**Abstract:** Currently, a significant portion (~50%) of global warming emissions, such as CO<sub>2</sub>, are related to energy production and transportation. As most energy usage will be electrical (as well as transportation), the efficient management of electrical power is thus central to achieve the XXI century climatic goals. Ultra-wide bandgap (UWBG) semiconductors are at the very frontier of electronics for energy management or energy electronics. A new generation of UWBG semiconductors will open new territories for higher power rated power electronics and solar-blind deeper ultraviolet optoelectronics. Gallium oxide—Ga<sub>2</sub>O<sub>3</sub> (4.5–4.9 eV), has recently emerged pushing the limits set by more conventional WBG (~3 eV) materials, such as SiC and GaN, as well as for transparent conducting oxides (TCO), such as In<sub>2</sub>O<sub>3</sub>, ZnO and SnO<sub>2</sub>, to name a few. Indeed, Ga<sub>2</sub>O<sub>3</sub> as the first oxide used as a semiconductor for power electronics, has sparked an interest in oxide semiconductors to be investigated (oxides represent the largest family of UWBG). Among these new power electronic materials, Al<sub>x</sub>Ga<sub>1-x</sub>O<sub>3</sub> may provide high-power heterostructure electronic and photonic devices at bandgaps far beyond all materials available today (~8 eV) or ZnGa<sub>2</sub>O<sub>4</sub> (~5 eV), enabling spinel bipolar energy electronics for the first time ever. Here, we review the state-of-the-art and prospects of some ultra-wide bandgap oxide semiconductor arising technologies as promising innovative material solutions towards a sustainable zero emission society.

## 1. Introduction

According to the latest Intergovernmental Panel on Climate Change (IPCC) report released in August 2021 [1], climate change is widespread, rapid, and intensifying and some trends are now regarded as irreversible. Human-induced climate change is already affecting many weather and climate extremes in every region across the globe. Scientists are also observing changes across the whole Earth's climate system; in the atmosphere, in the oceans, ice floes, and on land. Many of these changes are unprecedented and some of the shifts are now in motion, while some—such as rising sea levels—are already irreversible for the coming centuries to millennia. Stabilizing the climate will require strong, rapid, and sustained reductions in greenhouse gas emissions, and reaching net zero CO<sub>2</sub> emissions. Limiting other greenhouse gases and air pollutants, especially methane, could be beneficial for the health of the climate as well as the population [1]. The breakdown for

the different greenhouse gas emissions can be seen in Figure 1 [2], where transport and electrical production account for up to 40%. Therefore, many energy-related megatrends of our modern society must focus on themes such as energy efficiency, e-mobility, smart grid and digitalization requiring green energy management electronics or power electronic solutions [3].

Around half of the power used in the world is electrical and this is expected to increase steadily in the near future [5]. The vast majority (if not all) of this electricity will flow through, at least, one power electronic device during its generation, transmission, and final use. This is a critical aspect of power management which is sometimes overlooked, as power electronics make renewable (and non-renewable) energy impactful by increasing their efficiency [6]. As Si-based devices are replaced with other materials which are more energy efficient, this will affect the overall power consumption which will have a knock-on effect on CO<sub>2</sub> emissions by a significant amount [7]. Furthermore, devices made with a semiconductor having a bandgap larger than silicon can be made with less material and have lower cooling requirements, hence saving a lot of space and weight in applications such as electrical transport. This integration obviously impacts the amount of power required and, therefore, saves energy and its associated emissions. Since the 1980s, there has been a lot of work towards replacing silicon-based (E-gap of 1.12 eV) power electronics devices with wide bandgap (3–3.4 eV) semiconductor (WBG) based devices (in particular, silicon carbide (SiC) and gallium nitride (GaN)) and power devices with superior specs (higher temperature of operation, higher power handling capability, etc.) are now commercially available (typically in the range of 650 V–3.5 kV) [8,9] (Figure 1). While SiC devices and GaN transistors are already qualified in many emerging applications, silicon-based devices are still dominating in most applications. There are several reasons for this dominance, to start with, Si-based devices still have substantial potential. Their electrical and thermal performance is outstanding, their reliability is proven as can be seen from their years in application, as well as their low cost. In contrast WBG devices are starting their development, where we are still learning about materials development and device design. The benefits on the system level needs to be qualified and long-term reliability issues need to be determined; as these materials are developed, the costs for high-quality large volume production should decrease.

More recently, the frontier in the field is now given by ultra-wide bandgap semiconductors (UWBG), which have the promise of further upshifting the power rating and operation temperature. The same UWBG oxides also offer the potential for deeper ultraviolet optoelectronics [10]. Although another UWBG semiconductor, diamond, has been investigated over the last forty years, there has been limited progress and only recently have other materials, such as gallium oxide (Ga<sub>2</sub>O<sub>3</sub>) or aluminum nitride (AlN), yielded device demonstrations with appropriate performances. In particular, Ga<sub>2</sub>O<sub>3</sub> is a newer UWBG material (4.5–5 eV) and is receiving a lot of attention as a novel semiconductor, owing to its unusual material properties. The doping (*n*-type) is very tunable with an extremely high breakdown field and unique optoelectronic properties, these alongside the possibility of growing large native substrates (over 6") with a low cost [11]. Besides, representing the first viable oxide semiconductor for power electronics, Ga<sub>2</sub>O<sub>3</sub> has opened the door to many more oxide compounds to be scrutinized (e.g., spinel ZnGa<sub>2</sub>O<sub>4</sub>) as they represent the largest family of ultra-wide bandgap semiconductors. UWBG oxide semiconductors are now at the very frontier of energy electronics, and much cutting-edge research, challenges, and opportunities are taking place [12]. These will be succinctly overviewed in this paper.

## 2. Oxide Semiconductors for Power Electronics

As an alternative to silicon, there is a new generation of wide bandgap semiconductors which have the capability to operate at higher voltages, temperatures, and switching frequencies with greater efficiencies compared to existing Si devices. This characteristic results in lower losses and enables significantly reduced volume due to decreased cooling requirements and smaller passive components contributing to overall lower system cost. Wide bandgap semiconductors (in the context of power electronic devices) usually represent materials whose band gap is larger than that of silicon. A (non-exhaustive) list of different wide bandgap semiconductors is presented in Figure 2. There are several families of wide bandgap semiconductors depending on their chemical composition. The III–

V wide bandgap semiconductors are primarily nitrides, phosphides, and arsenides. Chalcogen semiconductors are those containing a transition metal and a chalcogen anion (S, Se, or Te), therefore forming sulfides, selenides, and tellurides. There are few halogen wide bandgap semiconductors in the form of chloride, iodides, and bromides. Silicon carbide (which exhibits a very large number of polytypes) and diamond are both carbon-based materials. SiC is a relevant wide bandgap semiconductor since it is the only compound semiconductor that can be thermally oxidized to form SiO<sub>2</sub> in the same fashion as silicon [13].

Group	Material	Formula	Band gap (eV)

**Figure 2.** Wide bandgap semiconductors (in the context of power electronic devices) usually represent materials whose bandgap is larger than that of silicon. In practice, wide bandgap materials of choice have a bandgap of around ~3 eV, with silicon carbide and gallium nitride in a prominent position. Recently, a new family of semiconductor materials with even larger bandgaps (known as ultra-wide bandgap semiconductors) is being investigated for the new generation of optoelectronic and power electronic applications. As a rule of thumb, an ultra-wide bandgap semiconductor is one whose bandgap is larger than that of GaN (i.e., 3.4 eV). Perhaps the most investigated ultra-wide bandgap semiconductors are diamond, some nitrides (AlGa<sub>3</sub>N, AlN, and BN), and a few oxides. Among these oxides, gallium oxide is the only oxide semiconductor with ultra-large bandgap where it is possible to modulate the conductivity (i.e., doping) to define power electronic devices.

A special case of chalcogenides would be oxides; although group 16 is defined as chalcogens, the term chalcogenide is more commonly reserved for sulfides, selenides, and tellurides only. Oxides are ubiquitous in nature due to the large abundance of oxygen in the earth and the large oxygen electronegativity (i.e., the atom tendency to attract electrons and thus form bonds) that easily creates largely covalent stable chemical bonds with almost all elements to give the corresponding oxides. Indeed, almost the entire Earth's crust

parts are oxides as the individual crust elements are incrementally oxidized by the oxygen present in the atmosphere or in the water [14]. Besides, the Earth's mantle (which represents 60–70% and ~80% of the Earth's mass and volume, respectively) is predominantly a layer of silicate (i.e., compounds containing silicon and oxygen including silica, orthosilicates, metasilicates, pyrosilicates, etc.) and magnesium oxide (MgO)-rich rock between the crust and the outer core [14]. The upper mantle is dominantly peridotite, composed primarily of variable proportions of the minerals olivine ((Mg,Fe)<sub>2</sub>SiO<sub>4</sub>), pyroxenes (XY(Si,Al)<sub>2</sub>O<sub>6</sub>), and aluminous phases, such as feldspar (NaAlSi<sub>3</sub>O<sub>8</sub>–CaAl<sub>2</sub>Si<sub>2</sub>O<sub>8</sub>) and spinel (MgAl<sub>2</sub>O<sub>4</sub>). The lower mantle is composed primarily of bridgmanite ((Mg,Fe)SiO<sub>3</sub>) and ferropericlase ((Mg, Fe)O), with significant amounts of calcium perovskite (CaSiO<sub>3</sub>) and calcium-ferrite oxides [15].

Thus, in general, oxides can be regarded as naturally abundant and stable compounds. Since the early days of solid-state physics, (undoped) oxides have been considered to be insulators (or more precisely, highly resistive wide bandgap semiconductors). The bandgap of many common oxides, such as Al<sub>2</sub>O<sub>3</sub>, SnO<sub>2</sub>, TiO<sub>2</sub>, In<sub>2</sub>O<sub>3</sub>, Cu<sub>2</sub>O, WO<sub>3</sub>, ZnO, or NiO, is much wider than that of silicon (1.12 eV). Therefore, they are intrinsically poor conductors at room temperature if they are not properly doped into a degenerated state. Recently, much effort has been put into increasing the conductivity of some of these oxides (in particular those where *s* and *p* electrons propagate with a large mobility) while maintaining the optical transparency. Good examples are the doping of Al in ZnO, Sn in In<sub>2</sub>O<sub>3</sub>, and F in SnO<sub>2</sub>, which are known as transparent conducting oxides (TCOs).

In practice, wide bandgap materials of choice have a bandgap of around ~3 eV, with silicon carbide and gallium nitride in a prominent position. Recently, a new family of semiconductor materials with even larger bandgaps (known as ultra-wide bandgap semiconductors) is being investigated for the new generation of optoelectronic and power electronic applications. As a rule of thumb, an ultra-wide bandgap semiconductor is one with a band gap larger than that of GaN (i.e., 3.4 eV). Perhaps the most investigated ultra-wide bandgap semiconductors are diamond, some nitrides (AlGaN, AlN, and BN), and few oxides. Among oxides, gallium oxide (Ga<sub>2</sub>O<sub>3</sub>) is the only oxide semiconductor with ultra-large bandgap where it is possible to modulate the conductivity (i.e., doping) to define power electronic devices. SiC and GaN power devices have already attracted much attention in higher efficiency electrical power conversion [4]. The major advantage of β-Ga<sub>2</sub>O<sub>3</sub> is that the single crystal structure can be synthesized via several standard melt growth methods, e.g., the Czochralski (CZ) technique. This is a huge advantage of Ga<sub>2</sub>O<sub>3</sub> over SiC, GaN, and diamond for scaling up production, hence we would expect the cost of β-Ga<sub>2</sub>O<sub>3</sub> power electronics to decrease and be more in line with silicon with respect to their SiC and GaN counterparts [16,17].

### 3. Gallium Oxide (Ga<sub>2</sub>O<sub>3</sub>)

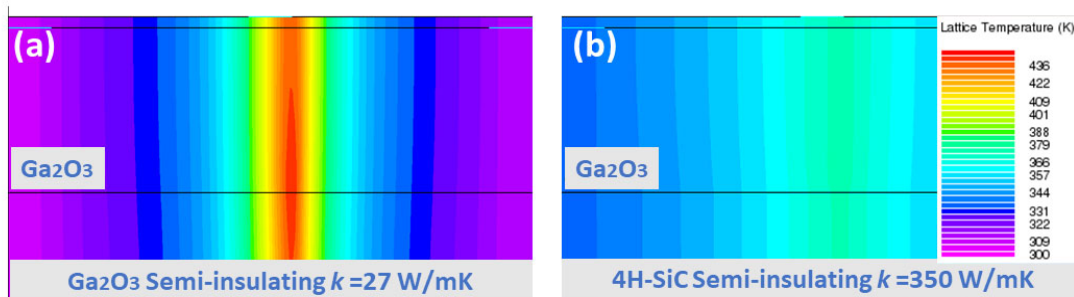

Ga<sub>2</sub>O<sub>3</sub> has, at least, six polymorphs of which only one is thermodynamically stable at high temperatures (β phase, monoclinic), while the others are metastable and tend to convert to β upon high-temperature treatments including the phases α, corundum, δ, cubic, and ε, hexagonal, γ, defective-spinel, and orthorhombic κ polymorph [18]. The basic principles of polymorphism in crystals are clear: the lattices adapt to the minimum energy with respect to the temperature and pressure. Nearly all Ga<sub>2</sub>O<sub>3</sub>-containing devices utilize the monoclinic β phase, the most stable and best-characterized polymorph. As a well-known representative of a binary metal-oxide, gallium oxide cannot therefore be regarded as a new material, but as a revisited and rejuvenated one. For example, early crystallographic studies for single crystals [19] together with diverse luminescence studies of doped β-Ga<sub>2</sub>O<sub>3</sub> were reported as early as the 1960s [20]. Lorenz et al. [21] already published in 1966 that *n*-type Ga<sub>2</sub>O<sub>3</sub> exhibits mobilities in the range of 100 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup> and an adequate device doping of 10<sup>18</sup> cm<sup>-3</sup> can be achieved just by controlling the native oxygen vacancies' density. Its deep-ultraviolet intrinsic bandgap of around 4.5–4.9 eV and excellent photoconductivity are also well-known from early contemporary studies [22]. It was not until

this decade that the potential of Ga<sub>2</sub>O<sub>3</sub> for a certain class of extreme or power electronics was realized due to further availability of large-area single crystals with high quality and the control of doping. In the past, Ga<sub>2</sub>O<sub>3</sub> was somehow ignored as an ultra-wide bandgap material, as it was eclipsed by the potential of diamond which has never been fully realized [23].

Previously, SiC and GaN were the wide bandgap materials of choice [6]. However, from an ultra-high energy electronics perspective, Ga<sub>2</sub>O<sub>3</sub> transistors and diodes exhibit the potential of delivering outstanding performances in the form of high breakdown voltage, high power and low losses because of superior material properties, thus extending the power handling limits given by the SiC and GaN integration into the mainstream [4]. Indeed, an ultra-large breakdown electric field, (which is usually assumed to be of the order of  $E_c \sim 8 \text{ MVcm}^{-1}$ ), is a prime material advantage of Ga<sub>2</sub>O<sub>3</sub>. However, this value may be well underestimated; it was very recently suggested that the critical electric field of Ga<sub>2</sub>O<sub>3</sub> could be as large as  $13.2 \text{ MVcm}^{-1}$ , if the residual donors are efficiently removed [24].

A high critical field crucially promotes the suitability of a semiconductor material for power devices that would be able to manage a large amount of electrical energy per unit area. Baliga's figure of merit [25] for power electronics is proportional to  $E_c^3$ , whilst only being linearly proportional to the bulk electron mobility ( $\mu$ ). Although Ga<sub>2</sub>O<sub>3</sub> presents a similar conduction band dispersion (i.e., effective mass) than GaN, a relatively small bound limit of  $\mu \sim 300 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$  is frequently given [26]. This is due to a massive Fröhlich interaction which is common to many conducting oxides. Balancing critical field and mobility, the on-state losses can be still an order of magnitude lower than those for SiC and GaN for a given breakdown voltage (Figure 3). Comparing these values to other power semiconductors (see Figure 3),  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> appears favorable, surpassing SiC and GaN. A major additional technological advantage of the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> is that the single crystal structure can be synthesized via several standard melt growth methods including the Czochralski (CZ) technique [27]. This, in practice, would imply SiC performances (or better ones) at a fraction of cost.

WBG	Bandgap $E_g$ [eV]	Permitt. $\epsilon_r$ [ $\epsilon_0$ ]	Mobility $\mu_n$ [ $\text{cm}^2/\text{Vs}$ ]	Crit. Field $E_c$ [MV/cm]	BFOM $\times 10^6$ [ $\text{V}^2/\text{Wcm}^2$ ]	Ther. Cond. $k$ [W/mK]

**Figure 3.** A summary of the main power device figure of merit (or Baliga's figure of merit, BFOM) parameters of the most popular wide bandgap semiconductors. Gallium oxide has a particularly

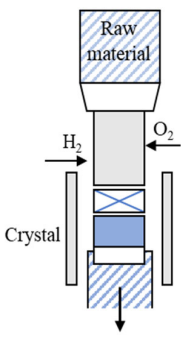

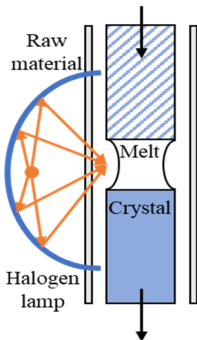

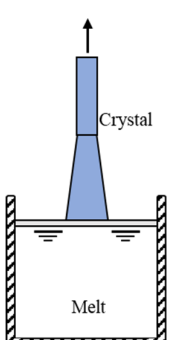

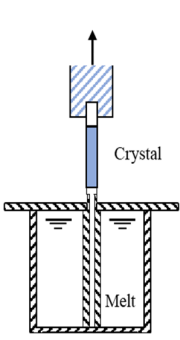

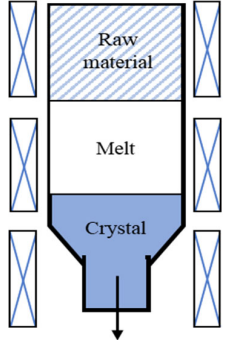

poor thermal conductivity. However, when integrated into devices, heterojunctions with other better suited heat sinks (such as silicon carbide) area way to circumvent that limitation. As shown in the bottom panels, the simulate lattice temperature is lower on SiC (b) when compared with Ga<sub>2</sub>O<sub>3</sub> substrates (a). Furthermore, thinning the Ga<sub>2</sub>O<sub>3</sub> active film helps thermal performances. Adapted with permission from [11] ©2018 COPYRIGHT Society of Photo-Optical Instrumentation Engineers (SPIE).

There are certain applications, such as maritime and air transport, that are difficult to electrify as the power ratings are generally larger than, say, urban electric cars (Figure 1d,e). For electric cars, devices delivering at or below the 1.2 kV perform well as rapid chargers or drive converters. These power ratings are well covered with “conventional” WBG, such as SiC and GaN. As the critical electric field of Ga<sub>2</sub>O<sub>3</sub> has been reported to be at least two times, (or even four times larger), than that of these WBGs, the blocking voltage range of single electronics devices may be significantly extended in the future beyond what is theoretically possible today. These promises will impact directly on the size and weight of planes and ships resulting in less energy and emissions. As energy and transportation represents a major portion of the current CO<sub>2</sub> emissions contributing to global warming, it is expected that UWBG such as Ga<sub>2</sub>O<sub>3</sub> may open new opportunities in sectors that are now difficult to decarbonize. Other prominent examples where the advantage of ultra-wide bandgap semiconductors can be exploited are as more solar-blind (UV transparent) transparent conducting electrodes [11] and electron (or hole) transport layers within solar cells or photodiodes [28].

### 3.1. Gallium Oxide Bulk Crystal Growth

Commonly used growth techniques of bulk  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> crystal are (Table 1): Verneuil method [21,29], Czochralski (CZ) method [30–33], floating-zone (FZ) method [34], edge-defined film fed (EFG) method [16,17], and Bridgman (horizontal or vertical, HB and VB) method[35,36],summarizing the basic features of melt growth methods reported so far.

**Table 1.** Overview of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> bulk crystal growth methods.

Method	Verneuil	FZ	CZ	EFG	VB
Schematic illustration					
Bulk size	3/8-inch diameter 1-inch length	1-inch diameter	2-inch diameter	6-inch width 4-inch diameter	2-inch diameter
Growth rate (mm/h)	10	20–40	2	15	5

Refs.	[21,28,37,38]	[34,38–43]	[16,17,30,33,43–45]	[16,17,46,47]	[35,36,48]

The Verneuil method, being a crucible-free technique, enables both oxidizing and reducing of growth conditions [21]. The synthesis under a reducing condition benefited electron conductivity [49]. *N*-type doping was realized by Harwig et al. [37], the free carrier concentration was determined to be  $\sim 10^{19} \text{ cm}^{-3}$  by Mg doping, and  $\sim 10^{21} \text{ cm}^{-3}$  by Zr doping at  $900^\circ\text{C}$ . The  $\beta\text{-Ga}_2\text{O}_3$  bulk crystal grown by this method has poor quality, and it was used mainly last century, as other more efficient techniques were well developed. The FZ method is also a crucible-free technique, it was recently used to grow bulk  $\beta\text{-Ga}_2\text{O}_3$  crystal to investigate the scintillation features [50,51] as it can be employed in an air atmosphere, which may allow for creation of fewer oxygen defect centers being the emission origin of  $\text{Ga}_2\text{O}_3$  [52]. Tomioka et al. [41] analyzed the residual impurities of  $\beta\text{-Ga}_2\text{O}_3$  grown by the FZ method by inductively-coupled plasma mass spectroscopy; besides Si or Sn, Al, Mg, and Fe have also been detected with a concentration of  $\sim 10^{16} \text{ cm}^{-3}$ . Al was presumed to be a neutral impurity, while Mg and Fe were considered as deep ionized acceptors and could compensate Si donors. To our knowledge, the lowest FWHM reported is  $\sim 22$  arcsec for the peak  $\beta\text{-Ga}_2\text{O}_3$  (400) by Hossain et al. [39], in this work, the Laue diffraction patterns also confirmed that the grown  $\beta\text{-Ga}_2\text{O}_3$  crystal has a good crystallinity. However, FWHM of  $\beta\text{-Ga}_2\text{O}_3$  rocking curves larger than 100 arcsec has also been measured [38,53]. However, both these techniques mentioned above suffer from small crystal size (wafer is no more than 1 inch so far, as summarized in Table 1).

Using an Irucible, the CZ method has been predicted to be a potential candidate for large boule, but thermal instability is an issue at high temperature that leads to decomposition of  $\text{Ga}_2\text{O}_3$ . Thus, this technique requires atmosphere control. Being a crack-free technique, the  $\beta\text{-Ga}_2\text{O}_3$  crystal grown by the CZ method has small or even no boundaries. Several works reported by Galazka et al. [32,43,44] evidenced that the FWHM of the X-ray rocking curve could be as low as 22–50 arcsec on average, and the dislocation density was  $\sim 10^3 \text{ cm}^{-2}$ . Moreover, Galazka et al. [31] recently reported that bulk  $\text{Ga}_2\text{O}_3$  grown by the CZ method has an electron mobility of  $80\text{--}152 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$  with a low residual Si impurity concentration of  $\sim 10^{16} \text{ cm}^{-3}$ . Similar to the CZ method, the EFG method has the same technique issue. However, this technique is available for a 4-inch wafer and recently became commercially available. Commonly observed twin-boundaries in the EFG grown  $\beta\text{-Ga}_2\text{O}_3$  were efficiently avoided by optimizing the growth process (the so-called shouldering process). Different from the traditional growth direction (010), Oshima et al. [54] demonstrated that the (001) oriented  $\beta\text{-Ga}_2\text{O}_3$  grown by the EFG is more suitable than (010) for a Schottky barrier diode (SBD). A weak correlation between pits and electrical properties has been revealed [27,54]. The use of the VB method allows withstanding of high oxygen concentrations as a Pt-Rh (70–30%) alloy crucible. Additionally, this crucible also facilitates the pulling-up process as the grown crystal does not adhere to the wall. The major residual impurities are generally Rh ( $\sim$ several tens wt.ppm) from the crucible, Sn and Si ( $\sim$ several wt.ppm) from raw materials, and Fe and Zr ( $\sim$ several wt.ppm) from the furnace [36,48]. This technique recently became *n*-type doping available by using a resistance heating VB furnace, and electron concentration and electron mobility were determined to be  $3.6 \times 10^{18} \text{ cm}^{-3}$  and  $60 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$ , respectively, by 0.1 mol% Sn-doped [35,48]. As the CZ, EFG, and VB method use the crucible, they all have a high level of scalability.

### 3.2. Gallium Oxide Thin-Film Growth

Bulk devices and subsequent epitaxy of  $\beta\text{-Ga}_2\text{O}_3$  layers could be provided by bulk growth, while high-quality epitaxial growth technologies are still required in order to study and fabricate more complex devices. Halide vapor phase epitaxy (HVPE), metal-organic vapor phase epitaxy (MOVPE), pulsed laser deposition (PLD), atomic layer deposition (ALD), molecular beam epitaxy (MBE), mist-chemical vapor deposition (CVD), and metal-organic chemical vapor deposition (MOCVD) are all involved in thin-film growth of  $\text{Ga}_2\text{O}_3$ .

Vapor phase epitaxy is a commercially promising technique for mass production of  $\beta\text{-Ga}_2\text{O}_3$ . Based on VPE, the halide vapor phase epitaxy (HVPE) method enables a growth

rate as high as 250  $\mu\text{m}/\text{h}$  [55] and the wafer size from 2 to 6 inches [56], it is thus a suitable technique for thick films with high purity for high voltage vertical switching devices. Furthermore, with the presence of chlorine catalyst in the growth chamber, this technique exhibits the growth of metastable phases of  $\text{Ga}_2\text{O}_3$ , such as  $\alpha$  and  $\varepsilon$  [57]. The HVPE method suffers from a high level of roughness on the surface even at a relatively low growth rate [56,58]; an electrical mechanical [59] or a chemical mechanical [60] polishing can be employed to remove further deep surface pits formed during the growth. Leach et al. [61] reported a vast difference in surface morphology and XRD full-width half-maximum (FWHM), between sufficiently and insufficiently CMP polished (discriminated by the polishing times of the various polishing steps)  $\beta$ - $\text{Ga}_2\text{O}_3$  wafers grown by HVPE. Despite the poor morphology, the FWHM of the films grown on on-axis substrate were as narrow as 28 arcsec. Moreover, Murakami et al. [62] revealed that effective donor concentration without intentional doping could reach as low as  $10^{13} \text{ cm}^{-3}$ .

Metal-organic vapor phase epitaxy (MOVPE) can provide a highly scalable growth as its deposition areas are large. Triethylgallium (TEGa), trimethylgallium (TMGa), and  $\text{O}_2$  are most commonly the precursors for gallium and oxygen, respectively. The homoepitaxial growth of  $\beta$ - $\text{Ga}_2\text{O}_3$  by MOVPE can be strongly affected by substrate orientation. The growth rate is approximately 1.6–2.0 nm/min on the (100) plane, 0.65–1  $\mu\text{m}/\text{h}$  on the (010) plane, and 1.6–4.3 nm/min on the (00-1) plane with miscut angles [63]. Recently, the growth rate can be elevated to 3.6 nm/min on the (100) plane [64] by tuning the growth pressure. A high-quality homoepitaxial growth on  $\beta$ - $\text{Ga}_2\text{O}_3$  the (100) with an FWHM of 43 arcsec has been reported by Gogova et al. [65]. The study of residual donor source is still in progress [66] while an electron concentration of  $8 \times 10^{19} \text{ cm}^{-3}$  by Si-doping was realized by Baldini et al. [67], which is the highest doping level by this technique so far.

Pulsed laser deposition (PLD) has often been used for doped layers of  $\text{Ga}_2\text{O}_3$  as it can transport materials from the target to the substrate stoichiometrically, thus the thickness of layers can be incisively controlled. It also has a relatively low operating temperature compared to other techniques. However, the quality of the materials deposited and the deposition rate are relatively low compared with other CVD and MBE methods. The roughness measured on the surface of  $\text{Ga}_2\text{O}_3$  films had a root mean square between 1 and 7 nm [68–70].

A growth rate of 10.8 nm/min could be reached without oxygen, while it decreased to 6.5 nm/min by increasing oxygen pressure to 50 mbar [71]. Indeed, oxygen partial pressure and temperature are considered as the dominant parameters for properties of materials grown by the PLD [72]. The crystallinity was enhanced by increasing oxygen pressure at either low deposition temperature (250°C [71]) or high deposition temperature (780°C [68]). A higher oxygen partial pressure also leads to self-trapped holes at  $\text{O}_1\text{s}$  and between two  $\text{O}_2\text{s}$  sites [68], which could further act on the transport properties. Unlike the influence of oxygen pressure, a higher temperature does not always lead to a better film quality [73,74]. While, as expected, a higher annealing temperature could improve the crystallinity, as it helps the re-arrangement of Ga and O atoms to their optimal sites [75,76]. The highest  $n$ -type doping level achieved by the PLD is  $1.7 \times 10^{20} \text{ cm}^{-3}$  by Si doping [69].

Atomic layer deposition (ALD), initially called atomic layer epitaxy (ALE), is a subset of the chemical vapor deposition (CVD) technique based on self-saturation, sequential surface reactions. ALD is a more general deposition containing ALE and molecular layering (ML) techniques [77]. The highly controlled thickness of films and conformal coverage are the main advantages of ALD over other techniques, it also allows a relatively lower deposition temperature compared to MBE and CVD techniques and a lower growth rate (generally less than 0.1 nm/cycle). Sn-doped  $\text{Ga}_2\text{O}_3$  grown by ALD was investigated by Siah et al. [78], however the concentration of Sn was estimated as  $2 \times 10^{20} \text{ cm}^{-3}$ , with the free electrons determined to be  $4 \times 10^{18} \text{ cm}^{-3}$ . This was due to the low growth temperature.

Thus, post-annealing is generally also required to improve the crystalline quality. Additionally, the temperature during growth depends mainly on the gallium precursor

chosen [79,80]. Besides the conventional ALD, the plasma-enhanced atomic layer deposition (PEALD) further permits a lower deposition temperature and better Ga<sub>2</sub>O<sub>3</sub> film properties with very smooth surface roughness (<1 nm) [81–83].

Molecular beam epitaxy (MBE) suits research purposes better than commercial use, as it enables the growth of high structural quality  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> with a relatively low growth rate (<1  $\mu\text{m}/\text{h}$ ) and high production cost, while high voltage vertical devices often require thick drift regions (dozens of microns). The orientation of growth has been found to be one factor that influences the growth rate [84]. Mazzolini et al. [85] further demonstrated the growth rate of different orientations  $\Gamma(010)$  (2.3 nm/min) >  $\Gamma(001)$  >  $\Gamma(-201)$  >  $\Gamma(100)$  of In-catalyzed  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> layers; this phenomenon was believed to be associated with the surface free energy related to the binding energy of the In ad-atom. Nepal et al. [86] reported a heteroepitaxial growth on SiC with (-402) having a relatively high FWHM (694 arcsec), which can be reduced to 30–60 arcsec by homoepitaxial growth [87]. The thin films grown by MBE also benefit a smooth surface with a roughness of less than 1 nm [88,89]. The densities of the threading dislocation etch pits was determined to be  $\sim 10^5 \text{ cm}^{-2}$  for the film grown at 850 °C [89]. An electron concentration of  $10^{20} \text{ cm}^{-3}$  has been achieved by Sn doping [90].

Techniques based on chemical vapor deposition (CVD) have also been employed for the growth of Ga<sub>2</sub>O<sub>3</sub>. Scalability and mass production are the most advantageous characteristics of the mist-CVD technique, as it is a vacuum free, low-cost, and solution-processed approach. This technique is also often used for epitaxial growth of  $\alpha$ -Ga<sub>2</sub>O<sub>3</sub> on sapphire [91–94]. Morimoto et al. [94] also pointed out the facilities of mist-CVD for Ga<sub>2</sub>O<sub>3</sub> by F doping. Both homoepitaxial [95,96] and heteroepitaxial [97] growth of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> have been successfully performed. It is also worth noting that the FWHM of rocking curves was 39–91 arcsec for homoepitaxial growth with growth rate of 0.5–3.2  $\mu\text{m}/\text{h}$  [96,98]. An electron concentration was measured as  $5 \times 10^{20} \text{ cm}^{-3}$  by Sn doping [98].

The metal-organic chemical vapor deposition (MOCVD) technique uses Ga-based organic material as metal precursors, such as trimethylgallium (TMGa) and triethylgallium (TEGa), which usually leads to C-contamination of the as-grown film (relatively less carbon by using TEGa than TMGa). It is well-known that such contamination can be efficiently reduced by high growth temperature, and eliminated by post-annealing. Li et al. [99] reported a high-quality homoepitaxially grown film with FWHM and surface roughness of 21.6 arcsec and 0.68 nm, respectively. The growth rate is generally from several hundred nm/h [100,101] to 10  $\mu\text{m}/\text{h}$  [102–104]. This technique is also available for both *n*- and *p*-type dupability [24,105] (Figure 4).

**Figure 4.** Ga<sub>2</sub>O<sub>3</sub> and related oxides have been demonstrated to exhibit some remarkable features, such as (a) ultra-high critical electric field, (b) potential bipolar operation due to its demonstrated *n*-type and *p*-type conductivity, (c) ultra-stable interfaces that may host a 2D electron gas, (d) extended transparency into the UV-A region for transparent conducting oxide (TCO) applications (tail state density is located deeper in the ultraviolet than conventional TCOs). ### 3.3. Gallium Oxide Doping Issues and Recent Progress

$\beta$ -Ga<sub>2</sub>O<sub>3</sub> is very easily doped *n*-type to the degenerate state, *n*-type doped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> with carrier concentration from 10<sup>16</sup> to 10<sup>20</sup> cm<sup>-3</sup> [110,111] has been achieved by Sn and Ge doping by MBE, Si and Sn doping by MOVPE, and Sn doping by MOCVD [69]. A high mobility at room temperature of 145–184 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup> [100,101,112] has been reached by Si doping, and even till 10<sup>4</sup> cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup> at 46 K [109]. Having a high critical field (5.2 MV.cm<sup>-1</sup> without intentional doping [113]), the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> devices demonstrate high performance. Nevertheless, all the Ga<sub>2</sub>O<sub>3</sub> devices demonstrated thus far have been unipolar in nature (i.e., only *n*-type). In order to realize the full potential for WBG opto-electronics  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> and to sustain high breakdown voltage (>6.5 kV), we need vertical geometry bipolar-junction-based devices. Therefore, the realization of *p*-type  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> is a primary challenge today for the gallium oxide scientific community (Figure 4).

There is a tendency in oxide compounds to have *n*-type conductivity, caused by vacancies in the oxygen atoms. This, as well as the fact that it is a UWBG material, intrinsic conduction is rare and even causes *p*- and *n*-type doping tends not to be symmetrical. This asymmetry is seen in gallium oxide, the hole conductivity is poor and is likely the main limitation for development of gallium oxide technology. Fundamental restrictions such as this area recurring issue in oxides, such as: (i) acceptor point defects with high formation energy; (ii) native donor defects with low energy—resting holes; and (iii) *p*-type oxides suffer from a high effective mass of the holes (this results in a low mobility), due to the top of the VB predominantly from localized O 2-p derived orbits.

Native *p*-type conductivity: Using thermodynamical calculations for the point defects on gallium oxide it can be seen that gallium oxide is “lucky”, as when  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> is at 500°C,  $P_{hole} \approx 1.33 \times 10^{-2}$  atm with a hole concentration around  $p \approx 10^{15}$  cm<sup>-3</sup> [114]. Comparing this to calculations for ZnO gives  $P_{hole} \approx 10^3$  atm, for the same temperature. This divergence is believed to be from higher formation energy of the donor vacancies in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> (approximately 1 eV higher per vacancy), making compensation mechanism by point defects less favorable in gallium oxide than in ZnO. As a consequence, it can be expected that *p*-type samples of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> with higher carrier concentrations (then intrinsic) can be obtained when doping with shallow acceptor impurities.

The native hole concentration was investigated by Nanovation (SME, France) [114] where undoped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> thin film grown on c-sapphire substrates by pulsed laser deposition (PLD) showing resistivity of  $\rho = 1.8 \times 10^2$  Ω.cm, hole concentration of  $p = 2 \times 10^{13}$  cm<sup>-3</sup> and a hole mobility of 4.2 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup> [114]. The determination of conductivity mechanism showed that Ga vacancies act as deep level acceptors with the activation energy of 0.56 eV in the low compensated sample, having  $E_a = 1.2$  eV ionization energy. Later, the improvement was shown that native *p*-type conductivity by post-annealing in an oxygen atmosphere for  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> thin film was grown on c-sapphire substrates by MOCVD [115]. After oxygen annealing, the hole concentration was increased from  $5.6 \times 10^{14}$  cm<sup>-3</sup> to  $5.6 \times 10^{17}$  cm<sup>-3</sup> at 850 K. The author claimed that the annealing effect is related to the formation of V<sub>Ga</sub>-V<sub>O</sub><sup>++</sup> complexes as a shallow acceptor center with  $E_a = 0.17$  eV activation energy.

Device applications require higher hole concentrations (at operating temperature), which could be achieved via external acceptor impurity incorporation.

There are already extensive theoretical studies (standard density functional theory (DFT and DFT with GGA+U) of acceptor impurity doping of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> in order to identify efficient *p*-type dopant. Kyrtsov et al. [116] demonstrated by DFT calculations that dopants, such as Zn, Li, and Mg, will introduce deep acceptor level with ionization energies of more than 1 eV, thus, they cannot contribute to the *p*-type conductivity. However, this result could be influenced by the underestimation of the bandgap due to the semi-local approach. Varley et al. [117] predicted that self-trapped holes are more favorable than delocalized holes due to their energies and by theoretical calculation (self-trapping energy is 0.53 eV and barrier to trapping is 0.10 eV). This indicates that free holes are unstable and will spontaneously localize towards small polarons.

Lyons [118] examined the elements of group 5 and group 12 (Be, Mg, Ca, Sr, Zn, Cd) as acceptor impurities in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> by hybrid DFT, all of them will exhibit the acceptor ionization levels of more than 1.3 eV. Mg was determined to be the most stable acceptor species, followed by Be. Sun et al. [119] used ab initio calculations to simulate the doping by Ge, Sn, Si, N, and Cl. Among them, N has been predicted to be a deep acceptor with an impurity level of 1.45 eV, as it has a similar atomic size as oxygen but has one less valence electron, and a higher 2*p* orbital than oxygen. While all others act as donors, another ab initio calculation also demonstrated that nitrogen doping could introduce an acceptor level at 1.33 eV above the VBM.

Very recently, Goyal et al. [120] simulated a growth-annealing-quench sequence for hydrogen-assisted Mg doping in Ga<sub>2</sub>O<sub>3</sub> by using the first principles defect theory and defect equilibrium calculations. The H<sub>2</sub>O partial pressure and H exposure can strongly influence the Mg dopants concentration during the growth, by increasing the solubility limit

of the acceptor, or by reducing the compensation. A conversion from *n*-type to *p*-type was achieved by annealing at O-rich/H-poor conditions. A Fermi level at +1.5 eV above the VB has been found after quenching.

Doping with two elements (co-doping) has been predicted by DFT which showed a promising method to obtain *p*-type  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>, as it can break the solubility limit of mono-doping and improves the photoelectric properties of semiconductor materials which results in increasing the conductivity.

The principle is to increase carrier concentration and decrease the compensating defect formation energy. This is inherently caused by the localized nature of the O<sub>2p</sub>-derived VB that leads to difficulty in introducing shallow acceptors and large hole effective mass [121].

Co-doping has been successfully used for II-VI compounds, co-doping containing N (Zn-N, N-P, Al-N, and In-N) has been demonstrated to be an effective way to improve the *p*-type conductivity [122–124], in particular, Zhang et al. [124] predicted two shallow impurity levels above the VB of about 0.149 eV and 0.483 eV in N–Zn co-doped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>. Co-doping by N-P made an acceptor level decrease ~0.8 eV, and an impurity level appears at 0.55 eV above the VB of  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>. A significant loss of holes' effective mass was also evidenced [124]. There are a few experimental works reported regarding *p*-type doping of gallium oxide. Mg-doped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> was studied by Qian et al. [125] for the photo-blind detector, and the  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> containing 4.92 at% Mg has shown an acceptor level by XPS. A variation of bandgap has also been reported [83,126] however, the Hall effect measurement validity failed at room temperature due to the very high resistivity of the samples [127].

Suet al. [128] deposited Mg-Zn co-doped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> on sapphire (0001), however, antisites' impurity defects (i.e., ZnGa and GaZn) were determined as deep acceptors (0.79 eV for ZnGa and 1.00 eV for GaZn) by absorption spectra. Feng et al. [129] demonstrated Zn doping (1.3–3.6 at%) in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> nanowires can reduce the bandgap slightly, they also proved the *p*-type conductivity by making *p-n* junction. Chikoidze et al. [24] suggested that Zn in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> has an amphoteric nature: it can be an acceptor as Zn<sub>Ga</sub> defect and at the same time, a donor being in Zn<sub>i</sub> interstitial sites. It was shown that in (0.5%) Zn:Ga<sub>2</sub>O<sub>3</sub> the auto-compensation of donor (Zn<sub>i</sub>) -acceptor (Zn<sub>Ga</sub>) defects takes place.

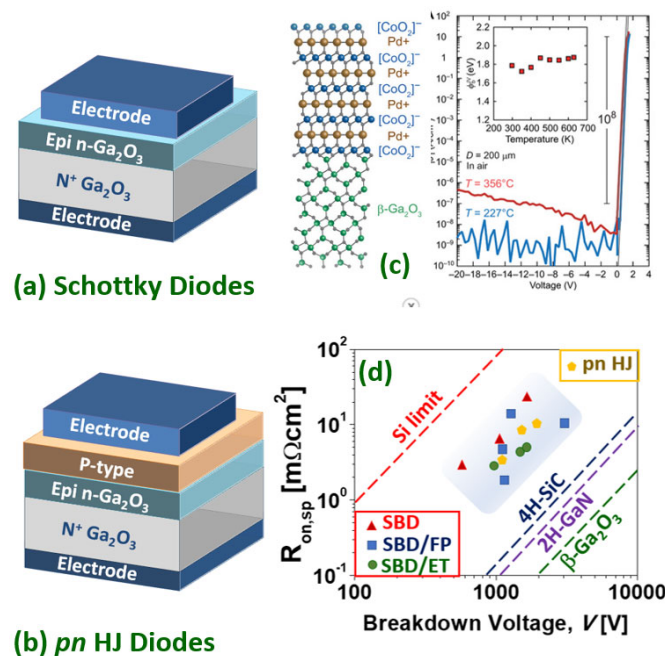

Islam et al. [130] reported that hydrogen annealing could vastly reduce the resistivity and reach a remarkable hole density of ~ 10<sup>15</sup> cm<sup>-3</sup> at room temperature. Besides, the ionization energy of acceptor is as low as 42 meV by incorporation of hydrogen in the lattice. This improvement is related to hydrogen decorated gallium vacancies V<sub>Ga-H</sub>: during the diffusion of hydrogen into the Ga<sub>2</sub>O<sub>3</sub> crystal, H<sup>+</sup> absorbed at the surface will be attracted toward the V<sub>Ga</sub><sup>3-</sup>, it stabilizes the negative charge and thus lowers the acceptor level. This mechanism leads to H<sup>+</sup> decorated Ga-vacancy V<sub>Ga-2H</sub><sup>1-</sup> and, therefore, the *p*-type conductivity.

Nitrogen-doped *p*-Ga<sub>2</sub>O<sub>3</sub> has been experimentally achieved by non-conventional growth technique. Wu et al. [131] demonstrated a multi-step structural phase transition growth from hexagonal P6<sub>3</sub>mc GaN to rhombohedral R3C  $\alpha$ -Ga<sub>1-x</sub>N<sub>x</sub>O<sub>3(1-x)/2</sub> and realized the monolithic C2/m N-doped  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> thin layer finally with an acceptor ionization energy of 0.165 eV. The resistivity, hole concentration, and hole mobility are 17.0  $\Omega$ .cm, 1.56 × 10<sup>16</sup>cm<sup>-3</sup>, and 23.6 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup>, respectively, by employing the Hall effect measurement. A performant field-effect transistor was also fabricated based on this *p*-type  $\beta$ -Ga<sub>2</sub>O<sub>3</sub>. Clearly, further experimental studies of optimal acceptor defects with room temperature activation are required.

### 3.4. Gallium Oxide Power Rectifiers

Once the device-grade epitaxial layers have been grown either homo- (bulk Ga<sub>2</sub>O<sub>3</sub>) hetero- (e.g., sapphire, silicon), or both, the simplest electronic devices one can define are rectifiers. In a Schottky rectifier, the counter-electrode (cathode) is processed to allow low

resistance Ohmic contact while the anode contact is intended as a Schottky junction over a lightly doped epitaxy; it conducts electrons in the forward mode while sustaining large electric fields (by the creation of a depletion space charge region) in the reverse mode. As mentioned previously, devices using  $\text{Ga}_2\text{O}_3$  are primarily limited to unipolar devices and Schottky diodes are made, in general, on  $n$ -type semiconductor layers as electrons are lighter than holes. However, it is also important to consider the appropriate metal contacts to  $\text{Ga}_2\text{O}_3$  as they are responsible for connecting the semiconductor to the surrounding electrical circuit/system and parameters such as the Schottky barrier height are crucial. For different contacts to  $\text{Ga}_2\text{O}_3$ , such as in GaN and AlGaN, which utilize stacks of different metals [132], this decision can make an important difference to the nature of the contact. Regarding Schottky contacts to  $\text{Ga}_2\text{O}_3$ , Ni/Au is a common choice (see Table 2). Other Schottky contacts investigated include Pt, Ni, Cu, W, Ir, TiN/Au, Pt/Ti/Au, Ni/Au, ndPt/Au [133–136]. Very recently, an ultra-large Schottky barrier of  $\sim 1.8$  eV was extracted for all-oxide  $\text{PdCoO}_2/\beta\text{-Ga}_2\text{O}_3$  Schottky diodes [137]. The polar layered structure of  $\text{PdCoO}_2$  generates electric dipoles, realizing a large Schottky barrier height of  $\sim 1.8$  eV (well beyond the 0.7 eV expected from the basal Schottky–Mott relation) along with a large on/off ratio approaching  $10^8$ , even at a high temperature of  $350^\circ\text{C}$  (Figure 5c). As there are a number of polar oxides, this is a promising approach to increase the reverse blocking voltage of  $\text{Ga}_2\text{O}_3$  diodes [138].

**Figure 5.** Schematics of (a) vertical  $\text{Ga}_2\text{O}_3$  Schottky diodes and (b)  $p$ - $n$  heterojunction diodes. (c) A  $\text{PdCoO}_2/\text{Ga}_2\text{O}_3$  exhibiting the ultra-large Schottky barrier of 1.8 eV. (d) Baliga's FOM for selected Schottky and  $p$ - $n$  HJ diodes from the literature. Panel (c) adapted with permission from Harada et al. [137] © 2022 AAAS 4.0 (CC BY-NC). Adapted with permission from [12] ©2021 copyright Society of Photo-Optical Instrumentation Engineers (SPIE).

In the counter-electrode, highly doped regions beneath the metallization are deployed to assist ohmicity of the contacts [139]. The dopants for this have previously been discussed. Another approach to this is using thin films of highly-conducting oxides [140].

**Table 2.** Table displaying varying SBD designs: L—lateral, V—vertical, TCO—thin conductive oxide film, FP—field plate, BET—bevel edge termination, FPET—field plate edge termination, MDS—metal-dielectric-semiconductor Schottky diode. Included here are different structures which exhibited SBD (some exhibiting Schottky contacts as opposed to useable device) using a range of different designs and metal stacks.

Device Configuration	Schottky Metal Stack	Ohmic Metal Stack	$V_{br}$	Ideality Factor	Ref
V-SBD-BET	Ni/Au	Ti/Al/Ni/Au	427 V	1.07	[133]
V-SBD-FP	Ni/Au	Ti/Au	730 V	1.02	[139]

Ohmic contacts to  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> are commonly based on Ti/Au, however other metal contacts have been utilized, such as In, Ti, Ti/Al/Au, In/Au, and Ti/Al/Ni/Au. Besides, there are other metals which have exhibited pseudo Ohmic behavior including Zr, Ag, and Sn [132]. This pseudo nature meant that, initially, ohmicity was observed but, after annealing, rectifying behavior became dominant. Therefore, the Schottky/Ohmic nature is also dependent upon the Ga<sub>2</sub>O<sub>3</sub>'s surface/interface states together with the exact choice of metal stack, explaining, in turn, the varying contact resistivity of certain metals. While delivering low contact resistance, it is worth mentioning that Au is not considered a CMOS-compatible metal. This is an issue shared with GaN-based technology [148].

For the continued development of high voltage  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> devices, edge termination is an important aspect as it is with its Si, GaN, and 4H-SiC counterparts. Edge termination in  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> is being explored and focused specifically on field plates (FP), imparted edge termination (ET), guard ring field plates, thermally oxidized termination, beveled mesas, and trench. These techniques are all deployed to further manage the electrical field to reduce the electric field crowding at the diode edges to increase its blocking capabilities. SBD devices can be made with either a vertical architecture, using homoepitaxial Ga<sub>2</sub>O<sub>3</sub> or with a lateral architecture using either homo- or heteroepitaxial (e.g., on sapphire) Ga<sub>2</sub>O<sub>3</sub>. In general, the vertical structure is preferred as the device pitch is reduced and the encapsulation is simpler. Hu et al. [141] demonstrated a field-plated lateral  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> SBD on a sapphire substrate with a reverse blocking voltage of more than 3 kV, an  $R_{on}$  of 24.3 m $\Omega$ cm<sup>2</sup> (anode–cathode spacing 24  $\mu$ m), and an FOM >0.37 GWcm<sup>-2</sup> (while an FOM of ~500 GWcm<sup>-2</sup> was achieved as the anode-cathode spacing (and  $V_{br}$ ) was reduced). Zhou et al. [149] implemented a Mg implanted ET device on a vertical  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> SBD with a reverse blocking voltage of 1.55 kV and a low specific on-resistance of 5.1 m $\Omega$ cm<sup>2</sup> (epi thickness 10  $\mu$ m) and an FOM of 0.47 GWcm<sup>-2</sup>. Analogously, Lin et al. [150] implemented a guard ring with or without an FP on vertical SBDs. The terminated devices exhibited a specific

on-resistance of  $4.7 \text{ m}\Omega\text{cm}^2$  and a  $V_{br}$  of 1.43 kV. Wang et al. [151] implemented a thermally oxidized termination on a vertical SBD with a  $V_{br}$  of 940 V, a specific on-resistance of  $3.0 \text{ m}\Omega\text{cm}^2$ , and an FOM of  $0.295 \text{ GWcm}^{-2}$ . Allen et al. [152] implemented a small-angle beveled field plate (SABFP), on thinned  $\text{Ga}_2\text{O}_3$  substrates and a non-punch-through vertical SBD design rendering a  $V_{br}$  of 1100 V, a peak electric field of  $3.5 \text{ MVcm}^{-1}$ , and an FOM of  $0.6 \text{ GWcm}^{-2}$ .

Somehow the state of the art is given by Li et al. [153]. They demonstrated an FP vertical  $\text{Ga}_2\text{O}_3$  trench SBDs with a  $V_{br}$  of 2.89 kV (which is  $\sim 500 \text{ V}$  higher than those without FPs). The trench SBDs exhibited a differential specific on-resistance of 10.5 (8.8)  $\text{m}\Omega\text{cm}^2$  from DC (pulsed) measurements leading to an FOM of 0.80 (0.95)  $\text{GWcm}^{-2}$ . This Baliga's power FOM is approaching that for the best vertical SBD GaN devices (e.g.,  $1.7 \text{ GWcm}^{-2}$ [154]) but is still several times smaller than lateral AlGaIn/GaN SBD (e.g.,  $3.6 \text{ GWcm}^{-2}$ [155]) and bipolar  $p$ - $n$  vertical GaN diodes (e.g.,  $\sim 4.6 \text{ GWcm}^{-2}$ [156]). Both, the 2D gas formed at the AlGaIn/GaN interface and the bipolar injection are effective ways of further reducing the on-resistance in these devices while keeping the breakdown voltage high. The lack of low resistivity  $p$ -type layer for the anode has to date, prevented a competitive homojunction  $p$ - $n$   $\text{Ga}_2\text{O}_3$  diode, but  $p$ - $n$  heterojunction diodes have been realized by integrating  $n$ -type  $\text{Ga}_2\text{O}_3$  with  $p$ -type semiconductors, such as CuO (1.49 kV) [157] and NiO (1.06 kV / 1.86 kV) [158,159]. Nickel oxide as the  $p$ -type blocking layer in heterojunction power diodes resulted in a particularly promising approach with this NiO/ $\text{Ga}_2\text{O}_3$  device [160] yielding a Baliga's FOM of  $0.33 \text{ GWcm}^{-2}$  (Figures 5c,d).

Recently, extremely high- $k$  dielectrics have been explored for electric field management in WBG semiconductor-based lateral and vertical device structures [160–164]. According to the TCAD simulations of Roy et al. [165], a super-dielectric  $\text{Ga}_2\text{O}_3$  SBD with practically achievable device dimensions with extremely high FOM should be possible; e.g., 20 kV can be achieved for an  $R_{on}$  of  $10 \text{ m}\Omega\text{-cm}^2$  with a dielectric constant of 300, a  $\text{Ga}_2\text{O}_3$  width/dielectric width ratio of 0.2, and an aspect ratio (drift layer length (anode to cathode spacing) / drift layer width ratio) of 10 resulting in a PFOM of  $40 \text{ GWcm}^{-2}$  (surpassing the theoretical unipolar FOM of  $\beta$ - $\text{Ga}_2\text{O}_3$  SBD by four times).

### 3.5. Gallium Oxide Power Transistors

A power MOSFET fabrication process generally includes a number of technological steps including either gate dielectrics, surface passivation, drain/source ohmic contacts, implant doping, isolation, mesa etch, or in combination. Due to the large bandgap of  $\text{Ga}_2\text{O}_3$ , the most suitable gate insulators are those with enough (conduction and valence) band-offsets to avoid current injection through the gate (e.g.,  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  and perhaps other oxides such as  $\text{Y}_2\text{O}_3$ ,  $\text{MgO}$ , and  $\text{Mg}_2\text{AlO}_4$ ). While balancing the dielectric constant to achieve more gate capacitance and more carriers in the conductive channel [166]. Defining a contact region by implantation, such as in Si, SiC, and GaN power MOSFET technologies, is a usual choice [167], in  $\text{Ga}_2\text{O}_3$  this is typically  $n^+$  Si-ion implantation. While other techniques have been suggested to further decrease the contact resistivity, such as formation of surface states [168] or the adoption of a TCO as a metallic interface [169].

As in, the more mature, AlGaIn/GaN HEMT technology, Ohmic contacts are typically made with a multilayer metal stack consisting of an adhesion layer (e.g., Ti, Ta), an overlayer (Al), a barrier layer (e.g., Ni, Ti, Mo), and a capping of Au [170,171]. Nevertheless, it has been argued that simpler metal structures, such as Ti/ $\text{Ga}_2\text{O}_3$ , are also efficient if there is an oxygen deficient  $\text{Ga}_2\text{O}_3$  surface [172] (a double charged oxygen vacancy is a well-known intrinsic donor in oxides [107]). Indeed, Yao et al. [132] suggested that the surface states appear to have a more dominant role in the transformation from a Schottky to an Ohmic interface than the choice of metal.

As with power SBDs, power MOSFETs can be defined in a vertical  $\text{Ga}_2\text{O}_3$  homoepitaxial structure (typical of SiC power MOSFETs) and lateral structure (typical of AlGaIn/GaN power HEMTs) which can be either homoepitaxial or heteroepitaxial (Figure 6).  $\text{Ga}_2\text{O}_3$  power MOSFETs are mostly unipolar  $n$ -type and operate in depletion mode (D-

mode or normally-on) but a number of techniques have been reported to make enhancement mode (E-mode or normally-off) Ga<sub>2</sub>O<sub>3</sub> devices. For example, Chabak et al. [173] reported an enhancement-mode  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> MOSFETs on a Si-doped homoepitaxial channel grown by molecular beam epitaxy and, using a gate recess process to partially remove the epitaxial channel under the 1- $\mu$ m gated region to fully deplete at zero gate bias. With a breakdown voltage of 505 V (8 mm source-drain spacing), a maximum current density of 40 mA mm<sup>-1</sup>, and an on/off ratio of 10<sup>9</sup>. Hu et al. [174] achieved (in 2018) a larger blocking voltage (1.075 kV), a larger threshold voltage (1.2–2.2 V), and a larger output current (~500 A cm<sup>-2</sup>) in a first demonstration of vertical E-mode MOSFET with significantly larger FOM (~80 MW cm<sup>-2</sup>).

**Figure 6.** Schematics of (a) a vertical Ga<sub>2</sub>O<sub>3</sub> power transistor (VFET) and (b) a lateral transistor (LFET). (c) Baliga’s FOM for selected LFETs and VFETs from the literature. (d) Prospects of Ga<sub>2</sub>O<sub>3</sub> devices as UV PDs,  $D^*$  refers to specific detectivity; dots symbols refer to diodes (either SBD or MSM), while square symbols denote transistors (data adapted from Wu et al. [131]). Adapted with permission from [12] ©2021 copyright Society of Photo-Optical Instrumentation Engineers (SPIE).

The E-mode was accomplished by doping profiling in a FinFET design (a type of 3D, non-planar transistor which has become the usual layout for the smallest CMOS 14 nm, 10 nm, and 7 nm nodes). This kind of E-mode vertical power device was later optimized to sustain up to a blocking voltage of 1.6 kV [175], a threshold voltage of 2.66 kV, a maximum current density of 25.2 mWcm<sup>-2</sup>, and a record FOM of 280 MW cm<sup>-2</sup> [176]. Among D-mode devices, the ones reported by Lv et al. [177] stand out for exhibiting a particularly large FOM. They reported (in 2019) [177] source-FP  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> MOSFETs on a Si-doped/Fe-doped semi-insulating  $\beta$ -Ga<sub>2</sub>O<sub>3</sub> substrate exhibiting 222 mA mm<sup>-1</sup> (18 mm source-drain spacing) with on-resistance of 11.7 m $\Omega$ cm<sup>2</sup>, a  $V_{br}$  of 680 V and an FOM of 50.4 MWcm<sup>-2</sup>. Later (in 2020) [178], they adopted a T-shaped gate and source connected FP structure to increase the  $V_{br}$  up to 1.4 kV/2.9 kV (for 4.8  $\mu$ m/17.8  $\mu$ m source-drain spacing), with a specific on-resistances of 7.08 m $\Omega$ cm<sup>2</sup>/46.2 m $\Omega$ cm<sup>2</sup>. These yielded a record high FOM of 277 MW cm<sup>-2</sup>, together with negligible gate or drain pulsed current collapse and a drain current on/off ratio of 10<sup>9</sup>.

Other lateral D-mode devices with high FOM were reported by Tetzner et al. [179]. By using sub- $\mu$ m gate lengths (combined with gate recess) and optimization of

compensation-doped high-quality crystals, implantation based inter-device isolation, and SiNx-passivation, breakdown voltages of 1.8 kV and an FOM of 155 MW cm<sup>-2</sup> were achieved. In 2020, Sharma et al. [180] reported Ga<sub>2</sub>O<sub>3</sub> lateral D-mode field-plated MOSFETs exhibiting an ultra-high V<sub>br</sub> of 8.03 kV (70 μm) by using polymer SU8 passivation. The current was rather low, however, due to plasma-induced damage of channel and access regions resulting in an impractical FOM of 7.73 kW cm<sup>-2</sup> (i.e., not above the silicon limit). As reported by Kalarickal et al. [164], ultra-high-*k* ferroelectric dielectrics, such as BaTiO<sub>3</sub>, can, in principle, provide an efficient field management strategy by improving the uniformity of electric field profile in the gate-drain region of lateral FETs. High average breakdown fields of 1.5 MV/cm (918 V) and 4 MVcm<sup>-1</sup> (201 V) were demonstrated for gate-drain spacings of 6 μm and 0.6 μm, respectively, in β-Ga<sub>2</sub>O<sub>3</sub>, at a high channel sheet charge density of 1.8×10<sup>13</sup> cm<sup>-2</sup>. An elevated sheet charge density together with a high breakdown field enabled a record power FOM of 376 MWcm<sup>-2</sup> at a gate-drain spacing of 3 μm (Figure 6c). As in the case of SBDs, these performances for the Ga<sub>2</sub>O<sub>3</sub> devices are already impressive and well beyond the silicon limit but still lag behind the best (much more mature) GaN devices in their respective power ratings [181,182].

All the above power MOSFET devices are unipolar *n*-type. These devices are sometimes referred as MISFETs so as to distinguish them from the conventional p-n junction based MOSFETs, since there are no *p*-regions in these MISFETs [175]. As mentioned in the previous sections, there are, however, several reports of *p*-type Ga<sub>2</sub>O<sub>3</sub> in nominally undoped, H-doped and N-doped β-Ga<sub>2</sub>O<sub>3</sub>. In particular, Wu et al. [131] proposed a growth mechanism of multistep structural phase transitions from hexagonal P63mc GaN to rhombohedral R3c α-GaN<sub>x</sub>O<sub>3(1-x)/2</sub>, and finally to monolithic C2/m N-doped β-Ga<sub>2</sub>O<sub>3</sub>. This improves the crystalline quality, facilitates acceptor doping, increases the acceptor activation efficiency, and thus enhances the *p*-type conductivity (acceptor ionization energy of 0.165 eV, Hall resistivity of 17.0 Ωcm, Hall hole mobility of 23.6 cm<sup>2</sup>V<sup>-1</sup>s<sup>-1</sup>, hole concentration of 1.56×10<sup>16</sup> cm<sup>-3</sup>). *P*-type β-Ga<sub>2</sub>O<sub>3</sub> films-based lateral MOSFET deep-ultraviolet (DUV) PDs were fabricated with extremely high responsivity (5.1×10<sup>3</sup> A/W) and detectivity (1.0×10<sup>16</sup> Jones) under 250 nm light illumination (40 μW/cm<sup>2</sup>) conditions. Figure 6d shows the responsivity and detectivity (D\*) for state-of-the-art DUV PDs based on various WBG materials (adapted from [131]), in which it can be seen how β-Ga<sub>2</sub>O<sub>3</sub> surpasses conventional Si-, SiC-, and AlGaIn-based devices in terms of responsivity and detectivity.

#### 4. Other Emerging Oxide Semiconductors for Power Electronics

**Ga<sub>2</sub>O<sub>3</sub> phase engineering:** Owing to the nonpolar nature of β-Ga<sub>2</sub>O<sub>3</sub> crystals, modulation-doped heterostructure is one of the possible approaches to realize Ga<sub>2</sub>O<sub>3</sub>-based FETs [183]. Analogously, *p*-type semiconductors (e.g., *p*-type nitrides such as GaN) may be introduced to yield normally-off β-Ga<sub>2</sub>O<sub>3</sub> field-effect transistors with tunable positive threshold voltages [184]. Other phases of Ga<sub>2</sub>O<sub>3</sub> have also received attention due to potentially favorable growth characteristics, and to the possibility of polarization engineering made possible by the polar nature of their crystal structures. In principle, this polarization could be utilized to produce Ga<sub>2</sub>O<sub>3</sub> two-dimensional electron gases (2DEGs) in analogy with GaN/AlN-based transistors [185].

**Ga<sub>2</sub>O<sub>3</sub> alloy engineering:** The aluminum gallium oxide, Al<sub>x</sub>Ga<sub>1-x</sub>O<sub>3</sub>, is a ternary alloy of Al<sub>2</sub>O<sub>3</sub> and Ga<sub>2</sub>O<sub>3</sub>. It was already noted by Roy [186] in 1952 that the gallium ion closely resembles the aluminum ion and substitutes for it in several structures. Because β-(AlGa)<sub>2</sub>O<sub>3</sub> is not the energetically favored crystalline phase for large Al compositions, the crystal converts to competing structural phases when grown on β-Ga<sub>2</sub>O<sub>3</sub> substrates [187]. Thus, it has been difficult to obtain gallium oxide UWBG materials exceeding the bandgap of ~6 eV which is available to the materials in the nitride family in AlN. Very recently however, it was found that single-crystalline layers of α-(AlGa)<sub>2</sub>O<sub>3</sub> alloys spanning bandgaps of 5.4–8.6 eV can be grown by molecular beam epitaxy [188]. By varying the alloy composition, bandgap energies from ~5.4 up to 8.6 eV with a bowing parameter of 1.1 eV are achieved, making α-(Al<sub>x</sub>Ga<sub>1-x</sub>)<sub>2</sub>O<sub>3</sub> the largest bandgap epitaxial material family

to date. If these layers can be controllably doped, it would pave the way for  $\alpha$ - $(\text{Al}_x\text{Ga}_{1-x})_2\text{O}_3$ -based high-power heterostructure electronic and photonic devices at bandgaps far beyond all materials available today [189].

**Spinel electronics:** The spinel zinc gallate,  $\text{ZnGa}_2\text{O}_4$ , is a nearly stoichiometric mixed oxide made of  $\text{Ga}_2\text{O}_3$  and  $\text{ZnO}$ . A potential advantage of spinel  $\text{ZnGa}_2\text{O}_4$  is its great dopability prospects owing to the spinel's inherent diversity in cation coordination possibilities [106]. Normal spinels have all A cations in the tetrahedral site and all B cations in the octahedral site, e.g., Zn-tetrahedral site  $\text{Zn}^{2+}(\text{T}_d)$  and Ga-octahedral site  $\text{Ga}^{3+}(\text{O}_h)$ , so that normal  $\text{ZnGa}_2\text{O}_4$  is  $\text{Zn}^{2+}(\text{T}_d)\text{Ga}_2^{3+}(\text{O}_h)\text{O}_4^{2-}$ . The spinel's off-stoichiometry, from the ideal 1:2:4 proportions, or the creation of cation antisite defects are known routes for doping these compounds. Dominant defects in spinels are antisite donors (e.g.,  $\text{Zn}_{\text{Ga}}$ ) or donor-like  $\text{Ga}^{3+}(\text{O}_h)$ -on- $\text{T}_d$  and antisite acceptors (e.g.,  $\text{Ga}_{\text{Zn}}$ ) with acceptor-like  $\text{Zn}^{2+}(\text{T}_d)$ -on- $\text{O}_h$  antisite defects resulting in an intrinsic bipolar power semiconductor [190].  $\text{ZnGa}_2\text{O}_4$  is therefore a potential outstanding UWBG (~5 eV) oxide semiconductor but is only one among the many possible spinel oxides. There are over 1000 compounds that are known to crystallize in the spinel structure. The sub-family of spinel oxides is a large and important class of multi-functional oxide semiconductors with many optoelectronics applications in areas such as batteries, fuel cells, catalysis, photonics (phosphors, bio-imaging, photodetectors), spintronics (magnets, bio-magnets), or thermoelectricity [191]. Other magnesium-based Ga-spinels, such as  $\text{MgGa}_2\text{O}_4$  and  $\text{Zn}_{1-x}\text{Mg}_x\text{Ga}_2\text{O}_4$ , are related oxides that are currently being investigated [192,193].

## 5. Conclusions

The rational use of electrical energy and information are central themes in the greatest climatic challenge of the 21st century. UWBG oxides, such as  $\text{Ga}_2\text{O}_3$  and related materials, are promising power electronic candidates since their critical electric field is large compared to beyond silicon WBG (i.e., SiC and GaN), while still yielding a moderate mobility, high quality epi-layers, and large bulk single crystals (more than 6-inch) using low cost and scalable fabrication approaches. During the last decade, the  $\text{Ga}_2\text{O}_3$  power diode and transistor progress has been impressive, with devices now approaching the frontier of the field. The material system also opens new optoelectronics avenues (owing its UVC spanning bandgap), and new electronics perspectives based on stable interfaces and a natural integration with extremely high- $k$  functional oxides. The advances offered by  $\text{Ga}_2\text{O}_3$  are also opening the door to many more UWBG oxides (the largest family of wide bandgap semiconductors), such as the spinel,  $\text{ZnGa}_2\text{O}_4$ , along with many more that are anticipated. Therefore, the ever-increasing family of UWBG oxides is at the very frontier of a more efficient energy electronics which is adapted to tackle the 21st century climatic targets, although there still is a lot of room for performance improvements, technical innovation, and new discoveries.
