart, 2015), as suggested for early Pleistocene *Paranthropus robustus*
486 (Caley et al., 2018).

487 According to our results, the coastal regions of southern Somalia and eastern Kenya would have
488 been suitable even during extreme insolation changes (Fig. 5). This region is included in the extent of
489 the coastal mosaic forest proposed by Kingdon (2003) and Joordens et al., (2019) (the coastal ape
490 hypothesis). However, our vegetation model does not reproduce forest in this area, but rather tropical
491 xerophytic shrubland (this biome does contain the tropical raingreen tree plant functional type); our
492 model also supports the hypothesis that *Australopithecus* did not live in forest contexts, but rather in

493 semi-arid zones. Small-scale patches of gallery forest could have been favoured by local conditions in
494 this area, without being visible in the model, since the coastal forest at present only measures a few
495 tens of kilometres of width at its maximum extent. The fact that occurrence points of Pliocene
496 *Australopithecus* are located in semi-arid areas, which were already semi-arid areas during the
497 Pliocene, does not mean that these species were restricted solely to these areas, since it remains
498 possible that fossils have not been observed elsewhere. Our model, which effectively indicates areas
499 where remains have been recovered, does predict that this region of southern Kenya and northern
500 Tanzania had some tropical trees, and was climatically favourable for *Australopithecus* during the
501 Pliocene even across climate changes linked to orbital precession variability.

502

503 5. Conclusions

504

505 During the mid-to-late Pliocene, different hominin species are identified in Africa at localities that
506 are geographically separated (central Sahel, eastern Africa and southern Africa). When using a
507 climatic envelope model, the estimated areas suitable for mid-to-late Pliocene hominins cover most of
508 eastern Africa, the Sahelian corridor from the Atlantic coast to the Red Sea, large portions of southern
509 Africa, and a restricted portion of the African northwestern Mediterranean coast. The climatic
510 envelope associated with these areas is predominantly characterized by strongly seasonal precipitation
511 and annual thermal amplitude up to 15°C, in accordance with the two variables selected by the kuenm
512 R package to create the final model (i.e., mean annual precipitation and thermal amplitude between
513 coldest and warmest month). The estimated envelope is geographically continuous between eastern
514 Africa and the Lake Chad region, while a similar pattern is not observed between eastern Africa and
515 southern Africa, suggesting that this environmental barrier was crossed during periods of extreme
516 summer insolation maxima or that hominins had a broader climatic envelope than the one estimated
517 with our occurrence data. The Turkana Basin, the region covering southern Somalia, eastern Kenya
518 and northern Tanzania (including Laetoli and coastal regions), and a vast portion of southern Africa
519 remain suitable during periods of orbital variability, contrary to the Sahelian corridor and the Awash
520 valley. Those refugia are located in eastern and southern Africa and are only connected during certain

521 orbital configurations, potentially explaining the diversity of hominin species observed in eastern
522 Africa at that time.

523 Further studies could improve our results, notably, due to the scarce nature of presently available
524 data, but this is certainly a long-term perspective. For the immediate future, the increased capability of
525 climate models to simulate Pliocene conditions via PLIOMIP2 (Haywood, 2020; Tan et al., 2020;
526 Zhang et al., 2020) warrants pursuing.

Climate-inferred distribution of mid-to-late Pliocene hominins

Corentin Gibert, Anaïs Vignoles, Camille Contoux, William E. Banks, Doris Barboni, Jean-Renaud Boisserie, Olivier Chavasseau, Frédéric Fluteau, Franck Guy, Camille Noûs, Olga Otero, Pierre Sepulchre, Antoine Souron, Gilles Ramstein

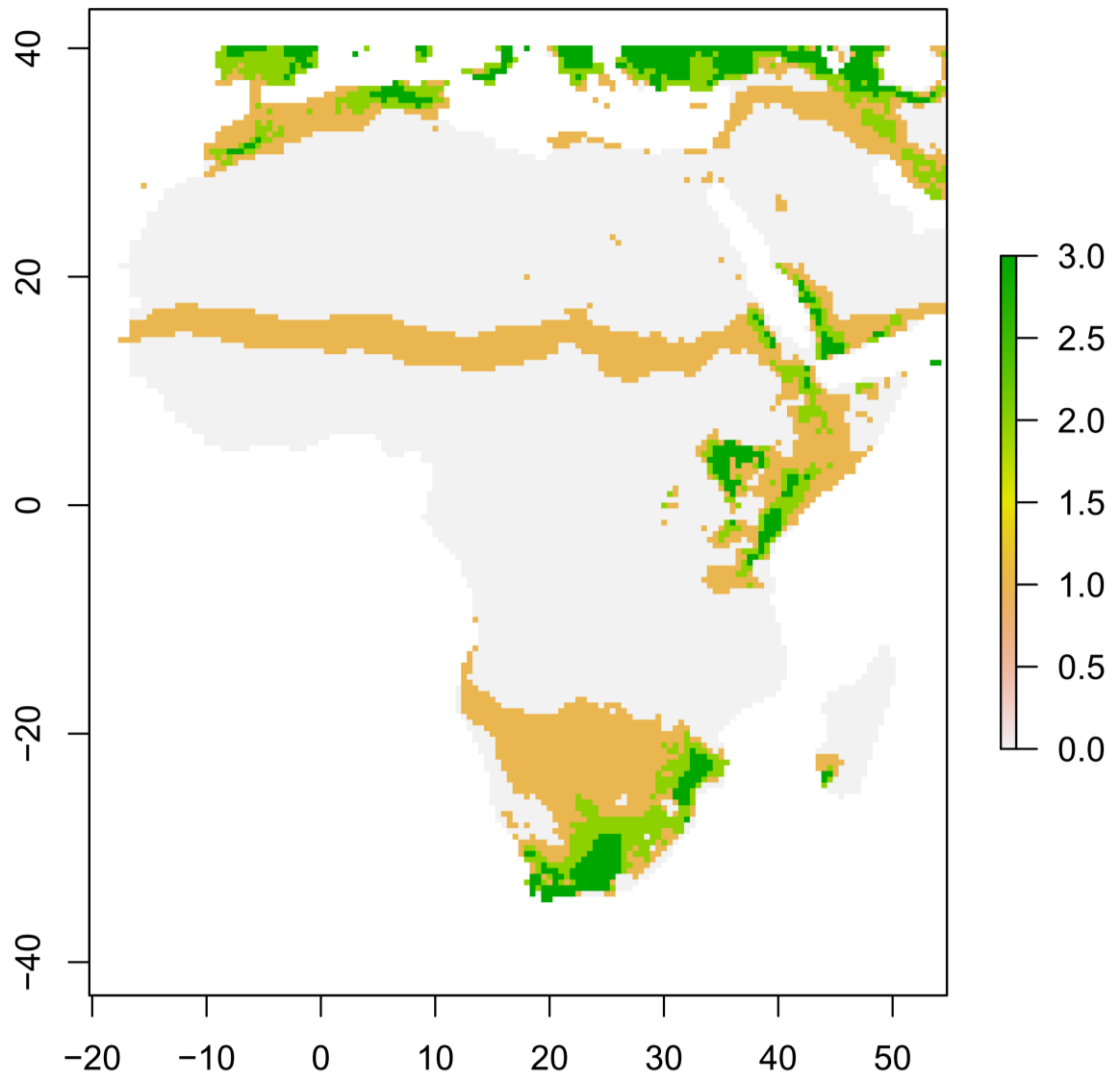

Appendix 1

Supplementary Figures 1 to 8

Supplementary Table 1

Supplementary Figure 1. Binary map (green for suitable areas) for the 18 jackknife kuenm final models. Named locality is removed, number refers to Table 1. Map in the bottom right is the consensus map of the 18 final models.

Supplementary Figure 2. Sensitivity test on temporal window of sampling. *Au. anamensis*, *Au. prometheus* and *Au. africanus* are removed resulting in the removal of the three localities from southern Africa. HSM obtained with KUENM and Maxent algorithms. Climatic layers are Pliocene 'mean' climate.

PlioMin June
precession angle : 90.7°

Supplementary Figure 3. Biomes, Mean annual precipitation (MAP), driest month precipitation (DMP), temperature difference between the coldest and warmest months (DT). Areas suitable for hominins from figure 4 PlioMin June final model are marked by contours.

PlioMax September
precession angle : 7.5°

Supplementary Figure 4. Biomes, Mean annual precipitation (MAP), driest month precipitation (DMP), temperature difference between the coldest and warmest months (DT). Areas suitable for hominins from figure 4 PlioMax September final model are marked by contours.

PlioMax June
precession angle : 271.4°

Supplementary Figure 5. Biomes, Mean annual precipitation (MAP), driest month precipitation (DMP), temperature difference between the coldest and warmest months (DT). Areas suitable for hominins from figure 4 PlioMax June final model are marked by contours.

PlioMin September
precession angle : 173.3°

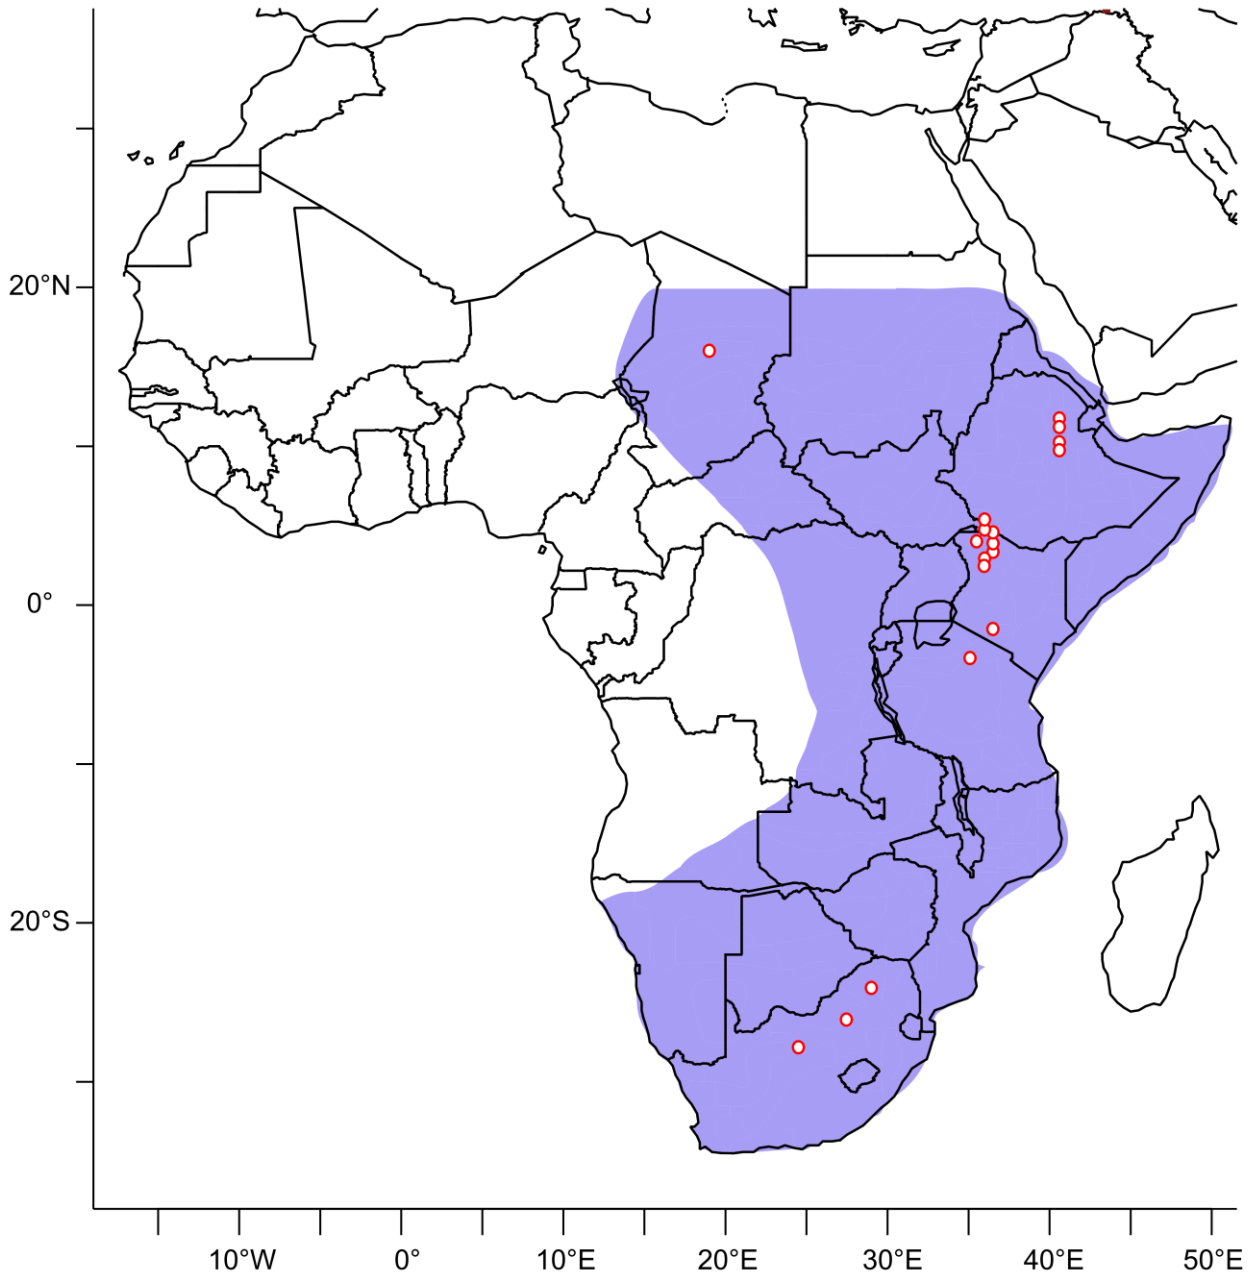

Supplementary Figure 6. Biomes, Mean annual precipitation (MAP), driest month precipitation (DMP), temperature difference between the coldest and warmest months (DT). Areas suitable for hominins from figure 4 PlioMin September final model are marked by contours.

Supplementary Figure 7. Orbital eccentricity, June solstice and September equinox insolation at 30°N from 3 to 4 Ma (Laskar 2004). Red lines represent the values used for the Pliocene ‘mean’ climate (present-day values). Red stars indicate values chosen for orbital climate simulations.

Calibration area

Supplementary Figure 8. Calibration area. The purple area is used to compute KUENM-Maxent model, the probability distribution associated with occurrences is compared with background points randomly sampled in the environment within calibration area. It should encompass all occurrences points, but should not be too large to avoid model overfitting.

Supplementary Table 1. Model-data comparison at hominin sites.

Site	Modeled biome	Data-inferred paleovegetation	Water resource
Koro-Toro	Tropical xerophytic shrubland	Gallery forest, wooded savannah, open grassland (Fara et al. 2005, Novello et al. 2017)	Freshwater lake (Schuster et al. 2009, Novello et al. 2017)
Woranso-Mille	Tropical xerophytic shrubland	Swamp, open woodland, grassland (Behrensmeyer & Reed 2013), riparian forest (Saylor et al., 2019)	River, springs (Haile-Selassie et al. 2007, Barboni et al. 2019), lake (Saylor et al., 2019)
Hadar & Dikika	Tropical xerophytic shrubland	Tropical xerophytic shrubland (Bonnefille et al., 2004), open grassland (Behrensmeyer & Reed 2013)	River, lake (Taieb et al., 1975)
Middle Awash	Tropical xerophytic shrubland	Grassy woodland-bushland (Behrensmeyer & Reed 2013)	
Galili	Tropical xerophytic shrubland	Woodland to bushland with some open grassland (Behrensmeyer & Reed 2013, Kullmer 2008)	
Usno	Tropical savanna	Ecotonal environment at the edge of woodland and grassland (Bobe 2011)	River (Bobe 2011)
Shungura	Tropical xerophytic shrubland	Same as Usno	Same as Usno
Fejej	Tropical xerophytic shrubland	unknown	
Koobi Fora	Tropical xerophytic shrubland	Tropical savannah (Salzmann et al. 2008)	Floodplain (Behrensmeyer & Reed 2013)
Allia Bay	Tropical xerophytic shrubland	Seasonal, mosaic of woodland-grassland (Behrensmeyer & Reed 2013)	
Lomekwi	Tropical xerophytic shrubland	Tropical deciduous woodland (Salzmann et al. 2008)	Fluvio-lacustrine (Boyd et al. 2018)
Lothagam	Tropical xerophytic shrubland	Dry and seasonally open (Behrensmeyer & Reed 2013)	
Kanapoi	Tropical xerophytic shrubland	Grassy woodland (Quinn & Lepre 2018), shrub savannah (Head & Muller 2018)	Lake, river margin (Head & Muller 2018)
Kantis	Tropical deciduous woodland	Mosaic of woodland, shrubland, grassland (Mbua et al. 2016)	
Laetoli	Tropical savanna	mosaic of woodland, bushland, shrubland, grassland (Su & Croft 2018)	River margin (Su & Croft 2018), probable springs (Barboni et al. 2019)
Makapansgat	Tropical xerophytic shrubland	Mosaic of riparian woodland, bushland, edaphic grassland (Reed 1997)	River or spring (Behrensmeyer & Reed 2013)
Sterkfontein	Warm mixed forest	Temperate sclerophyll woodland (Salzmann et al. 2008), riparian forest, bushland (Behrensmeyer & Reed 2013)	
Taung	Temperate sclerophyll woodland	Dense woodland (Behrensmeyer & Reed 2013)	Spring (McKee & Kuykendall, 2016, review in Barboni et al., 2019)

Koro-Toro site, Chad

Fara et al., (2005) conclude that “*paleoenvironments were heterogeneous*”, with “*lakeside environments surrounded by a patchwork of gallery forest, wooded savannah and open grassland*”. Diatom data indicate freshwater lake, and phytolith data confirm the heterogeneous pattern and abundance of C₄ grasses (Novello et al. 2017). The model simulates tropical xerophytic shrubland, here dominated by tropical raingreen trees and C₄ grasses, with some woody desert plants, corresponding to the vegetation reconstructions. There is also evidence of lacustrine conditions (Schuster et al., 2009) at Koro-Toro site. A lake large enough would have locally impacted surrounding vegetation, even to a larger extent than gallery forest, especially on its eastern side, where the hominin site is located and where precipitation could have been increased by the presence of the lake (Contoux et al., 2013).

Awash Basin, Ethiopia

For the Awash sites, the model simulates tropical xerophytic shrubland for which the LAI of tropical raingreen trees is between 2.51 and 3.13, i.e. values typical of open woodlands. Data describe mosaic environments mixed C₃-C₄, grassy woodlands and bushlands (Behrensmeyer and Reed, 2013) likely to correspond to tropical savanna or to tropical xerophytic shrubland. In the model, tropical savannah (for which LAI must be superior to 4 in the model) is simulated on the grid cells located just to the west of each Afar site (Fig. 1), in agreement with plausible greater humidity and cooler temperature on the escarpments, which even today sustains a slightly more wooded and green vegetation compared to the lowlands.

Turkana Basin

At Usno the model simulates tropical savannah. For all the other sites in the Turkana basin, the model simulates tropical xerophytic shrubland. The data suggest, similarly to the Awash basin, a mosaic of woodland and grassland, more wooded at Usno and Shungura than in the rest of the basin, in agreement with the presence of the large and permanent Omo River fluvial complex (fluvio-deltaic context at Shungura, floodplain at Koobi-Fora, fluvio-lacustrine environments at Lomekwi, Behrensmeyer and Reed 2013).

Kantis, Kenya

Mbua et al., (2016) indicate a mosaic of woodland, shrubland, grassland with more C₄ than other *Au. afarensis* sites. Here the model simulates more mesic environments than those of the Awash and of the Turkana basins, with the same mix of PFTs (tropical raingreen trees, C₄ grass and woody desert plants). All PFTs are more productive, leading to the tropical deciduous woodland biome.

Laetoli, Tanzania

Via a combination of faunal and floral analyses, Su and Croft (2018) find that vegetation at Laetoli was a “*mosaic of woodland, bushland, shrubland, grassland with riverine woodland in a relatively arid and seasonal environment*”. The review of Barboni (2014) also indicates a mosaic of dry and moist woodlands and grassland, and few components of Afromontane forest. In our study, the simulated biome at Laetoli for the Pliocene mean climate is tropical savannah, with dominant tropical raingreen trees, the presence of conifer forest, C₄ grass and woody desert plants. Thus, our simulated biome at Laetoli is consistent with the reconstructions.

South Africa

Makapansgat

The biome simulated at Makapansgat is tropical xerophytic shrubland, dominated by tropical raingreen trees, with the presence of temperate broad-leaved evergreen trees, conifer forest, C₄ grass and woody desert plants, suggesting a strong heterogeneity of the landscape. This could correspond to the habitat mosaic recognized by Reed (1997).

Sterkfontein

Salzmann et al. (2008) interpret data from Reed (1997) and Bamford (1999) as being representative of temperate sclerophyll woodland, while Reed (1997) suggests that Sterkfontein is more open than Makapansgat. Our model however simulates warm mixed forest, i.e. a landscape dominated by temperate broadleaved evergreen trees, with tropical raingreen trees, conifer forest, C₄ grass and woody desert plants. This can hardly be reconciled with the reconstructions.

Taung

Fauna suggest relatively dense woodland (Behrensmeyer and Reed, 2013) while the model simulates temperate sclerophyll woodland, i.e. a rather open landscape composed of mainly temperate broadleaved evergreen trees, conifer forest, grass and woody desert plants.

In summary, hominin sites are mostly mosaic environments of tropical trees, grasses and shrubs. Because data reconstructions are mostly qualitative, it is difficult to compare to model results, which also represents a larger spatial

scale which smoothes heterogeneity, notably because it does not include water sources. Nonetheless, the model simulates a mix of trees, grasses and shrubs at all the hominin sites, in broad agreement with reconstructions. Thus the simulated large-scale vegetation is coherent with local-scale vegetation reconstructions at hominin localities, except for Sterkfontein and Taung localities (2 sites over 18). We are therefore confident that our model's climatic variables can be used to reconstruct the *Australopithecus* climatic envelope at a broad geographic scale.

Appendix 2

R scripts for KUENM and Maxent analysis

Example script for Pliocene 'mean' climate

Computed with Rmarkdown

Environmental layers

Import of the simulated climatic layers from files beforehand cropped with calibration area (see Annexe 1) and preparation of the 2210 KUENM variables sets. "Plio_vars_noncor/var/m3_clipped" is the folder where non-correlated cropped layers are stored, "Plio_vars_noncor/FullVar" is the folder where non-cropped (all Africa) layers are stored.

```
library(kuenm)
library(raster)
library(rgeos)

setwd("yourKUENMfolder")

## preparing M variables (cropped layers for model computation)
kuenm_varcomb(var.dir = "Plio_vars_noncor/var/m3_clipped", out.dir = "M_variables", min.number = 2, in.format = "ascii", out.format = "ascii")

## preparing G variables (non-cropped layers for projection of the model)
kuenm_varcomb(var.dir = "Plio_vars_noncor/FullVar", out.dir = "G_variables", min.number = 2, in.format = "ascii", out.format = "ascii")
```

Occurrences of Pliocene hominids

Import of the occurrences of Pliocene hominids living in Africa between 4 and 3 Ma, see Table 1 for references and coordinates. The 18 occurrences are then splitted in training and testing datasets to conduct model calibration. For jackknife, leave-one out approach, 18 datasets are constructed by removing one occurrence point. The models used to evaluate the impact of orbital configuration are based on the full (18) dataset.

```
## Import from .csv files
hom <- read.csv("all0ccurrence.csv", sep = ";")

## Splitting in training and testing datasets
kuenm_occsplit(occ = hom, train.proportion = 0.75, method = "random", save = TRUE, name = "occ")
```

Candidate models, evaluation and selection

In this step, 2210 candidate models are produced and their performance are evaluated to select the best Maxent parameterization.

```
## Parameters for model calibration

# names for directory and files
occ_joint <- "occ_joint.csv"
occ_tra <- "occ_train.csv"
M_var_dir <- "M_variables"
batch_cal <- "Candidate_models"
out_dir <- "Candidate_Models"

# regression parameters
reg_mult <- c(seq(0.1, 1, 0.1), seq(2, 6, 1), 8, 10)
f_clas <- c("q", "lq", "lp", "qp", "lqp")
args <- NULL
```

```

maxent_path <- "C:/Maxent"
wait <- FALSE

run <- TRUE
occ_test <- "occ_test.csv"
out_eval <- "Calibration_results"
threshold <- 5
rand_percent <- 50
iterations <- 100
kept <- TRUE
selection <- "OR_AICc"
paral_proc <- FALSE

## Computation of the candidate models
kuenm_cal(occ.joint = occ_joint, occ.tra = occ_tra, M.var.dir = M_var_dir, batch = batch_cal, out.dir = out_dir, reg.mult = reg_mult, f.clas = f_clas, args = args, maxent.path = maxent_path, wait = wait, run = run)

## Computation of model evaluation and selection
cal_eval <- kuenm_ceval(path = out_dir, occ.joint = occ_joint, occ.tra = occ_tra, occ.test = occ_test, batch = batch_cal, out.eval = out_eval, threshold = threshold, rand.percent = rand_percent, iterations = iterations, kept = kept, selection = selection, parallel.proc = paral_proc)

```

Final models

Computation of the final models and projection on G_variables (i.e. the entire Africa)

```

batch_fin <- "Final_models"
mod_dir <- "Final_Models"
rep_n <- 10
rep_type <- "Bootstrap"
jackknife <- FALSE
out_format <- "logistic"
project <- TRUE
G_var_dir <- "G_variables"
ext_type <- "all"
write_mess <- FALSE
write_clamp <- FALSE
wait1 <- FALSE
run1 <- TRUE
args <- NULL

kuenm_mod(occ.joint = occ_joint, M.var.dir = M_var_dir, out.eval = out_eval, batch = batch_fin, rep.type = rep_type, jackknife = jackknife, out.dir = mod_dir, out.format = out_format, project = project, G.var.dir = G_var_dir, ext.type = ext_type, write.mess = write_mess, write.clamp = write_clamp, maxent.path = maxent_path, args = args, wait = wait1, run = run1)

```

Computation of extrapolation risk analysis

As with any model fitting exercise, interpretation of model predictions outside the range of the independent variables on which models were calibrated is perilous. To estimate the extrapolation risk we use Mobility-Oriented Parity (MOP) analysis (Owen et al. 2013)

```

sets_var <- c("Set_8") #these are the variable combo sets used in Final models
out_mop <- "MOP_results"
percent <- 10
swd <- FALSE
paral <- FALSE

```

```

kuenm_mmop(G.var.dir = G_var_dir, M.var.dir = M_var_dir, is.swd = swd, sets.var = sets_var, out.mop = out_mop, percent = percent, parallel = paral)

# MOP summary
dir.create("MOP_summary")

mops <- stack(list.files(out_mop, pattern = ".tif$", full.names = TRUE, recursive = TRUE))

meam <- calc(mops, mean)
minm <- calc(mops, min)

writeRaster(meam, filename = "MOP_summary/Mean_MOP.tif", format = "GTiff")
writeRaster(minm, filename = "MOP_summary/Min_MOP.tif", format = "GTiff")

```

Computation of final model statistics

Last step of the KUENM analysis, caution incorrect `sp_name` and `scenarios` variables can prevent the analysis from running. The final model can be projected on multiples environmental layers by adding their names in “`scenarios`” variable (e.g. “Africa”, “PlioMin June”, “PlioMin September”) and the respective layers in `G_variables`.

```

# Model statistics: The final models to be analyzed will be found in the Final_Model_Stats folder.
format <- "asc"
project <- TRUE
stats <- c("med", "range", "avg")
rep <- TRUE
# the type of extrapolation can be selected according to user requirements
ext_type <- c("E", "EC", "NE")
out_dir <- "Final_Model_Stats"

# Select names of taxa name in occurrence file and G_variable name (i.e. Africa)
sp_name <- "Hominin"
scenarios <- c("Africa")

kuenm_modstats(sp.name = sp_name, fmod.dir = mod_dir, format = format, project = project,
               statistics = stats, replicated = rep, proj.scenarios = scenarios,
               ext.type = ext_type, out.dir = out_dir)

```
