37 **ABSTRACT**

38 Suffusion is a selective erosion of fine particles within the matrix of coarse soil particles under the
39 effect of seepage flow. Suffusion can induce important modifications in the hydraulic and
40 mechanical characteristics of the soil. At the scale of an earth structure, the flow direction can vary
41 and the soils which compose the structure and its foundations can be heterogeneous. Thus to
42 ensure the safety assessment of hydraulic earth structures, the suffusion tests need to match with
43 the reality of the body of dikes or dams with a possible horizontal or vertical flow and
44 heterogeneous soils. In this paper, a new multi-directional flow apparatus was developed for
45 characterizing soil susceptibility facing suffusion process and to study the effect of flow direction.
46 The apparatus allows the specimen tests under a vertical or a horizontal flow and it permits to
47 select the layer in which the flow is injected. Two cohesionless soils which slightly differ from each
48 other in their gradations were used to prepare eight specimens by compaction per layer. Suffusion
49 tests were performed under multi-stage hydraulic gradient and the suffusion susceptibility was
50 evaluated by the energy based method. In the case of specimens composed by one soil, whatever
51 the flow direction compared to the interface between soil layers, tested soils appear slightly more
52 erodible under vertical downward flow. These results highlight the combination effect of the
53 hydraulic loading and the gravity on the detached particles. In the case of specimens constituted
54 by a layer of each tested soil, the results show that under a perpendicular flow to the interface
55 between soil layers, the suffusion susceptibility is mainly influenced by the more resistant soil. But
56 conversely, in the case of a parallel flow to the interface between both soils, the suffusion
57 susceptibility is mostly influenced by the less resistant soil.

58 **Keywords** Internal erosion, laboratory testing, flow direction, suffusion, susceptibility
59 classification.

60 Introduction

61 Internal erosion is one of the main causes of instabilities within hydraulic earth structures such as dams,
62 dikes or levees (Foster et al. 2000). According to Fell and Fry (2013), there are four types of internal
63 erosion: concentrated leak erosion, backward erosion, contact erosion and suffusion. This paper
64 focuses on suffusion which is a selective erosion of fine particles under the effect of seepage flow within
65 the matrix of coarser particles. It is recognized that suffusion may cause changes in porosity and can
66 also lead to important modifications in the hydraulic and mechanical characteristics of the soil (Marot
67 et al. 2009, Chang and Zhang 2011; Ke and Takahashi 2012; Moffat et al. 2011 among others).
68 Moreover, modifications of the porous medium can be the catalyst for slope instability at the scale of
69 hydraulic embankments (Fry et al. 2012). Thus, to ensure the safety assessment of hydraulic earth
70 structures, suffusion susceptibility must be characterized.

71 For the characterization of suffusion occurrence, Fell and Fry (2013) proposed three criteria that have
72 to be satisfied. The first criterion concerns the geometry of the porous media and points out that the
73 size of the constrictions between the coarser particles must be larger than the size of detached
74 particles. The second criterion is related to the stress applied on the fine fraction and the third one
75 takes into account the hydraulic load. The two first criteria are mainly related to the grain size
76 distribution, and proposals of various geometric assessment methods exist in the literature, mostly
77 based on the particle size distribution (Kenney and Lau 1985; Wan and Fell 2008; Chang and Zhang
78 2013, among others). However, the modification of the effective stress can also influence the suffusion
79 susceptibility (Moffat and Fannin 2006; Bendahmane et al. 2008; Chang and Zhang 2011). Finally, for a
80 given grain size distribution and a given value of effective stress, angularity of coarse fraction grains
81 contributes to increase the suffusion resistance (Marot et al. 2012). The third criterion is related to the

82 action of the fluid phase, i.e., to the seepage loading required to detach and then to transport the fine
83 particles. Fell and Fry (2013) proposed to model this loading by the velocity of flow through the soil
84 matrix. However, the suffusion development can also be accompanied by variations of interstitial
85 pressure (Moffat and Fannin 2006, Sail et al. 2011). In this context and further to results on interface
86 erosion tests, Marot et al. (2011a) proposed an analysis based on the total flow power which is the
87 summation of the power transferred from the fluid to the solid particles and the power dissipated by
88 the viscous stresses in the bulk. According to Sibille et al. (2015), the transfer appears negligible in the
89 case of suffusion and the authors suggested characterizing the fluid loading from the total flow power
90 (expressed in W) which is computed by:

$$P_{flow} = (\gamma_w \Delta z + \Delta P) Q \quad (1)$$

92 where Q is the fluid flow rate (in $\text{m}^3 \text{s}^{-1}$), γ_w is the specific weight of water (in N m^{-3}), $\Delta P = P_A - P_B$ is the
93 pressure drop (in Pa) between the upstream section A and the downstream section B, $\Delta z = z_A - z_B$, z_A
94 and z_B are altitudes (in m) of sections A and B respectively. $\Delta z > 0$ if the flow is in downward direction,
95 $\Delta z < 0$ if the flow is upward and the total flow power is equal to $Q \Delta P$ if the flow is horizontal.

96 The expended energy E_{flow} (expressed in J) is the time integration of the instantaneous power dissipated
97 by the water seepage and it is computed until reaching the steady state (i.e., hydraulic conductivity
98 tends to stabilize and the erosion rate tends to decrease). Hence the expended energy is expressed by:

$$E_{flow} = \int_0^{t_f} P_{flow}(t) dt \quad (2)$$

100 where t_f is the time (in s) corresponding to the stabilization of the hydraulic conductivity and the
101 decrease of the erosion rate.

102 For the same duration, the cumulative eroded dry mass is determined (expressed in kg) and the erosion
103 resistance index is expressed by:

$$104 \quad I_{\alpha} = -\log \left(\frac{\text{Cumulative eroded dry mass}}{E_{flow}} \right) \quad (3)$$

105 Depending on the values of I_{α} index, Marot et al. (2016) proposed six categories of suffusion
106 susceptibility from highly erodible to highly resistant (corresponding susceptibility categories: highly
107 erodible for $I_{\alpha} < 2$; erodible for $2 \leq I_{\alpha} < 3$; moderately erodible for $3 \leq I_{\alpha} < 4$; moderately resistant for
108 $4 \leq I_{\alpha} < 5$; resistant for $5 \leq I_{\alpha} < 6$; and highly resistant for $I_{\alpha} \geq 6$). This suffusion susceptibility chart brings
109 a more sensitive characterization of the erodibility compared to grain size based criteria which only
110 distinguish two types of gradation: stable or unstable. Moreover it is complementary to the charts
111 defined for the other erosion processes. These include the charts proposed by Briaud (2008) based on
112 erosion tests performed with Erosion Function Apparatus, by Hanson and Simon (2001) and by Wan
113 and Fell (2004) for Jet Erosion Test and Hole Erosion Test, respectively, and by Marot et al. (2011a) for
114 both Jet Erosion Test and Hole Erosion Test.

115 For characterizing the initiation and development of this complex internal erosion process,
116 experimental devices comprise a rigid wall permeameter (Kenney and Lau 1985; Skempton and Brogan
117 1994; Moffat and Fannin 2006; Wan and Fell 2008; Sail et al. 2011) or a modified triaxial cell designed
118 to force fluid to percolate throughout the sample (Bendahmane et al. 2008; Marot et al. 2009; Chang
119 and Zhang 2011; Ke and Takahashi 2014; Slangen and Fannin 2017). These laboratory devices permit to
120 apply a vertical flow in upward or downward direction. However, the suffusion process could be
121 influenced by the flow direction, which can be completely different from vertical flow direction in situ.
122 Pachideh and Mir Mohammad Hosseini (2019) developed a new apparatus to study the effect of the

123 flow direction on the suffusion susceptibility of compacted specimens. They distinguished three types
124 of hydraulic gradients: (i) threshold, (ii) occurrence and (iii) development. These gradients are defined
125 by the start of: rotational movement of fine particles, formation of micropipes and creation of pipes.
126 Pachideh and Mir Mohammad Hosseini concluded that the bigger the angle between the flow direction
127 and the gravity axis, the more these gradients increase. However, the visual detection of such gradients
128 is not easy and in addition, Rochim et al. (2017) showed that the history of hydraulic loading can
129 substantially modify the value of the critical hydraulic gradient at which suffusion occurs. Finally, Smith
130 and Konrad (2011) showed that the soil fabric has an influence on the hydraulic conductivity of
131 compacted soil which suggests the interest of the suffusion susceptibility characterization on
132 undisturbed specimens.

133 In this context, the main objective of this research is to develop a multidirectional flow apparatus which
134 can be used to study soil suffusion susceptibility of undisturbed or compacted specimens. The device
135 also gives the opportunity to apply vertical or horizontal flows and parallel or perpendicular ones with
136 interface between two layers of soils.

137 Testing Apparatus

138 The general configuration of the testing apparatus is shown in Fig. 1. It is composed of an acrylic cylinder
139 cell, a system for applying axial stress, a soil collection system, a water supply system, instrumentation
140 and a data acquisition system.

141 **CYLINDER CELL**

142 This device has been developed to perform suffusion test directly in the cell of the core sample. Such
143 cells have an acrylic cylinder form with an inner diameter of 80 mm and its height can reach up to

144 500 mm. The device gives the possibility to test specimen with various heights between 300 mm and
145 400 mm. The methodology which is defined by the Patent (2018) permits to avoid pushing the sample
146 out of the cell and so limits the soil disturbances. However for this study, in order to reach the same
147 order of magnitude of density for all tested specimens, soils were compacted per layers in the cell of
148 core sampler (see Fig. 1). For applying a vertical flow along the specimen length, the cell is vertically
149 fixed by two vertical beams with two clamps to avoid any disturbances. Two configurations can be used
150 in order to apply a horizontal flow: (i) the cell can be placed horizontally and the seepage flow
151 percolates along the specimen length (configuration named horizontal #1 flow), (ii) the cell can be
152 vertical and a horizontal flow can be injected along the specimen's diameter. For this second
153 configuration, the horizontal flow (named horizontal #2 flow) is injected through an inlet and outlet
154 ports fixed on the vertical beams. For the three possible test configurations, the letters A and B show
155 in Fig. 1 the positions of upstream and downstream sections, respectively (in detail: Av and Bv for
156 vertical flow, Ah#1 and Bh#1 for horizontal #1 flow and finally, Ah#2 and Bh#2 for horizontal #2 flow).
157 Figure 2 shows the different parts, identical in form for both inlet #2 and outlet #2. In the buffer zone
158 of inlet #2, a 15 mm thick layer of glass beads is introduced to diffuse the fluid. The pedestal base (the
159 corresponding section is named Bv for vertical flow and Bh#1 for horizontal #1 flow) and the horizontal
160 outlet #2 are specially designed to perform suffusion tests i.e., to catch the detached particles and also
161 to act as a downstream filter. The specimen is positioned on a 10 mm opening size grid (see Fig. 3) and
162 a mesh with a selected pore opening size can come in between. The inner diameter of the outlet #2 is
163 10 mm (see Fig. 2) and a same type of aforementioned mesh is fixed on the opening. The vertical funnel-
164 shaped draining system and the horizontal outlet #2 are both connected to an effluent tank by a pipe
165 having a glass portion. Figure 4 shows the cell's upstream end (the corresponding section is named Av

166 for vertical flow and Ah#1 for horizontal #1 flow) which is closed by a cap equipped with an inlet port,
167 an opening for the passage of the axial load ram and a vent. For the measurement of the gradient of
168 interstitial pressure, the cell is equipped with four pressure ports: at the horizontal inlet and outlet #2
169 (see Fig. 2), the base pedestal (see Fig. 3) and the top cap (see Fig. 4).

170 **AXIAL LOADING SYSTEM**

171 The loading system is used to apply axial stress on both vertical and horizontal specimens, through a
172 pneumatic piston (see Fig. 4) which can move up or down. This piston contains a 15 mm thick layer of
173 glass beads to diffuse the fluid uniformly on the specimen top surface. The air pressure system is
174 controlled by using a valve and a dial gauge displays the value of air pressure from 0 to 12 bars.

175 **SOIL COLLECTION SYSTEM**

176 The effluent tank is equipped with three inlet valves and an overflow outlet to control the downstream
177 hydraulic head (see Fig. 5). Two inlets permit to collect the effluent for flow applied along the specimen
178 length or along the specimen diameter. The third inlet is connected to the upstream reservoir in order
179 to saturate the specimen by an upward flow (see Fig. 1). Within the effluent tank, a rotating system
180 contains 8 beakers with eight linen bags for the sampling of eroded particles carried with the effluent.
181 In the case of clay or silt suffusion, a multi-channel optical sensor can be placed around the glass pipe
182 (Marot et al. 2011b).

183 **WATER SUPPLY SYSTEM**

184 As suffusion is the result of the combination of three processes: detachment, transport and filtration,
185 which in particular depends on the history of hydraulic loading, Rochim et al. (2017) recommend
186 performing suffusion test under multistage hydraulic gradient. For this purpose, the water supply
187 system includes upstream and downstream reservoirs both equipped with an overflow and their

188 relative elevation that can be manually modified. By taking into account the difference of hydraulic
189 head between the free water surfaces in upstream and downstream reservoirs, the range of hydraulic
190 gradient is from 0 to 2.6 for a vertical flow through a 400 mm high specimen and up to 13 for a flow
191 along the specimen diameter.

192 **INSTRUMENTATION AND DATA ACQUISITION SYSTEM**

193 The instrumentation includes: two flow meters, a differential pressure transducer, an optical sensor
194 and a mass balance as shown in Fig. 1. The injected seepage flow is measured with two electromagnetic
195 flowmeters (of different capacities 0.05-2 L/min and 2-40 L/min) located between the upstream
196 reservoir and injection inlets. The corresponding accuracy is $\pm 1.5\%$ of the full scale. Depending on the
197 hydraulic conductivity of soils, a set of gates permits to select the appropriate flow meter. In case of
198 very low hydraulic conductivity, at the overflow outlet of the effluent tank, water falls in a beaker which
199 is continuously weighed in order to determine injected flow rate with a precision $\pm 0.01 \text{ cm}^3 \cdot \text{s}^{-1}$. The
200 same differential pressure transducer (pressure range of -50 kPa to 50 kPa, accuracy of $\pm 0.01\%$) is used
201 for horizontal or vertical flows. For vertical flow or for horizontal #1 flow, the differential pressure
202 transducer is connected to the pressure ports of the top cap and the pedestal base. For horizontal #2
203 flow, it is connected to the pressure ports of horizontal inlet and outlet. The accuracy of hydraulic
204 gradient measurement for flow along the specimen length and the specimen diameter is 0.01 and 0.17,
205 respectively. Thanks to a previous calibration, the optical sensor allows measuring the silt or clay
206 concentration within the effluent which is expressed as the ratio of the mass of fine particles to water
207 mass within the fluid with a maximum relative error of 5%. The time integration of the fine particle
208 concentration gives the cumulative eroded dry mass for the corresponding duration (Bendahmane et
209 al. 2008) with a maximum relative error of 7%.

210 The data acquisition is provided by a software which was written by the authors with LABVIEW
211 (Laboratory Virtual Instrument Engineering Workbench). This code also draws automatically the time
212 evolutions of hydraulic conductivity, hydraulic gradient, effluent mass, gradient of pressure and flow
213 rate during entire test phases.

214 Test Materials and Test Procedure

215 SOIL GRADATIONS AND POTENTIAL SUSCEPTIBILITY TO SUFFUSION

216 Two non plastic soils were selected with a slight variation of grain size distributions to investigate
217 suffusion susceptibility. A laser diffraction particle-size analyzer was used to measure the grain size
218 distribution of the tested soils (see Fig. 6) with demineralized water and without a deflocculation agent.
219 Both soils were created by mixing different materials. The gap-graded soil B is composed by the mixture
220 of sand S1 (25%) and gravel G3 (75%) marketed by Sablière Palvadeau (France). The widely-graded soil
221 R3 is created by the mixture of 28% sand S1 and 72% gravel from a French dike.

222 According to grain size based criterion proposed by Kenney and Lau (1985) both soils B and R3 are
223 indeed internally unstable (see Table 1). For the soil B, P (the percentage finer than 0.063 mm) is less
224 than 10% and the gap ratio $G_r = d_{max}/d_{min}$ (d_{max} and d_{min} : maximal and minimal particle sizes
225 characterizing the gap in the grading curve) is smaller than 3, thus Chang and Zhang's (2013) method
226 assessed the soil B as internally stable. For the soil R3, as the percentage of fine P is less than 5% and
227 $(H/F)_{min} < 1$ (F , mass percentage of grains lower than d ; H , mass percentage of grains between d and
228 $4d$) Chang and Zhang's (2013) method classified this soil as internally unstable. According to Wan and
229 Fell (2008), the method that they proposed seems not to be applicable for gap-graded soils and soils
230 with a mass of fine fraction lower than 15%. Further this method is only relevant for soil R3 which is

231 classified as internally stable. Finally, even if these two gradations slightly differ, no clear classification
232 can be drawn for soils B and R3 applying the three used criteria. Therefore, the erodibility
233 characterization needs suffusion tests.

234 **SPECIMEN PREPARATION**

235 Eight multilayer specimens were prepared by moist compaction to prevent soil segregation and per
236 layers of 5 cm in height (see Fig. 1) in order to limit the heterogeneity. Each layer was produced by using
237 a static compaction technique to limit the soil anisotropy, until the fixed density and a specimen height
238 of 350 mm were reached. All vertical and horizontal specimens were subjected to an axial stress of
239 200 kPa through the piston and the pore opening size of the downstream mesh is 1.2 mm in order to
240 allow the erosion of all fine particles.

241 The saturation step began with the injection of carbon dioxide (from the bottom) for a duration of ten
242 minutes to improve dissolution of gases into water and afterward, the specimen was saturated with
243 tap water in upward direction by gradually increasing the level of the upstream tank (see Fig. 1). For
244 preventing soil segregation in the specimen, to minimize the applied hydraulic gradient and to achieve
245 a high degree of saturation, the free surface rose with a constant velocity of about 2 cm/h until it
246 reached the top of the specimen. Approximately 24h were necessary for the water level to reach the
247 specimen top. With horizontal #1 flow, all of the steps were identical to steps for vertical flow but after
248 saturation, the specimen was turned from vertical to horizontal. The first beaker in the rotating
249 sampling system was used to collect the particles lost during the saturation step. At the end of each
250 test, the eroded fine particles caught by the linen bags were dried in an oven for 24 hours and their
251 mass determined. The values of the initial dry density were determined by considering: (1) the soil mass

252 placed in the cell, (2) the loss mass during saturation phase and (3) the specimen height after saturation.

253 The initial dry density of each specimen is shown in Table 2.

254 **SUFFUSION TEST PROCEDURE**

255 Specimens were subjected to a seepage flow under multistage hydraulic gradient, in downward
256 direction or horizontal direction. For the purpose of improving readability, the name of each test starts
257 by the soil letter. The second letter, V or H clarifies the vertical or horizontal flow direction. Table 2
258 details the characteristics of all performed tests.

259 During experiment, the upstream reservoir was fixed and the downstream reservoir was moved down
260 step by step to stop at several predefined positions to apply the multi-stage hydraulic gradient. Fig. 7a
261 and Fig. 7b show the multi-stage hydraulic gradient applied on specimens of soil, under vertical and
262 horizontal directions, respectively. It can be noted that quite the same history of hydraulic gradient was
263 applied under both flow directions. A beaker with linen bag in the rotating sampling system (see Fig. 5)
264 is selected for the duration of each stage of hydraulic gradient. Finally, the repeatability of our specimen
265 preparation and testing procedure was verified by performing two tests under identical conditions: B-
266 V and B-V rep.

267 **COMPUTATION OF HYDRAULIC CONDUCTIVITY AND EROSION RATE**

268 The computation of hydraulic conductivity is based on the Darcy' formula.

$$269 \quad k = \frac{Q}{i S} \quad (4)$$

270 where i is the hydraulic gradient and S is the cross-sectional area of flow.

271 The erosion rate is computed by:

$$272 \quad \dot{m} = \frac{m_{eroded} (\Delta t)}{S \Delta t} \quad (5)$$

273 where $m_{eroded}(\Delta t)$ is the mass of eroded particles during the duration Δt .

274 In the case of vertical flow or horizontal flow along specimen length, the cross-sectional area of flow
275 corresponds to the cross section of the specimen. Whereas in the case of horizontal flow along
276 specimen diameter, the cross-sectional area of flow is expressed by:

$$277 \quad S = \frac{S_{min} + S_{max}}{2} \quad (6)$$

278 where S_{min} is the flow section at the horizontal inlet and outlet with the 10 mm diameter of pipe and
279 S_{max} is the biggest rectangular flow area: $S_{max} = D h_{flow-max}$, where D is the specimen diameter and h_{flow-}
280 max is the height of flow. For identifying the surface area of horizontal flow, simulations with Plaxis
281 software were carried out. Suffusion of the soil is not described with Plaxis, consequently these
282 simulations assume that the soil is undisturbed by drag forces all along the seepage flow. For the
283 boundary conditions, the specimen is modelled as closed boundary around the specimen except the
284 holes in horizontal direction. A Plaxis analysis is needed for each type of soil, but for this study, it is
285 assumed that the values of hydraulic conductivity in vertical direction and in horizontal direction are
286 equal to the average of the measured values of the initial hydraulic conductivity for soil B (i.e., $3 \cdot 10^{-}$
287 $^3 \text{m} \cdot \text{s}^{-1}$). The soil is assumed to be saturated with a dry unit weight equal to the initial dry unit weight of
288 specimens of soil B (i.e., $17.36 \text{ kN} \cdot \text{m}^{-3}$). The difference of water head is set to 0.05 m and these
289 simulations permit to compute the height: $h_{flow-max} = 10.80 \text{ cm}$ (Le 2017).

290 **ESTIMATION OF THE SUFFUSION SUSCEPTIBILITY**

291 Le et al. (2018) performed a statistical analysis to identify the main parameters and to focus on those
292 that can easily be measured on existing structures. This study is built on suffusion tests all performed
293 under vertical downward flow. By distinguishing gap-graded and widely graded soils, the authors
294 proposed an estimation of the erosion resistance index based on the initial dry density, the grain shape

295 (with the measurement of the internal friction angle φ) and the water sensitivity (with the
296 measurement of the blue methylene value VBS). Of course, the grain size distribution is also considered
297 with the measurement of the gap ratio G_r , the percentage P , d_5 , d_{60} and d_{90} (diameters of the 5%, 60%,
298 90% mass passing, respectively). Table 3 details the values of each physical parameter used for this
299 estimation which leads to the value of I_α for specimens of soil B and for R3 specimens equal to 3.1 and
300 3.7, respectively. Thus the corresponding classification for both tested soils is moderately erodible. It is
301 worth noting that as the discrepancy of grain size distributions and specimen densities is slight, soil B
302 appears slightly less resistant than soil R3.

303 Test Results and Discussion

304 SPECIMENS COMPOSED BY ONE SOIL

305 Two tests were carried out on soil R3, one under vertical flow (test R3-V) and the second under
306 horizontal flow (test R3-H). Two specimens of soil B were performed under vertical flow (tests B-V and
307 B-V rep) and two others under horizontal flow: along specimen length for test B-H#1 and along
308 specimen diameter for B-H #2. The time evolution of hydraulic conductivity and erosion rate are shown
309 in Fig. 8a and Fig. 8b for tests of soil R3 and in Fig. 9a and Fig. 9b for B tests.

310 Fig. 8a shows that the hydraulic conductivity of soil R3 under horizontal flow is higher than under
311 vertical flow. Under both flow directions, the hydraulic conductivity is smaller than $1.5 \cdot 10^{-3} \text{ m}\cdot\text{s}^{-1}$ and
312 continuously decreases during the suffusion process. The erosion rate fluctuates during the testing
313 process but it is always smaller than $9 \cdot 10^{-4} \text{ kg}\cdot\text{s}^{-1}\cdot\text{m}^{-2}$ (see Fig. 8b). The conjunction of hydraulic
314 conductivity decreasing and small magnitude of erosion rate suggests that the predominant process
315 induced by the seepage flow is the filtration process.

316 Fig 9a and Fig 9b first show that repeatability of specimen preparation is fairly good, as the initial values
317 of hydraulic conductivity and erosion rate are very close for tests B-V and B-V rep. However, the time
318 evolutions of both parameters are rather scattered. It is worth noting that the imprecision regarding
319 the hydraulic conductivity computation is estimated at $\pm 0.8 \cdot 10^{-4} \text{ m.s}^{-1}$ for a flow along specimen height
320 and at $\pm 1.0 \cdot 10^{-4} \text{ m.s}^{-1}$ for a flow along specimen diameter. The accuracy of the erosion rate
321 measurement is estimated at $\pm 5 \cdot 10^{-6} \text{ kg.s}^{-1}.\text{m}^{-2}$. Thus those spread-out results cannot be attributed to
322 imprecision, but rather to the complexity of the suffusion process. For all tests on soil B, the initial
323 hydraulic conductivity is between $2.4 \cdot 10^{-3} \text{ m.s}^{-1}$ and $4.6 \cdot 10^{-3} \text{ m.s}^{-1}$ and the erosion rate corresponding
324 to the first hydraulic gradient stage is between $2.2 \cdot 10^{-5} \text{ kg.s}^{-1}.\text{m}^{-2}$ and $6.5 \cdot 10^{-5} \text{ kg.s}^{-1}.\text{m}^{-2}$. It is worth
325 stressing that under vertical flow, the hydraulic conductivity stays relatively constant during a stage of
326 hydraulic gradient. However, when the erosion rate exceeds $5 \cdot 10^{-4} \text{ kg.s}^{-1}.\text{m}^{-2}$, the hydraulic conductivity
327 starts to increase during a hydraulic gradient stage. Whereas, under horizontal flow, even with an
328 erosion rate smaller than $5 \cdot 10^{-4} \text{ kg.s}^{-1}.\text{m}^{-2}$, the hydraulic conductivity can be higher than $5 \cdot 10^{-3} \text{ m.s}^{-1}$. Only
329 test B-H#2 was performed under a parallel flow to the interface between soil layers, and for this test
330 the hydraulic conductivity appears slightly higher. This result is in agreement with results of Pachideh
331 and Mir Mohammad Hosseini (2019). At the end of all tests on soil B, the hydraulic conductivity is
332 around $6 \cdot 10^{-3} \text{ m.s}^{-1}$.

333 With the objective to explain the discrepancy of the evolution of hydraulic conductivity of B specimens
334 under vertical and horizontal flows, the post suffusion gradation was determined. The specimen B-V
335 was divided into three parts: top, middle and bottom layers. With the same goal, specimen B-H#1 was
336 frozen after suffusion test, in order to permit a longitudinal cut in top and bottom layers. These
337 designations: top, middle and bottom of layer position are related to the vertical position and are not

338 relative to the flow direction. Moreover for specimen B-H#1, each layer was subdivided in upstream
339 and downstream parts (see Fig. 10). Fig. 11 a shows that under vertical flow, the largest decrease of
340 fine fraction is measured in the top layer (which corresponds to the upstream part of the specimen B-
341 V), followed by the middle layer. The post-suffusion fine fraction in top, middle and bottom layers is
342 about 19.2%, 21.5%, and 22.2%, respectively. These results are in agreement with the results of Ke and
343 Takahashi (2012) and they suggest that the transport of detached particles from upstream to
344 downstream parts can partly offset the loss of particles in the middle and downstream parts.

345 Under horizontal flow, Fig. 11b shows that for both layers, it is not possible to distinguish the gradation
346 of upstream and downstream parts. However, the percentage of fine particles is 17.4% in top layer and
347 it exceeds the initial percentage of fine in bottom layer, with around 27.4%. This result suggests that in
348 comparison with the loss of fine particles under vertical flow, the loss under horizontal flow is larger in
349 top layer, but the process of filtration is enhanced in bottom layer. Thus when the direction of flow is
350 perpendicular to gravity, the specimen becomes more heterogeneous and a preferential flow can
351 appear in the top layer. This explains why under this flow direction, the hydraulic conductivity is higher
352 and quite constant during the suffusion process.

353 Post-suffusion gradation of specimens R3-V and R3-H, are plotted in Fig. 12a and 12b respectively. The
354 results show a small loss of fine particles under horizontal flow but quite no variation of grain size
355 distribution under vertical flow. This result confirms that soil R3 is more resistant when undergoing
356 suffusion process. Thus the absence of gap in the gradation improves the auto-filtration.

357 Thanks to the measurement of the time variations of hydraulic gradient, flow rate and erosion rate, it
358 is possible to characterize the suffusion initiation by the mean of a critical value of: the hydraulic
359 gradient, the flow velocity or the hydraulic shear stress. However, the suffusion initiation is influenced

360 by the hydraulic loading path (Rochim et al. 2017). Moreover Zhong et al. (2018) showed that the critical
361 hydraulic gradient decreases with the flow length. Thereby the authors interpret the test results by the
362 energy based method and the cumulative loss of dry mass versus the cumulative expended energy of
363 soil B is shown in Fig. 13. As the applied hydraulic gradient was quite identical for all performed tests,
364 Figure 13 shows for all tests on soil B , the same trend of suffusion development. For a final cumulative
365 expended energy comprised between 500 and 1000 J, the cumulative loss dry mass is between 0.05
366 and 0.2 kg. At the steady state, which corresponds to the final data point for all tests, the erosion
367 resistance index (I_{α}) is computed by equation (3). Under vertical flow the value of I_{α} for test B-V and B-
368 V rep is 3.8 and 3.7, respectively. The corresponding suffusion classification is moderately erodible.
369 Under horizontal flow, the classification is moderately resistant corresponding to the erosion resistance
370 index equal to 4.0 for test B-H#2 and 4.1 for test B-H#1. It is worth noting that these values are close,
371 highlighting the ability to characterize with accuracy, the suffusion susceptibility under horizontal flow
372 in both conditions, i.e., #1 and #2. The comparison of the results of these four tests shows that the soil
373 B appears slightly more resistant under horizontal flow. Similarly, Fig. 14 shows the cumulative loss dry
374 mass versus expended energy of soil R3. As this soil is slightly less permeable than soil B, under quite
375 identical multi-stage hydraulic gradient, the final cumulative expended energy is slightly smaller and
376 comprised between 300 and 800 J. However, the cumulative loss dry mass is also slightly smaller and
377 between 0.01 and 0.03 kg. At steady state, the erosion resistant index is equal to 4.3 and 4.4 under
378 vertical and horizontal flows, respectively. These results confirm that in comparison with soil B, the soil
379 R3 is more resistant (i.e., classified as moderately resistant) and both tested soils appear less resistant
380 to suffusion process under vertical flow.

381 It should be noted that in literature, most of the tests were performed under vertical flow and this study
382 shows that in this case, the value of the erosion resistance index could be slightly underestimated.
383 Consequently, the authors consider that a modification of the suffusion chart proposed by Marot et al.
384 (2016) appears not necessary, because it only induces a slight conservatism for horizontal flow.

385 **SPECIMENS COMPOSED BY TWO SOILS**

386 A real earth structure is generally built by the compaction of several soil layers which are globally
387 horizontal, whereas the core sample is generally realized in vertical. In consequence a sample obtained
388 by core sampling in site may be composed by several layers of soils, which slightly differ by their
389 gradations with a horizontal interface. As already mentioned, the most often used method for suffusion
390 tests consists to apply a vertical flow (i.e., perpendicular with the interface). In this context, a specimen
391 B/R3-V was prepared by moist compaction of 4 layers of soil B topped with 3 layers of soil R3. Then, it
392 was subjected to a vertical flow and the evolution of the cumulative loss mass depending on the
393 cumulative expended energy is slightly the same as for specimen R3-V (see Fig. 14). At the steady state,
394 the value of I_{α} is equal to 4.6 and consequently, the suffusion classification is moderately resistant, as
395 soil R3.

396 By contrast, in site the flow is generally horizontal and parallel with the interface of soil layers. The
397 specimen B/R3-H (prepared under identical condition as specimen B/R3-V) was subjected to a
398 horizontal flow in condition #2, which means a flow parallel with the interface between the two soils.
399 Fig. 14 shows that the cumulative loss mass versus the cumulative expended energy is very close to the
400 result of test B-H#2 and with the same I_{α} value of soil B (i.e., 4.0).

401 Conclusions

402 A new device and associated data acquisition code were developed in order to give the opportunity to
403 perform suffusion tests on undisturbed specimen and to allow applying a vertical or a horizontal flow.

404 Two cohesionless soils which slightly differ by their grain size distributions were selected. Eight
405 specimens were prepared by moist and static compaction to limit the soil anisotropy. The energy based
406 method is used to compute the erosion resistance index at the steady state (i.e., when the hydraulic
407 conductivity tends to stabilize and the erosion rate tends to decrease). By this way, the suffusion
408 susceptibility is classified.

409 First, a series of suffusion tests was carried out under vertical or horizontal flow on specimens
410 composed by one soil. The test results show that the repeatability of specimen preparation is fairly
411 good. Under horizontal flow, both tested soils appear more permeable, and they are also slightly more
412 resistant to suffusion process. The comparison of post-suffusion gradations with the initial ones permits
413 to note that under horizontal flow, the specimens become more heterogeneous with a higher loss of
414 fine particles in the top layer. A preferential flow can then appear in this layer which limits the suffusion
415 development and explains the higher hydraulic conductivity. Thus, these results demonstrate the
416 significant influence of the seepage flow direction on the suffusion susceptibility.

417 Two specimens were composed of a layer of each tested soils. When the injected flow is perpendicular
418 to the interface between soil layers, the suffusion susceptibility is mainly influenced by the more
419 resistant soil. By contrast, the suffusion susceptibility is mostly influenced by the less resistant soil in
420 the case of a parallel flow to the interface.

421 Therefore in the comparison with the mostly used configuration of suffusion test (i.e., flow
422 perpendicular to the interface between soil layers), the new device permits to avoid a slight
423 overestimation of the soil strength face to suffusion susceptibility.

424 This new device and the energy based method permit to assess the suffusion soil susceptibility, which
425 is a material property. Thanks to this energy based method and tests performed with this device under
426 various hydraulic loading paths, a relation will be proposed between the hydraulic loading and the
427 corresponding soil response in time.

428 **ACKNOWLEDGMENTS**

429 The authors thank the company IMSRN, the Ministry of Education and Training of Vietnam, the
430 University of Danang, Vietnam, for providing financial support for this work.
