11 **Abstract**

12 *The South China Sea (SCS) is a marginal basin characterized by propagating breakup and*
13 *subsequent seafloor spreading during the Cenozoic. Our study investigates the crustal*
14 *architecture and tectonic evolution of the Xisha Islands - Northwest Borneo conjugate margins*
15 *using a 1000 km long seismic profile and two shorter seismic lines. This system is characterized*
16 *by wide margins showing a succession of rift basins with thinned continental crust, associated*
17 *with large extensional detachment faults soling on top of the lower crust. In relation with crustal*
18 *extension, several syn-rift sequences have been identified. The lower syn-rift unit (syn-rift I)*
19 *shows well expressed wedge-shape growth strata. The upper one (syn-rift II) presents a more*
20 *uniform thickness, and is slightly offset by normal faults dipping toward the depocenters. To*
21 *illustrate the evolution of the southwestern SCS margins during continental breakup, we restore*
22 *two conjugate sections near the oceanic magnetic anomaly C5En (18.8 Ma). The conjugate*
23 *COT presents an asymmetrical hyper-extension architecture in cross sections, with the*
24 *southern margin being the lower plate margin. In map view, the spatial variation of crustal*
25 *structures illustrates a bayonet shape characterized by an initial N-S extension coeval with the*
26 *first phase of seafloor spreading in the east sub-basin in the SCS. The extension direction*

27 *changed shortly later (circa 23Ma) to NW-SE opening in the southwest sub-basin in relation to*
28 *a ridge jump. We suggest that variable extension direction is linked to changes in the*
29 *compressional tectonic regime along Borneo and Palawan.*

32

33

34

35 **1 Introduction**

36 Continental extension and lithospheric breakup are transient processes controlling crustal
37 thinning, sedimentary architectures and magmatic budget at passive rifted margins. The
38 increase in quality of deep seismic profiles across examples of rifted margins provided critical
39 new constrains on rift basin architecture, crustal structure and magmatic additions (e.g., [Reston,](#)
40 [2009; Sutra et al., 2013; Tugend et al., 2018](#)). These new datasets highlighted the important
41 structural variability between distinct conjugate margins (e.g., [Ranero and Pérez-Gussinyé,](#)
42 [2010, Brune et al. 2017; Sapin et al. 2021](#)) but even across ([Franke 2013, Nirrengarten et al.,](#)
43 [2020](#)) or along strike ([Mohn et al. 2015, Ding et al., 2020; Péron-Pinvidic et al., 2017; Lei et](#)
44 [al., 2020](#)) of a continental margin. This variability is better expressed in small basins with
45 limited oceanic crust such as in Southeast Asia. Imaging, describing and interpreting in detail
46 the variations of the tectono-sedimentary evolution of a rifted margin covered by a large amount
47 of data, including a new seismic line crossing both conjugate margins, provides crucial
48 opportunities to unravel the tectonic processes and parameters involved in the opening of an
49 ocean (e.g., [Abdelmalak et al., 2019; Gernigon et al., 2019; Gillard et al., 2015](#)).

50

51 Numerous marginal basins have opened around the Pacific Ocean, for which subduction has
52 influenced the mode of extension and breakup ([Taylor and Hayes, 1983](#)). Compared to rift
53 systems in stable continents, rifting close to a subduction zone presents specific characteristics
54 in terms of crustal composition ([Persaud et al., 2003; Savva et al., 2014](#)), initial lithospheric
55 thermal structure ([Di Luccio et al., 2014; Li et al., 2019](#)) and instability in the orientation of
56 kinematic forces through time (e.g., Western Mediterranean Sea; [Van Hinsbergen et al., 2014](#)).
57 Our investigation area, the South China Sea (SCS), is the largest marginal basin of SE Asia and
58 is characterized by a remarkable oceanic V-shaped propagation form Early Oligocene to mid
59 Miocene ([Briais et al., 1993](#)). Its tectonic evolution has been extensively studied with a large

60 variety of geological and geophysical data (Nissen et al., 1995; Cameselle et al., 2015; Larsen
61 et al., 2018; Lei et al., 2018; Li et al., 2015; Liang et al., 2019; Luo et al., 2021) which provide
62 an exceptional dataset for analyzing rifting processes in 3D. However, most of the studies are
63 focused on the SE China margin and a better integration of the tectono-sedimentary evolution
64 along the Xisha Islands-NW Borneo conjugate margins is needed to analyze the spatial and
65 temporal variations of deformation style along and across the SCS.

66

67 This paper proposes to investigate the rift evolution of the SW sub-basin of SCS by combining
68 several seismic sections to illustrate both along strike and along dip architectural variations
69 (Fig.1). Our analysis of the extensional structures is focused near a 1000 km long seismic profile
70 (line CFT, Fig.1) crossing the Xisha Islands -NW Borneo conjugated continental margins. To
71 highlight the lateral variations of rifted structures along the margins, we include the
72 interpretation of seismic lines next to the CFT line, which are also crossing the continent-ocean
73 transition (COT) of the conjugate margins (Fig.1). Our analysis is then compared to another
74 segment of the SCS (E sub-basin) (Nirrengarten et al., 2020) which presents tectonic processes
75 resulting in a similar crustal architecture but from an earlier breakup before the propagation of
76 the oceanic system to the southwest. Integrated into the tectono-stratigraphic framework of the
77 SCS margins, this study provides solid arguments to discuss the mode of continental breakup
78 and the extensional process (symmetric or asymmetric architectures, Nirrengarten et al., 2016;
79 Ros et al., 2017 in terms of the rifting mode; depth-dependent extension, Clift et al., 2002; Davis
80 and Kuszniir, 2004). The inferred regional stratigraphic correlations provide implications on the
81 influence of the subduction zone on kinematic reorganizations.

82

83 **2 Geological Background**

84 Extension in the southeast of the South China Block initiated in Late Cretaceous in the tectonic
85 setting of convergence between the Pacific Plate and Eastern Eurasia (Jahn et al., 1976; Sewell
86 and Campbell, 1997; Chan et al., 2010, Nanni et al., 2017, Ye et al., 2018; Zhang et al., 2019).
87 This end of this convergence phase correlates with significant granitic intrusion events south of
88 China. The resulting granitoids have been sampled onshore and offshore by drilling and dredges
89 such as in the Spratly Islands and the Reed Bank area (Kudrass et al., 1986; Yan et al., 2010;
90 Khanchuk et al., 2019; Xiao et al., 2019). The compressional Mesozoic structures such as broad
91 folds flanks or thrust faults were later reactivated by localized normal faults along the granitoids
92 blocks (Savva et al., 2014; Ye et al., 2018). The first cycle of extension took place from the
93 Late Cretaceous to Paleocene with the development of narrow basins filled by coarse-clastic
94 sediments, which evolved into a distributed rifting event in the proximal margins (Teng and
95 Lin, 2004; Yan et al., 2001; Xie et al., 2006; Yao et al., 2012; Steuer et al., 2014). This first
96 extensional event reflects the initial stretching of the continental lithosphere and is observable
97 onshore (Chan et al., 2010; Nanni et al., 2017; Schlutter et al., 1996). The second extensional
98 event (Eocene-Oligocene) corresponds to the main thinning event (Ru and Pigott, 1986; Su et
99 al., 1989; Clift and Lin, 2001; Yan et al., 2001; Ding et al., 2013, Franke et al., 2014; Larsen et
100 al., 2018; Nirrengarten et al., 2020; Cameselle et al., 2020) leading to the propagation of
101 continental breakup from the Early Oligocene to Middle Miocene (Briais et al., 1993; Li et al.,
102 2014a). Most of the rifted basins in the northern (Savva et al., 2013; McIntosh et al., 2014; Gao
103 et al., 2015; Lei and Ren, 2016; Ding et al., 2020) and southern margin of the SCS (Franke et
104 al., 2011; 2014; Ding et al., 2013; Clerc et al., 2018; Peng et al., 2018; Liang et al., 2019) have
105 been shaped during this phase.

106

107 Many Cenozoic unconformities have been identified in the conjugate margins of the SCS
108 (Morley, 2016; Lunt, 2019), exhibiting a diachronous opening from east to southwest (Franke

109 et al., 2014; Chang, 2020; Luo et al., 2021; Pubellier et al., 2021). The identification of those
110 unconformities leads to the definition of a breakup sequence for the SCS margin (Zhao et al.,
111 2016; Alves et al., 2020) which is the sedimentary record during the phase of the diachronic
112 lithospheric breakup (Early Oligocene to Early Miocene). In the SE China margin, the
113 unconformities are associated with a series of normal faults and low-angle detachment faults
114 that accommodated the stretching of the crust (Lei et al., 2019; Xie et al., 2019; Luo et al., 2021).
115 The detachment faults rooted either at the top of ductile layers (lower crust) or at the Moho
116 (Gong et al., 2019; Xie et al., 2019; Deng et al., 2020; Luo et al., 2021). Recently IODP
117 Expedition 367/368 have discovered altered or fresh basalts and pre-rift sedimentary rocks in a
118 narrow distance, representing the oceanic and continental basement lithologies, respectively.
119 These drilling observations significantly constrain the breakup mechanism and the architecture
120 of conjugate margins along the Eastern oceanic sub-basin, disclosing a rapid transition from
121 continental rifting to oceanic spreading within a 10 Myr interval (Larsen et al., 2018;
122 Nirrengarten et al., 2020). The narrow COT in the SCS was independently recognized in the
123 geophysical dataset via various criteria, such as Moho reflection gap, basement morphology
124 and gravity anomaly characteristics (Song et al., 2019, Fig.1b). Some authors proposed an
125 asymmetrical breakup phase in the early times followed by a more symmetrical and stable
126 spreading after 28 Ma (Nirrengarten et al., 2020; Lei et al., 2019).

127

128 The conjugate margin in the southwestern SCS is less known because of the thick Eocene to
129 Late Miocene carbonate cover on the NW Borneo margin (Madon et al., 2013; Franke et al.,
130 2011; Steuer et al. 2014; Chang et al., 2015; Jamaludin et al., 2017) and on the Xisha Islands
131 Margin (Fyhn et al., 2013; Vu et al., 2017). These wide rifted margins (> 400 km) are
132 characterized by a relatively flat and shallow Moho (depth 20 km) imaged by refraction data
133 which suggest a weak lower crust in the Xisha Islands Margin (Hayes and Nissen, 2005, Pichot

134 et al., 2014; Lü et al., 2016; Dong et al., 2018; Huang et al., 2019; Cameselle et al., 2020).
135 There, extensional features, including large detachment faults, accommodated significant
136 thinning of the crust. Some of these structures may result from the reactivation of inherited low-
137 angle thrusts (Savva et al., 2013, Liang et al., 2019). The tectono-magmatic interpretation also
138 reveals a proto-oceanic crust, which corresponds to the incipient onset of seafloor spreading in
139 the southwestern SCS (Luo et al., 2021).

140

141 Based on bathymetry and magnetic anomalies (Fig. 1), a change in the spreading direction
142 linked with a ridge jump around 23 Ma has been suggested (Briais et al., 1993; Lee and Lawver,
143 1995; Barckhausen et al., 2014; Li et al., 2014b; Qiu et al., 2016). Sibuet et al. (2016) and Lei
144 and Ren (2016) have proposed an intermediate spreading event between the two stages around
145 23Ma. Numerical modelling shows that tectonic loading in the propagation direction may
146 explain a stalling phase of the E-W propagation from 32 to 23 Ma. A change in boundary forces
147 at the regional scale is then likely ending this stalling phase, eventually followed by NE-SW
148 propagation across the whole region from 23 to 16 Ma (Le Pourhiet et al., 2018; Jourdon et al.,
149 2020). However, the exact cause of the change in boundary forces leading to ridge re-orientation
150 is yet unclear.

151

152 **3 Data Acquisition, Processing and Methods**

153 **3.1 Data Acquisition and Processing**

154 We use the China-France Transect MCS profile (CFT) in the vicinity of Penxi Bank and Spratly
155 Islands (Nansha Islands) (Figs.2 and 4). This 1000 km long multichannel seismic (MCS) data
156 was collected by a project conducted by CNRS and Ecole normale supérieure (ENS, France)
157 and Guangzhou Marine Geological Survey (GMGS, PRC), from 2011 to 2013. The vessels,
158 R/V DongFang KanTan and R/V Tan Bao, triggered shots at a 50 meters interval for reflection

159 profiles after collecting a refraction profile along the transect. The volume of the airgun array
160 was roughly 7,000 cubic inches, and the streamer was 8 kilometers (640 channels) long in the
161 Qiongdongnan area and 6 km (480 channels) along the rest of the profile. Both streamers have
162 a 12.5 meters receiver interval. The record length is 16 sec TWT (seconds two-way travel time)
163 with a 2 ms sampling rate.

164

165 This study integrates the results of the whole CFT profile across the conjugate margin of the
166 southwest margin of the South China Sea. The processing was completed at ENS and was
167 designed to enhance the deep crustal structure by several procedures of multiple attenuation.
168 The workflow included geometry, filter, noise attenuation, trace editing, amplitude scaling, bin
169 centering, offset regularization, predictive deconvolution, multiple attenuation (SRME, Radon,
170 and F-K filter), and high-density velocity analysis, all using the CGG Geovation 2013 software.
171 The migration was achieved by pre-stack Kirchhoff time migration, and a dynamic gain (AGC)
172 was applied to the final output image. The high-resolution images are presented in Figure S1
173 and S2 in the supplementary material.

174

175 The efficiency of the anti-multiple procedure varies along the line because of the changes in
176 impedance contrasts of the seafloor and basement. In many areas where the sedimentary
177 package is thin, waves reflected from the basement scatter a lot of energy that is difficult to
178 attenuate (from km 450 to 550 on the CFT-N, and km 150 to 270 on the CFT-S). In addition,
179 two other pieces of seismic profiles, INL320 and NGH-1-3, were acquired and processed by
180 Guangzhou Marine Geological Survey in PRC with a workflow similar to the one already
181 described. The acquisition parameters are shown in the [Table.1](#).

182

183 **3.2 Interpretation Criteria**

184 For the interpretation, the seismic reflections allow us to distinguish the crust and the
185 sedimentary basins by interpretation of the Moho, basement and sedimentary sequences.
186 Around 9 sec TWT, strong-amplitude reflectors appear intermittently as the Moho surface along
187 the proximal domain. The Moho reflectivity is clearly visible along the north of the CFT line
188 where sedimentary basins are thick, but it is not so obvious in some other sections of the profile.
189 In areas of weak or absent Moho reflectivity, we use results from the refraction velocity models
190 in Pichot et al. (2014) and Liang et al. (2019) to indicate the Moho on our interpretations. These
191 refraction studies use wide angle reflections on the Moho along the coincident refraction line
192 to constrain the Moho depth (with 50 ocean bottom seismometers). More details on how to
193 differentiate the crustal reflectors and the residual multiples along the same seismic line can be
194 found in [Liang et al. \(2019\)](#).

195

196 The stratigraphic patterns can be consistently observed along the 1000 km-long seismic line
197 and two shorter lines. The typical syn-rift pattern characterizes the growth strata thickening
198 toward the major normal faults during the rifting stage. In this study, the syn-rift unit has been
199 delimited into two sub-units by an intra-rift unconformity (Fig.2-5). The lower sub-unit, syn-
200 rift I, characterizes strong amplitude reflectors and a wedge-shaped geometry in the proximal
201 margin (orange color on [Fig. 2](#)). The upper sub-unit, syn-rift II, overlying the unconformity
202 shows a relatively uniform thickness across the rift basins which only slightly thickens toward
203 depocenters. The intra-rift unconformity (green horizon, IRU) is delimiting two syn-rift
204 packages (I and II) which present an onset of developing the extensional detachment faults ([Fig.](#)
205 [2-3](#)). Similar intra-rift unconformities have been recognized in the Pearl River Mouth Basin
206 ([Xie et al., 2019](#)). On the top of the syn-rift II, the breakup unconformity (BU) correlate from
207 the other studies ([Yao et al., 2012](#); [Savva et al., 2013](#); [Steuer et al., 2014](#); [Lei and Ren, 2016](#);
208 [Vu et al., 2017](#)), characterizing the termination of developing growth strata ([Figs. 2 and 3](#)). The

209 later post-rift unit shows a horizontal to sub-horizontal depositional pattern indicating the rifting
210 has been terminated.

211

212 Due to absent of public well data along the seismic profiles in this study, the age for each unit
213 is correlated from the adjacent basins. In the north, Xisha Islands margin based on correlation
214 with seismic profiles tied with wells in adjacent Phu Khanh and Qiongdongnan basins (Vu et
215 al., 2017; Savva et al., 2013; Lei and Ren, 2016), which is identified an unconformity around
216 32 Ma (T70) and the BU at 23 Ma (T60). In the south, it shares a similar rifting history with the
217 northern margin during the Paleogene (Holloway, 1982; Liang et al., 2019; Bai et al., 2020;
218 Zhang et al., 2020b). The age constraint is established on the base of the well Sampaguita-1
219 continuously documenting Cenozoic strata and encountering the Mesozoic strata (location S-1
220 on Figs.1a and 6; Taylor and Hayes, 1980; Yao et al., 2012; Steuer et al., 2014). The result
221 shows two unconformities have been dated in Upper Eocene and Upper Oligocene in the
222 Paleogene strata.

223

224 **4 Interpretation Results along the CFT Line crossing the Conjugate Margins**

225 To decipher the crustal architecture and extensional processes of the conjugate margins of the
226 SW sub-basin, the long CFT transect is hereafter divided into two parts: the northern section
227 (CFT-N) and the southern section (CFT-S).

228

229 **4.1 Xisha Islands Margin of the SW sub-basin**

230 The CFT-N profile extends over a 600-kilometer length of thinned crust (from the shelf break
231 to the COT) along the Xisha Islands margin. The crustal thickness varies from 2 to 8 sec TWT
232 (Fig. 2), approximately 6.5 to 25 km thick, showing similarities with the thinned and hyper-
233 thinned domains described in others parts of the SCS (Savva et al., 2013; Lei and Ren, 2016;

234 Cameselle et al., 2020; Nirrengarten et al., 2020). The Moho shallows gently seaward within a
235 few hundreds of kilometers with local fluctuations lower than 1 sec TWT (Fig.2). On the top of
236 the basement, normal faults dip both seaward or landward and bound the edges of the basins
237 with various offsets from 1 to 3 sec TWT at the top of the basement (Fig.3). Large number of
238 normal faults affect the basement with limited throw within 1 sec TWT (grey arrows in distance
239 70 and 250 km on Figs. 3). These structures are mostly associated with the lower syn-rift unit,
240 suggesting an activity during the early stage of rifting, namely syn-rift I in this study. For the
241 larger offset of basement which can reach to 3 sec TWT, the fault bounding the main blocks
242 can be followed roughly until 7-8 sec TWT depth (black arrows in Fig.3), where some
243 horizontal reflectors may be traced to underline a detachment or décollement level (reflector D
244 at distance 70, 220, and 330 km on Fig. 3). The detachment faults rotated the continental block
245 above the lower crust and created accommodation space through most of the syn-rift period
246 (distance 220 km on Fig.3b). However, these detachment reflectors are not obvious in the distal
247 margin because of the strong artifact noise of basement multiple in the CFT-N profile (400 to
248 560 km on Fig.2).

249

250 Within the sedimentary unit, strong amplitude reflectors are traced at the bottom of the
251 Qiongdongnan and Zhongjiannan Basins within 2 sec TWT thickness, approximately 4 km
252 thick (distance 200 to 220 km on Fig.3). The same seismic characteristics are vanishing seaward
253 and are barely observed in the distal part. The syn-rift II is characterized by a slight thickening
254 of the unit toward low angle detachment faults (black arrows on Fig.3), associated with their
255 development. Within syn-rift II, several newly developed faults dipping toward the depocenter
256 offset mainly syn-rift II (Fig.3a and 3b), and terminate at a similar depth as the detachment
257 faults. After the breakup unconformity, the post-rift unit characterizes generally horizontal to
258 sub-horizontal sedimentation under the thermal subsidence. A significant unconformity within

259 post-rift succession marks the end of extension in the SCS around the Middle Miocene (blue
260 on Fig.3), and has been identified in the southwestern SCS margins (Hutchison, 2004;
261 Hutchison, 2005; Clift et al., 2008; Savva et al., 2013; Vu et al., 2017; Li et al., 2014b). Fluid
262 or gas migration and volcanic bodies can be sporadically found in the post-rift succession
263 shallower than 2 sec TWT (Fig.3). Large amount of delta sediments sourced from the Vietnam
264 coast cover the proximal margin (Fig.3a).

265

266 **4.2 Northwest Borneo Margin of the SW Sub-basin**

267 The NW Borneo margin rift basins associated with rift basins extends over 600 kilometers
268 southward to Sabah as seen on the seismic and gravity data (Cullen et al., 2010; Bai et al., 2020).
269 The 330 km long seismic profile CFT-S across the NW Borneo Margin illustrates a part of the
270 configuration of the southern margin (Fig. 4). Nevertheless, the crustal structures provide
271 similarities with the northern margin in terms of crustal thickness as well as style of faults. The
272 limited throw faults offset the top of the basement 1 sec TWT (Fig.5c). Detachment faults have
273 been identified underlying a deep basin (reflector D at distance 90 and 30 km on Fig.5b and 5c)
274 as documented in Liang et al. (2019). Several closely-spaced normal faults appear between
275 these detachments (arrows on Fig. 5c).

276

277 The lower sedimentary package (syn-rift I) in the proximal domain (distance 0 to 50 km on Fig.
278 5c) resembles in age with those of the Xisha Islands margin and vanishes seaward (orange color
279 on Fig. 4). Compared to the syn-rift I, the thick sedimentation of syn-rift II reveals major
280 subsidence prior to the breakup at distance 70 km (Figs. 5b and 5c). The syn-rift II unit thickens
281 toward low-angle detachment faults and is also offset by several newly developed faults (arrows
282 on Fig.5c). A post-rift erosional surface (blue horizon) overlies the lower post-rift sediments
283 and part of the syn-rift succession (distance 30 km on Fig.5c) with significant P-wave velocity

284 contrast (approximately from 1.6 km/s to 3.8 km/s or 2.9 km/s to 5.3 km/s estimated by Wang
285 et al., 2016). Many post-rift volcanic rocks are observed along the profile (Figs. 4 and 5a) and
286 the adjacent area in the NW Borneo Margin (Chang et al., 2017; Zhang et al., 2020b).

287

288 **5 Interpretation results along two profiles crossing the Continent-Ocean Transition**

289 Around the previously described CFT line, the rifted margin displays lateral structural
290 variations along the COT of the Southwest SCS. An abrupt bathymetric contrast marks an N-S
291 lineament at the eastern edge of the Penxi Bank and the western edge of the Spratly Islands
292 crustal morpho-structures (Fig.6a). In contrast, a gradual slope characterizes an E-W morpho-
293 structure at the south of the Penxi Bank (Fig.6a). Two extracted profiles illustrate the crustal
294 architecture of the N-S segment (Fig.7a and 7b) and the E-W segment (Fig.9a and 9b). We
295 completed the observation by interpreting two other pieces of seismic profiles, namely INL320
296 and NGH-1-3 (Fig.9a and 9b).

297

298 We have reconstructed the conjugated margin on a cross-section (Fig.7 and 9) at C5En (18.8
299 Ma, Briaies et al., 1993, which is the similar age in Li et al., 2014a) (Fig.6b) by removing the
300 oceanic crust. This study extrapolates the magnetic anomalies along the bathymetric features
301 and suggests ages for the formation of the oceanic crust in areas where the magnetic anomalies
302 are blurred southwestward (Fig.6b). Interestingly, the magnetic modelling along profiles
303 defined the earliest anomaly at C6n (20.1 Ma) on southern side and at C5En (18.8 Ma) on the
304 northern side (Fig.6b).

305

306 **5.1 N-S Trending Segments of the Margin**

307 The thickness of the crust, tracked by intermittent Moho reflectors, thins oceanward from a
308 depth of 10 sec to 8 sec TWT (Fig.7). This reflector runs beneath the continental basement

309 around 10 sec TWT in the NW Borneo margin, and ascends seaward adjacent to the oceanic
310 crust near the magnetic anomaly C6n (Fig.8b). The extension at the edge of the basin (black
311 arrows on Fig.7a) may reach a possible level of detachment fringing the lower crust, although
312 the base reflector is not as clear as the detachment level seen in the landward basins. Next to
313 the magnetic anomalies, the basement slope at the COT area steepens along the E Vietnam
314 margin than at the conjugate NW Borneo margin, displaying an asymmetric structure (Fig.7).

315

316 The overlying syn-rift II sediments are restricted to small depressions, which displays a
317 relatively thin sedimentary infill. Stratigraphy may record a hiatus (breakup unconformity)
318 indicated by significant erosional surfaces from basin to basement on both margins (red horizon
319 on Fig.8a). It indicates that the crust did not undergo significant subsidence during the rifting
320 and was sustained at shallow water depth before breakup (Liang et al., 2019). Some chaotic
321 facies at the bottom sedimentary succession probably resulted from mass transport deposits
322 along the abrupt slope adjacent to the COT (Fig. 8b).

323

324 **5.2 E-W Trending Segments of the Margins**

325 By contrast, the E-W trending segments display a thinner crust with a large amount of sediments
326 near the COT (Fig.9). The asymmetrical architecture of the crust is shown by the thinner crust
327 and lower basement slope in the south. The basement is offset by northward-dipping faults in
328 the NW Borneo Margin whereas the top of the basement is rather smooth in the E Vietnam
329 Margin (Fig.10b and Fig.10c). Part of the basement with magmatic addition is barely covered
330 by syn-rift succession and no significant Moho reflector is observed, adjacent to the location of
331 the first magnetic anomaly in the NW Borneo Margin (Figs.9b and 10c). Such a configuration
332 may perhaps indicate an exhumation of sub-continental lithospheric mantle (Ding et al., 2016)
333 or part of the lower continental crust. The syn-breakup volcanic additions are also revealed, for

334 instance, intruded magmatic bodies in the NW Borneo Margin and a high-amplitude reflector
335 beneath the Moho in the E Vietnam Margin (Figs. 10b and 11c).

336

337 The horizon at the top of the syn-rift II correlates to the top of the basement in the oceanic
338 domain and, therefore, is interpreted as a period occurring the continental breakup (Figs. 9-10).

339 The correlation of the top of the syn-rift II may be extended landward (red horizon on Figs. 9a

340 and 10a). The underlain syn-rift II is characterized by a relatively uniform thickness (slightly

341 thicker toward the oceanic crust), and a total width of both margins reaches 75 km in length

342 (Figs. 10b and 10c). A series of dense normal faults mildly offset most of the syn-rift succession

343 and dip seaward in both conjugated margins (Fig.10), which is consistent with the observation

344 of syn-rift II in the proximal margins. This syn-rift II has concave-up disturbance and truncation

345 atop localized at the seaward boundary of the COT. The post-breakup unit overlapped the

346 unconformity, also interpreted as breakup sequence in the SCS (Lei et al., 2019; Alves et al.,

347 2020; Zhang et al., 2020b). The oceanic domain and the COT are overlain unconformably by

348 post-rift strata.

349

350 **5.3 Lateral Variation of the COT Structures**

351 In the Southwest SCS, the crustal architecture appears to differ depending on the orientation of

352 the COT. We have observed a significant variation of sediment thickness and a sharp difference

353 between the N-S and the E-W margin segments (crossed by obliquely oriented seismic profiles,

354 Figs.11b and 11c). At the COT, the E-W segment illustrates more hyper-extended crust and

355 more sediment infill (Fig. 11c). Instead, segments connected by N-S abrupt relays exhibit a

356 sharp COT with thin overlying sediments (Fig. 11d).

357

358 **6. Discussion**

359 **6.1 Margin Configuration prior to the Continental Breakup**

360 The observation of the two sections in the southwest of the SCS allows us to compare the
361 extensional and magmatic processes at the termination of the continental crust (COT) with the
362 margins of the eastern SCS (Fig. 11a). Being juxtaposed, the margins show a similar hyper-
363 extensional aspect in the profiles crossing the E-W margin segment (Fig.11c). The conjugate
364 profile selected for the East sub-basin (Nirrengarten et al., 2020, Fig 11a) and the Southwest
365 sub-basin (this study Fig. 11c) of the SCS show an asymmetrical architecture presenting a
366 respectively southward- and northward-dipping detachment fault. In fact, the orientation and
367 separation of the faults in the distal domain on the two conjugate margins allow us to retrieve
368 the tectonic evolution of an extensional wedge to determine the direction of the basal shear
369 (Xiao et al., 1991). Indeed, following the morphological criterion examine by Nirrengarten et
370 al. (2016), the SE China and the NW Borneo are defined as lower plate margins architecture.
371 Moreover, in terms of magnetic anomaly, it appears that both systems display their oldest
372 marine magnetic anomaly on the lower plate side, whereas it is absent from the conjugate side
373 (C11n and C6n on Fig. 11). This has been suggested to be related to an initial asymmetrical
374 spreading of the SCS ridge (Nirrengarten et al., 2020). In the distal margin morphology and on
375 the oldest oceanic crust the structures and magnetic properties of the conjugate margins of the
376 SW and E sub-basin are similar and seem to involve similar tectonic and magmatic processes
377 during the break-up.

378

379 We have restored the position of the Spratly Islands (Nansha Islands) and Penxi Bank around
380 breakup time using the magnetic anomaly from Briais et al, (1993) (Fig.12). The obtained map
381 presents basins with rhomboid shape, which is composed of a chain of “en echelon” basins
382 stretching in an N-S direction near the COT (Fig.12). Their geometry demonstrates E-W hyper-
383 extended basin terminated by N-S strike-slip faults. The syn-rift strata are mainly deposited in

384 an E-W orientated basin along the gradual slope in bathymetry, suggesting a thinning in
385 agreement with N-S extension. The N-S segments, on the contrary, would have suffered a
386 relative wrench component, thus making the early COT system compatible with the sediment-
387 starved segment.

388

389 These are compatible with a right-lateral motion between the Vietnam Fault (Marquis et al.,
390 1997; Roques et al., 1997; Fyhn et al., 2009) and the Zhongnan Fault (Li et al., 2015) (Fig.12).
391 Along the N-S segment, no clear strike-slip and transtensional structures are observed on the
392 seismic profiles but have been observed from potential-field data (Hwang and Chang, 2014).
393 The lateral variation of syn-rift thickness deciphers the former basin architecture in this study.
394 We suggest that the connection of the isolated basins produces a stress release which induces a
395 rapid propagation of breakup into the continental margin toward the southwest. This
396 propagation of the deformation has been proposed for the incipient breakup of the Red Sea
397 (Augustin et al., 2014; Ligi et al., 2018) highlighted by the node model described in Zwaan et
398 al. (2020) or oblique rifting described in Jourdon et al. (2020).

399

400 However, the later seafloor spreading in NW-SE direction forms an angle of 30° with these
401 pull-apart basins. It has been accepted that seafloor spreading changed progressively into NW-
402 SE direction based on the magnetic and bathymetry analysis (Briais et al., 1993; Sibuet et al.,
403 2016; Lee and Lawver, 1995). As a result, not only the direction of seafloor spreading recorded
404 the shift; the adjacent rifted basins also display changes in the direction of opening and the
405 amount of sediments deposited. We suggest that the N-S rifting in the southwestern SCS was
406 compatible in orientation with the first phase of seafloor spreading in N-S direction from 32 to
407 23 Ma (Briais et al., 2013; Barckhausen et al., 2014). It was followed by an “intermediate”
408 period around the ridge jump accommodated by the N165° extensional direction, proposed by

409 [Sibuet et al., \(2016\)](#). A similar change of extensional direction is also shown in the Phu Khanh
410 Basin after the Middle Miocene ([Savva et al., 2013](#)). Numerical simulation suggests that
411 oceanic propagation was stalled at the boundary between the eastern and southwestern basins
412 because of far-field compression in the EW direction ([Le Pourhiet et al., 2018](#)). The far-field
413 stress direction necessarily had to change to resume and shift propagation toward the southwest.

414

415 **6.2 Break-up Evolution in the SW Margin**

416 The tectono-stratigraphic analysis offers a scenario for the break-up evolution in the Southwest
417 SCS. The detachment faults play an important role in the thinning of the SCS continental crust
418 and in exhumation of the lower crust or the lithospheric mantle, preserving an asymmetrical
419 structure ([Fig.13c](#)). The deposition of the syn-rift II is associated with the development of
420 detachment faults, subsequently offset by seaward-dipping normal faults during the latest
421 rifting stage. A ductile layer is probably required underneath the detachment fault to
422 accommodate the subsidence at the depocenter ([Fig.13b](#)) as interpreted previously in adjacent
423 Qiongdongnan Basins and Xisha Trough ([Clift et al., 2002](#); [Davis and Kusznir, 2004](#); [Pichot et](#)
424 [al. 2014](#), [Lei and Ren, 2016](#); [Xie et al., 2019](#); [Lei et al., 2019](#); [Bai et al., 2020](#)). This could favor
425 the depth-dependent decoupling as suggested in several simulations in the case of wide rifted
426 margins ([Huisman and Beaumont, 2011](#); [Clift and Lin, 2001](#), [Brune et al., 2017](#); [Ros et al.,](#)
427 [2017](#)).

428

429 The tectono-stratigraphy of the syn-rift II has been discussed in several papers with varying
430 interpretations for pre-rift, syn-rift and post-rift, of the COT area, due to a lack of well-
431 established bio-stratigraphy studies ([Ding et al., 2013](#); [2016](#); [Song and Li, 2015](#); [Wang et al.,](#)
432 [2016](#); [Luo et al., 2021](#)). However, the sedimentary package underneath the red horizon (20Ma,
433 Early Miocene) can be confidently traced with similar seismic facies and mild-offset normal

434 faults on both margins vanishing toward the oceanic domain and is therefore considered as syn-
435 rift. (Fig. 10b and 10c). The significant unconformity (blue), which tops the unit offset by the
436 small normal fault, is considered as Late Miocene based on correlation from the biostratigraphy
437 of the IODP Site U1433 (Li et al., 2015).

438

439 The similarity of structural evolution enables us to propose that the U-shaped seismic facies of
440 syn-rift II (Lower Oligocene) in the East SCS may be also related to the similar development
441 of detachment faults (Fig.11a). The margins of the Southwest Sub-Basin experienced a longer
442 period of extension than margins of the East Sub-Basin, and hence resulted in thinner crust in
443 several basins, for instance, the Qiongdongnan Basin (Fig.2) and basins near the COT (Fig.11),
444 for which the crustal thickness reaches values thinner than 1.5 sec TWT. In several adjacent
445 basins, we can barely observe relics of crust at the depocenter, such as in the Phu Khanh Basin
446 and the Nam Con Son Basin (Savva et al., 2013; Lei and Ren, 2016; Clerc et al., 2018; Lei et
447 al., 2020). This period of the syn-rift II corresponds to mostly horizontal motion on low angle
448 detachment faults, varying in time as the breakup propagated toward southwest. (R2 unit in
449 Fig.14).

450

451 The continental lithosphere was finally broken up by the ascending asthenosphere which
452 produced volcanic edifices as well as magmatic intrusion within the crust (Fig.13b). The syn-
453 rift II succession adjacent to the COT with concave-up features implying an uplifting movement
454 possibly during oceanic crust formation (Fig.10b and 10c), and was therefore accompanied by
455 an unconformity on top. The later sequence as post-breakup shows the subsequent subsidence
456 after the lithospheric breakup, and described as the onset of deposition of breakup sequence in
457 Zhang et al. (2020b). The forced deformation of the syn-rift II is associated with the underneath
458 magmatic additions as well as subsequent seafloor spreading after the deposition of syn-rift II,

459 favoring the tectono-magmatic process in a narrow time span (Fig. 13b) rather than concurrent
460 with the depositing syn-rift units (unit T3 in Luo et al., 2021). The lithospheric breakup was
461 immediately followed by creating asymmetrically an extrusive volcano with the cone shape and
462 a first magnetic anomaly C6n in the south (Fig.11b and 11c). The narrow COT infers a rapid
463 process in which the propagator leads to the lithospheric breakup in the southwest SCS, as
464 proposed by recent studies (Cameselle et al., 2020).

465

466 **6.3 Impact of the Subduction South of the SCS**

467 On the seismic profile, a Miocene erosional event on Fig. 5c extends toward the accretionary
468 wedge of the PSCS subduction in the Palawan and Borneo area (Steuer et al., 2014; Ding et al.,
469 2015; Tong et al., 2019). As the tectono-stratigraphy of the SCS and the Borneo-Palawan area,
470 a correlation of the seafloor spreading shift in the South China Sea and the Borneo-Palawan
471 orogeny highlights a time around 23Ma (Top Crocker Unconformity, TCU on Fig. 14; Cullen,
472 2010; Lunt et al., 2019). The propagator continued advancing southwestward subsequently until
473 the extensional stress died out around 16 Ma as well as the termination of orogeny in Sabah
474 (Chang et al., 2019) (Fig. 14). The change of direction of seafloor spreading is also concurrent
475 with the rotational movement of the northern Borneo and Palawan as deduced from
476 paleomagnetic analysis, which shows a counter-clockwise rotation during Early Miocene
477 (Fuller et al., 1999; Cullen, 2010; Advokaat et al., 2018). Therefore, we suggest that the
478 orogeny-related tectonic in Borneo may have modified the direction of opening from N-S to
479 NW-SE by changing the far-field stress in the South China Sea.

480

481 **7. Conclusion**

482 This study has explored the crustal architecture and evolution of the southwestern South China
483 Sea. The 1000 kilometer long profile illustrates distributed rifted basins, which thinned owing

484 to low-angle detachment faults rooted into the top of ductile layers in the lower level of the
485 continental crust. The continental lithosphere stretching and thinning are accommodated by
486 ubiquitous large detachments in the Xisha Islands-NW Borneo margins. Tectono-stratigraphic
487 analysis in the vicinity of the COT suggests that hyper-extension is restricted to the E-W
488 segments of the distal margin, whereas the N-S segments are abrupt and covered by a thin
489 blanket of sediments overlying the basement. The conjugate E-W segment presents an
490 asymmetric distal margin with a well-defined lower plate structure on the NW Borneo margin
491 similar to the one observed on the SE China margin bordering the eastern SCS. These COT
492 boundaries delineate small “en echelon” rifted basins whose distribution is indicative of a right-
493 lateral motion prior to 23 Ma, during the first phase of seafloor spreading in the East SCS. Most
494 of the extension developed in the N-S direction prior to breakup, and then started to change
495 progressively to the NW-SE during the second phase of spreading. The pull-apart basins would
496 thus underline the transitional period. In that sense, the succession of events is strikingly coeval
497 to the far-field stress change induced from the adjacent subduction and closure of the Proto-
498 South China Sea in Palawan-Borneo.

499

500 **Acknowledgement**

501 This work is the result of a long-lasting cooperation, initiated in 2008, between ENS-PSL /
502 CNRS in Paris, France, and Guangzhou Marine Geological Survey (GMGS), in China. Ship
503 and seismic equipment were supplied by GMGS. MCS data processing had been performed at
504 ENS. We thank CGG for giving us access to the CGG Geovation 2013 software. The raw
505 seismic data set can be found online (www.geologie.ens.fr/imagerie/). We are also grateful for
506 the useful suggestions of S. Steuer, anonymous reviewers and the editor Dr Tiego Alves.

905 **Figure captions**

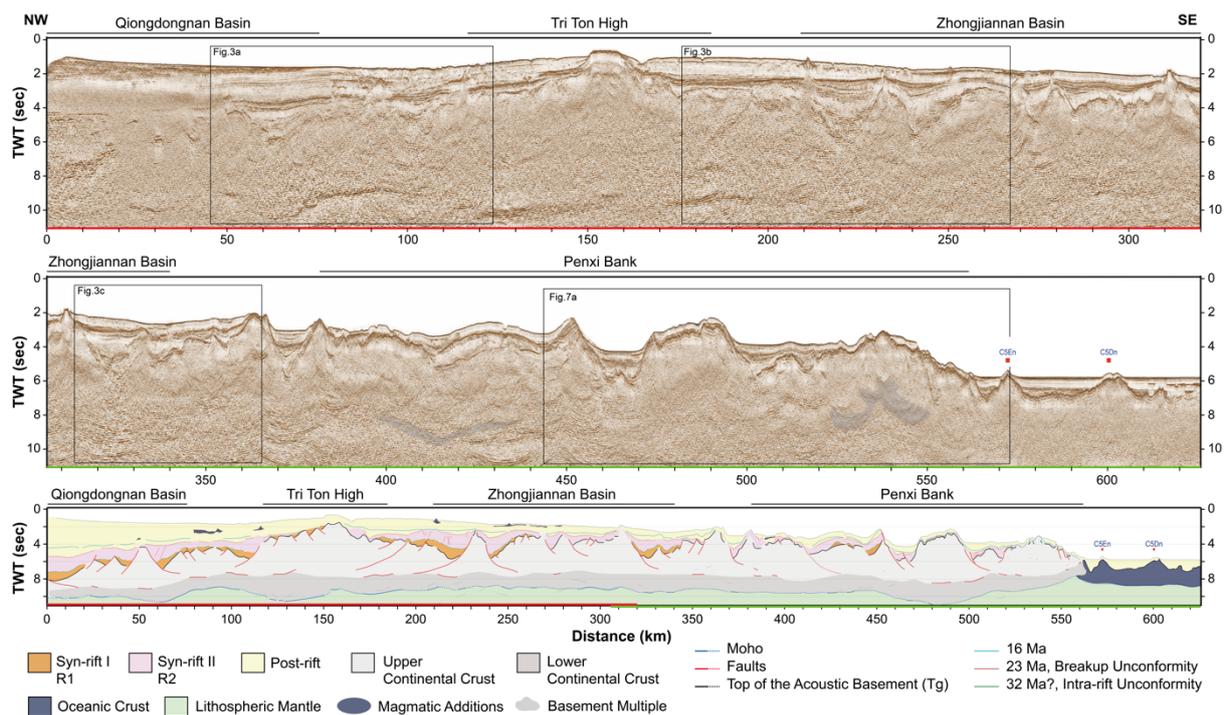

906

907 **Figure 1.** (A) Elevation with rifted basins including BBW: Beibuwan Basin, NCS: Nam Con

908 Son Basin, NWPB: NW Palawan Basin, PK: Phu Khanh Basin, PRMB: Pearl River Mouth

909 Basin, QDN: Qiongdongnan Basin, SH-Y: Song Hong-Yinggehai Basin, TXN: Taixinan Basin,
 910 ZJN: Zhongjiannan Basin. The bathymetric map has a non-linear colour bar to assist in
 911 highlighting certain features. The black solid lines represent the location of seismic profiles and
 912 the black dashed lines are Vietnam Fault (VF) and Zhongnan Fault (ZF) (Fyhn et al., 2009; Li
 913 et al., 2015). (B) Marine magnetic anomaly map. The magnetic map is compiled by Geological
 914 Survey of Japan and CCOP (1996). The white area represents areas devoid of data. The COT
 915 distribution is shown in the grey band (Song et al., 2019). MB: Macclesfield Bank (Zhongsha
 916 Islands), SI: Spratly (Nansha) Islands, PB: Penxi Bank, RB: Reed (Liyue) Bank. ESB: East
 917 Sub-Basin, NWSB: Northwest Sub-Basin, SWSB: Southwest Sub-Basin, BPT: Borneo-
 918 Palawan Trough.

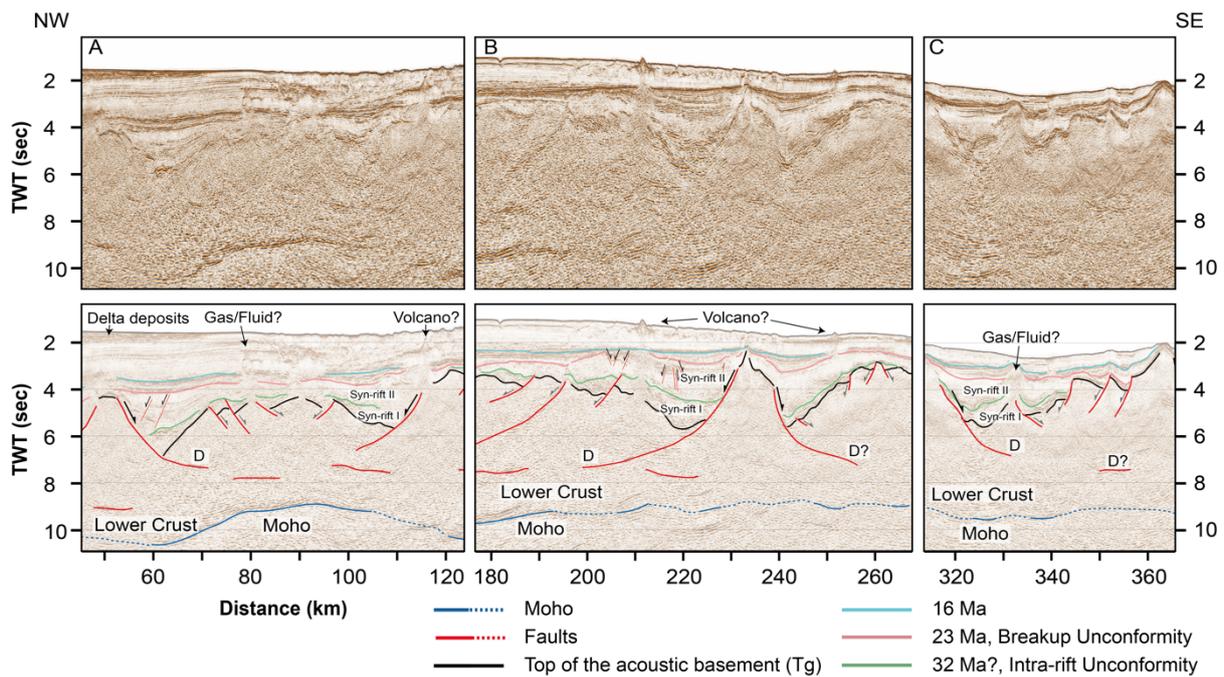

919

920

921 **Figure 2.** Original and interpreted seismic profiles of ENS processed line CFT-N across the
 922 Xisha Islands Margin. The wide rifted margin is characterized by distributed basins with two
 923 phases of syn-rift units, which are bounded by detachment faults. The location is shown on the
 924 Fig.1.

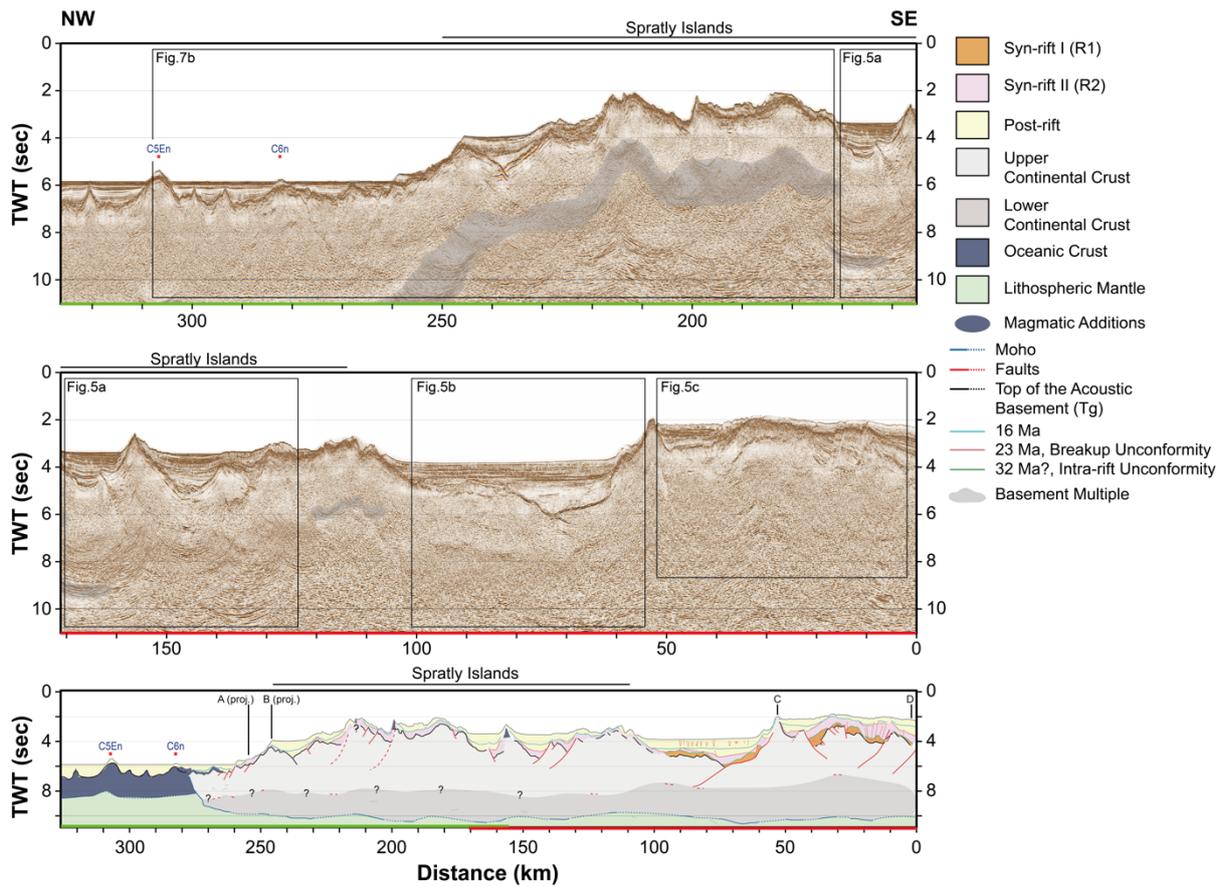

925

926

927 **Figure 3.** Original and interpreted seismic profiles, showing the extended crust in the
928 Qiongdongnan Basin and Zhongjiannan Basin showing that the detachment faults (D) thin
929 mainly the crust and root into the top of the lower crust. The Moho depth follows weak
930 reflectivity and refraction Moho from [Pichot et al. \(2014\)](#). Vertical exaggeration is
931 approximately 5 in the sediments and 2 in the crust, based on refraction data such as the average
932 velocity 2 km/s for sediments and 6.5 km/s for the continental crust. The location is shown on
933 Fig.1a and in Fig.2.

934

935

936 **Figure 4.** Original and interpreted seismic profiles of line CFT-S across the NW Borneo Margin

937 with the indication of dredge samples along the profile. A: monzo-granite and granodiorite

938 (127.2-153.6 Ma); B: tonalite (157.8-159.1 Ma); C: gneiss (115-123 Ma) and phyllite (113 Ma);

939 D: lagoonal-reefoid packstone-wackestone (E. Miocene) (Kudrass et al., 1986; Yan et al., 2012).

940 The location of the seismic profile is shown on Fig.1 and sample locations are shown on Fig.6.

941

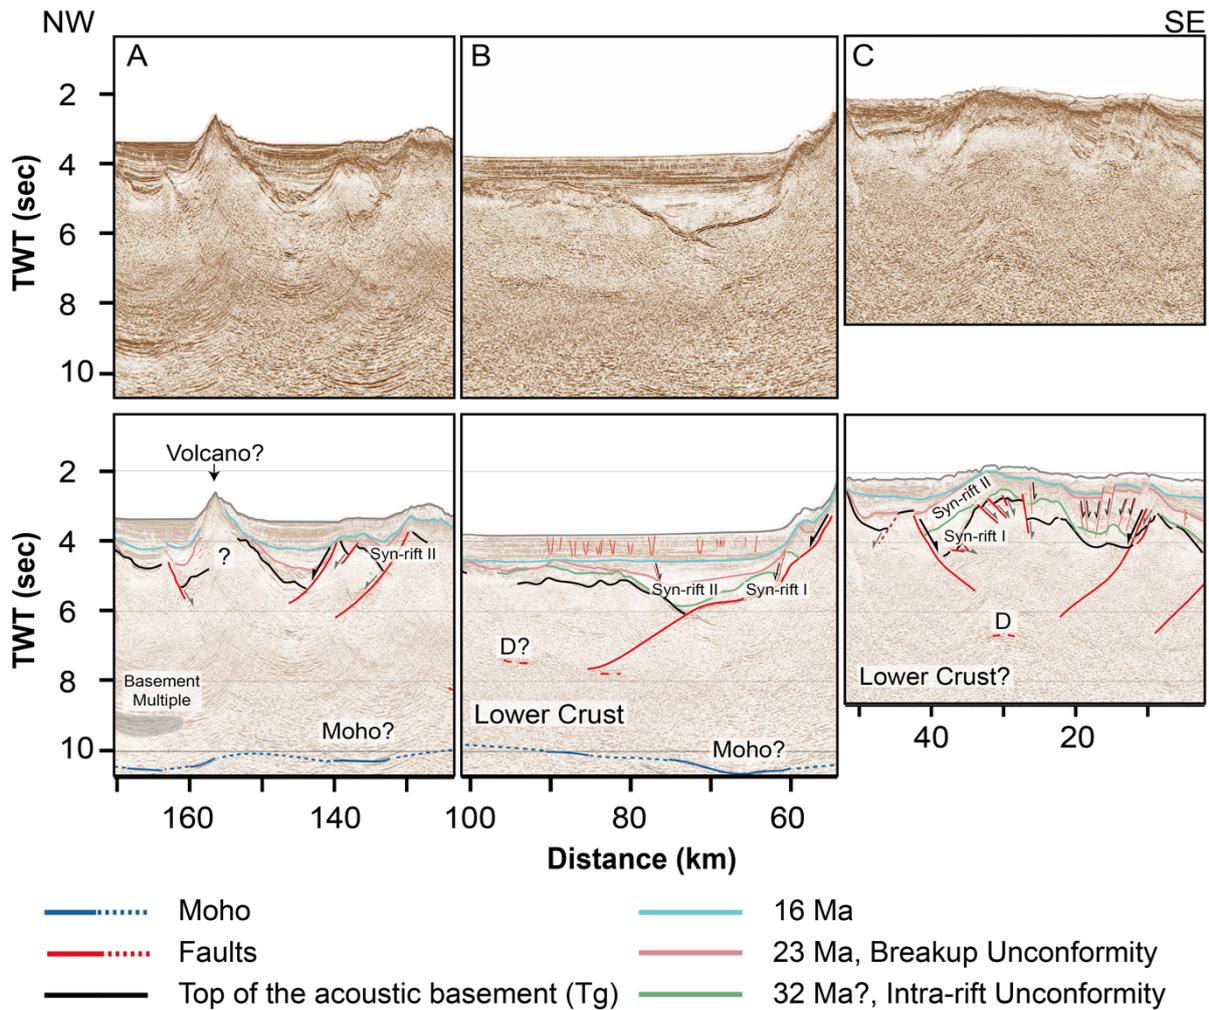

Figure 5. Original and interpreted seismic profile of the extended crust in the area of the Spratly Islands showing the detachment faults (D) rooting in the lower crust and creating the wedge-shaped syn-rift unit in the NW Borneo Margin. The Moho depth follows weak reflectivity and refraction Moho from [Liang et al. \(2019\)](#). Vertical exaggeration is approximately 5 in the sediments and 2 in the crust, estimated by the velocity 2 km/s for sediments and 6.5 km/s for the continental crust. The location is shown on the Fig.1a.

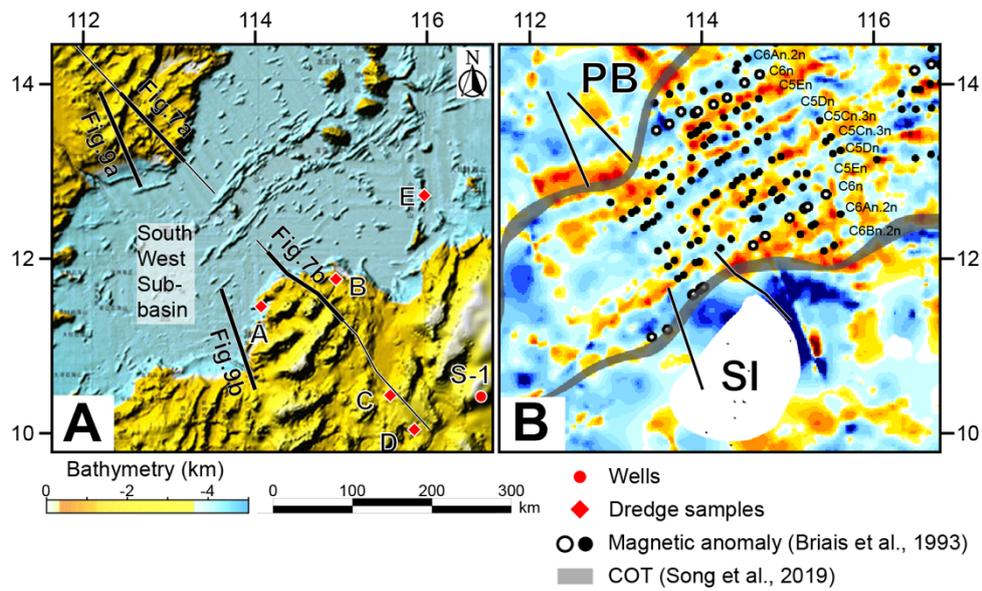

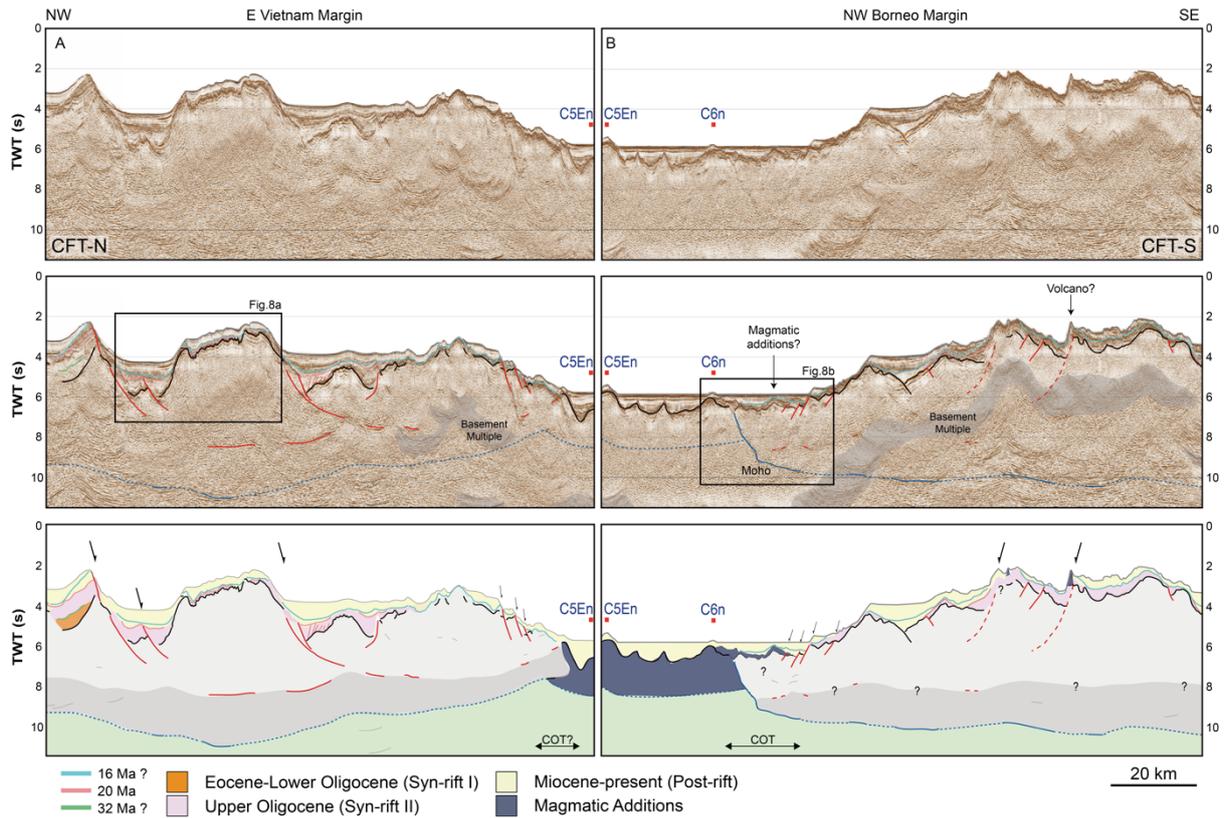

Figure 6. (A)

950

951 Bathymetry map in Penxi Bank (PB) and Spratly Islands (SI) in the southwestern SCS. The
 952 yellow to blue bathymetry threshold shows two orientations (E-W and N-S) segmenting the
 953 continent-ocean transition at the boundary of PB and SI. Two cross-sections present the crustal
 954 architecture of conjugated margins by juxtaposing the E Vietnam Margin and NW Borneo
 955 Margin along two segments individually. S-1: Well Sampaguita-1. (B) The magnetic anomaly
 956 map shows the ages of oceanic crust identified by [Briaies et al. \(1993\)](#). The open circle represents
 957 the C6n, which is the first anomaly along the seismic profiles. The reconstruction of the
 958 conjugated margins are established based on the C5En in this study.

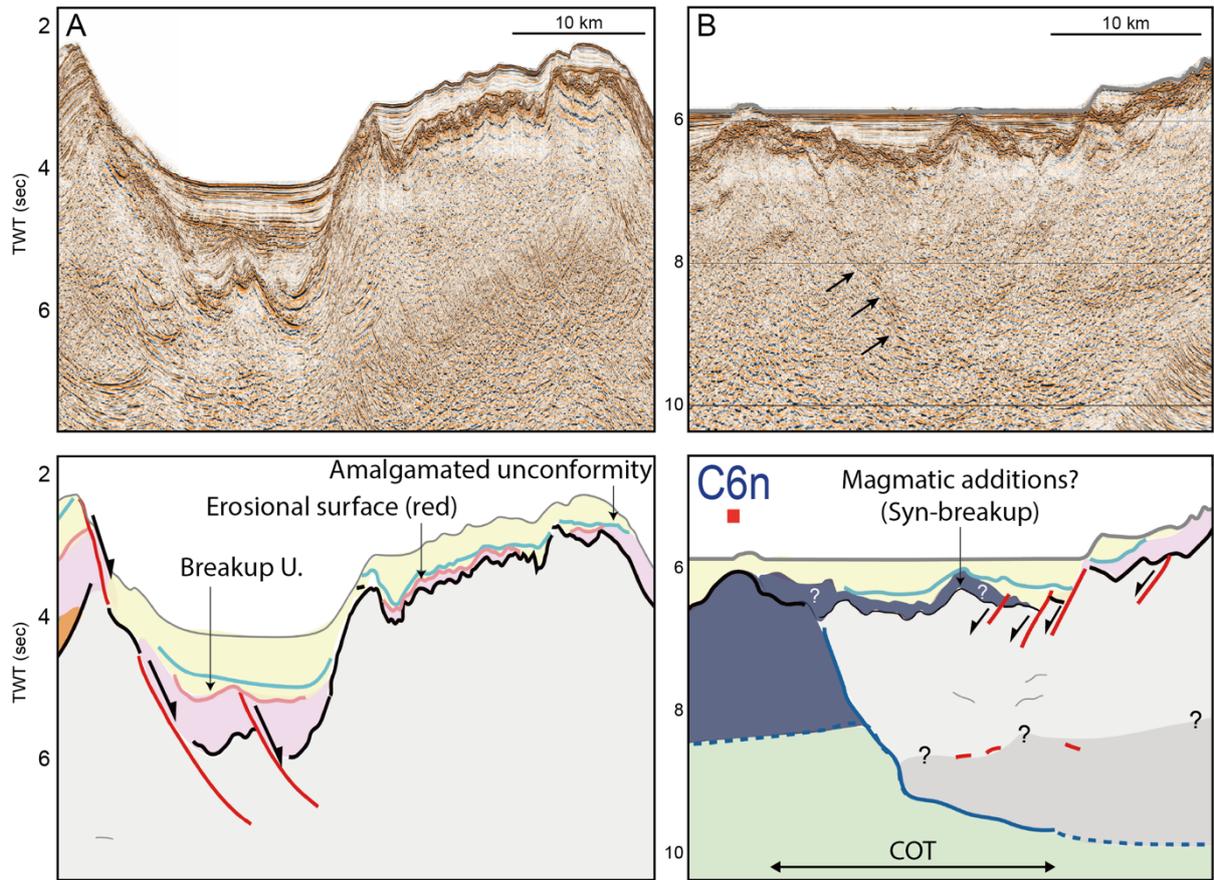

959

960

961 **Figure 7.** Seismic profiles of a conjugated cross-section along the N-S segment present the
 962 thinned crust covered by thin syn-rift sediment at the time of breakup (C6n, 20.1 Ma). The
 963 location of the profiles is shown in Fig.6a.

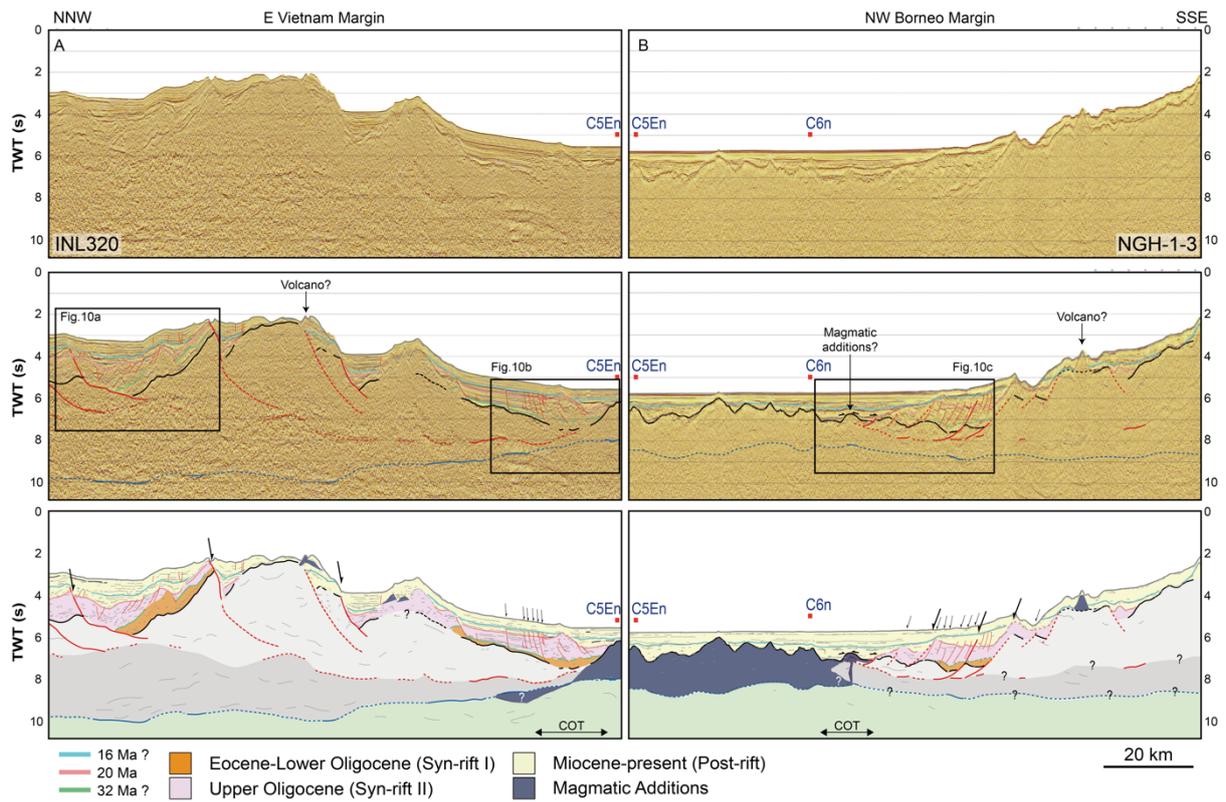

964

965

966 **Figure 8.** Seismic profiles of rifted basins illustrate (A) an erosional surface (red color)
 967 distributed along the rifted basins and basement high in the N-S segment and (B) a thin syn-rift
 968 succession covering the COT area.

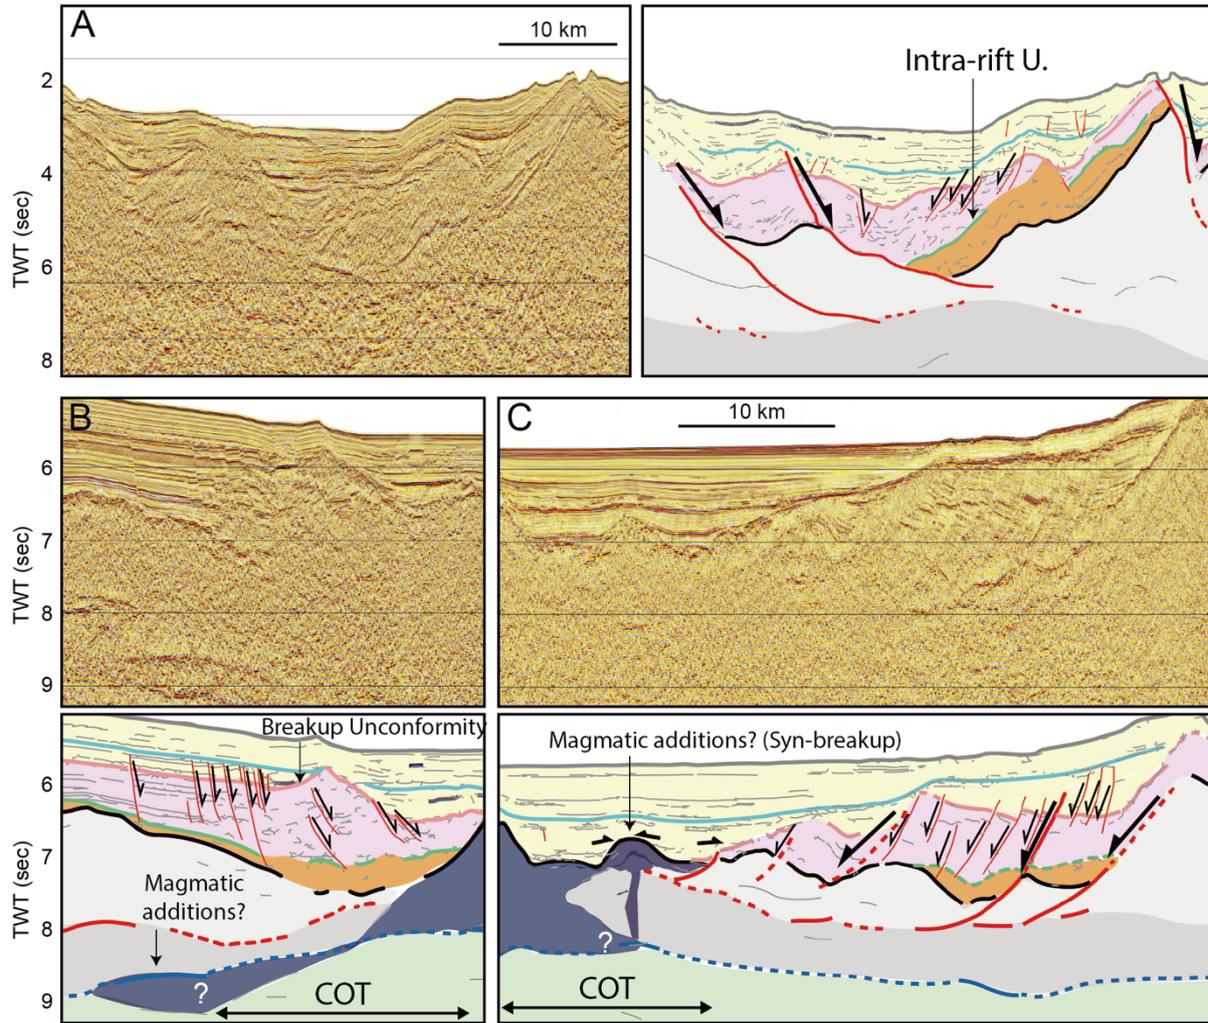

969

970

971 **Figure 9.** Original and interpreted seismic profile of a conjugated cross-section along the E-W
 972 segment presents the thick syn-rift sediment at the time of breakup (C6n, 20.1 Ma). The location
 973 of profiles is shown in Fig.6a.

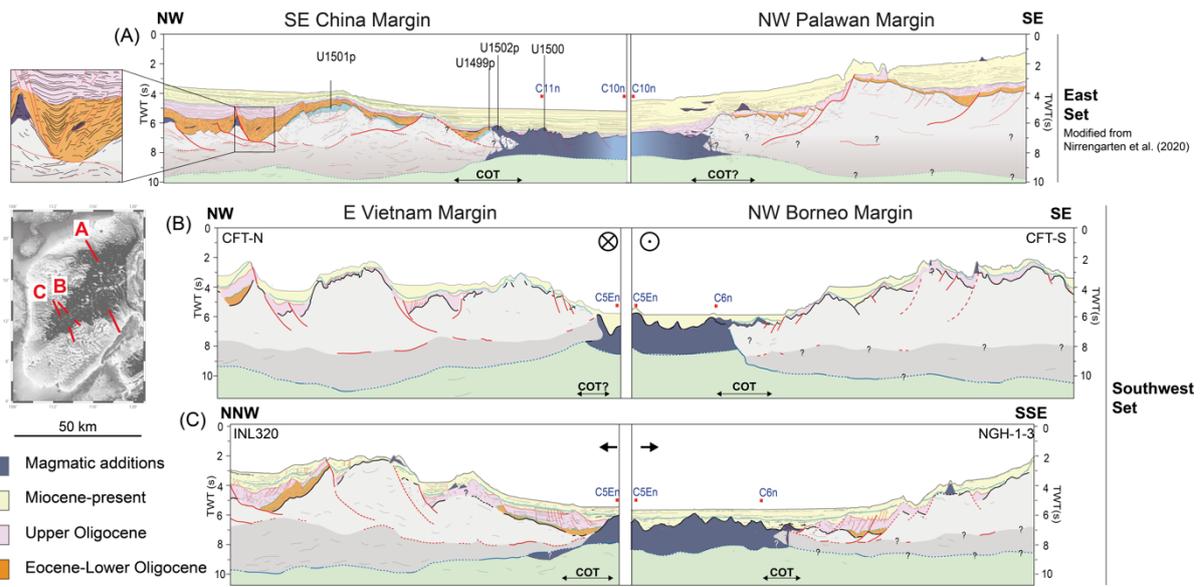

974

975

976 **Figure 10.** Seismic profiles show that thicker sediments cover the COT of E-W segment in a
 977 homogeneous thickness of the syn-rift II succession. The syn-rift unit next to the oceanic crust
 978 was disturbed and truncated to form the break-up unconformity. It is suspected that the green
 979 horizons (32 Ma) act as a decoupling level which facilitated the tilting of the overlying sequence
 980 (Syn-rift II, pink color).

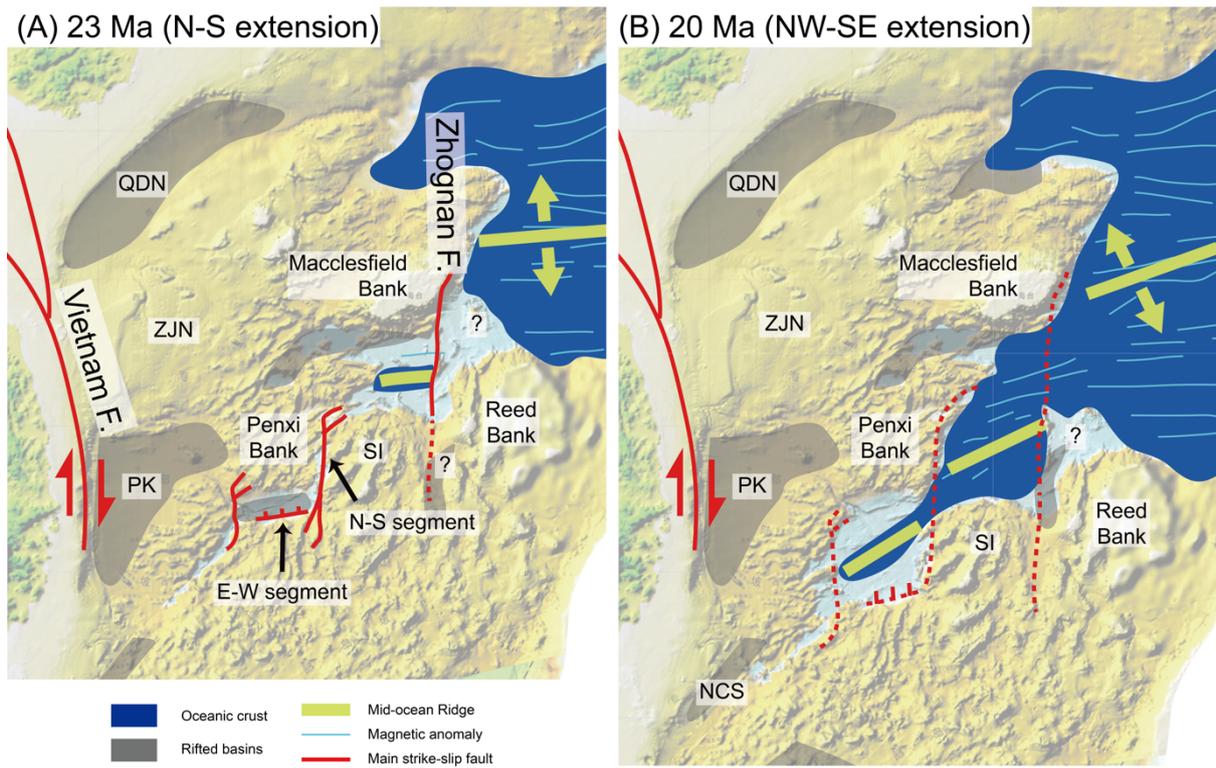

981

982

983 **Figure 11.** The comparison of crustal configuration between East and Southwest SCS. The
 984 wrench component leads the N-S segment (section B) prior to the breakup. The pull-apart basin
 985 along the E-W segment (section C) deposited thicker syn-rift sediment. Different ages of
 986 breakup and breakup unconformity are presented between E Vietnam-NW Borneo Margin and
 987 SE China-NW Palawan Margin, modified from Nirrengarten et al. (2020). The similarity of
 988 asymmetrical structure appears near the COT.

989

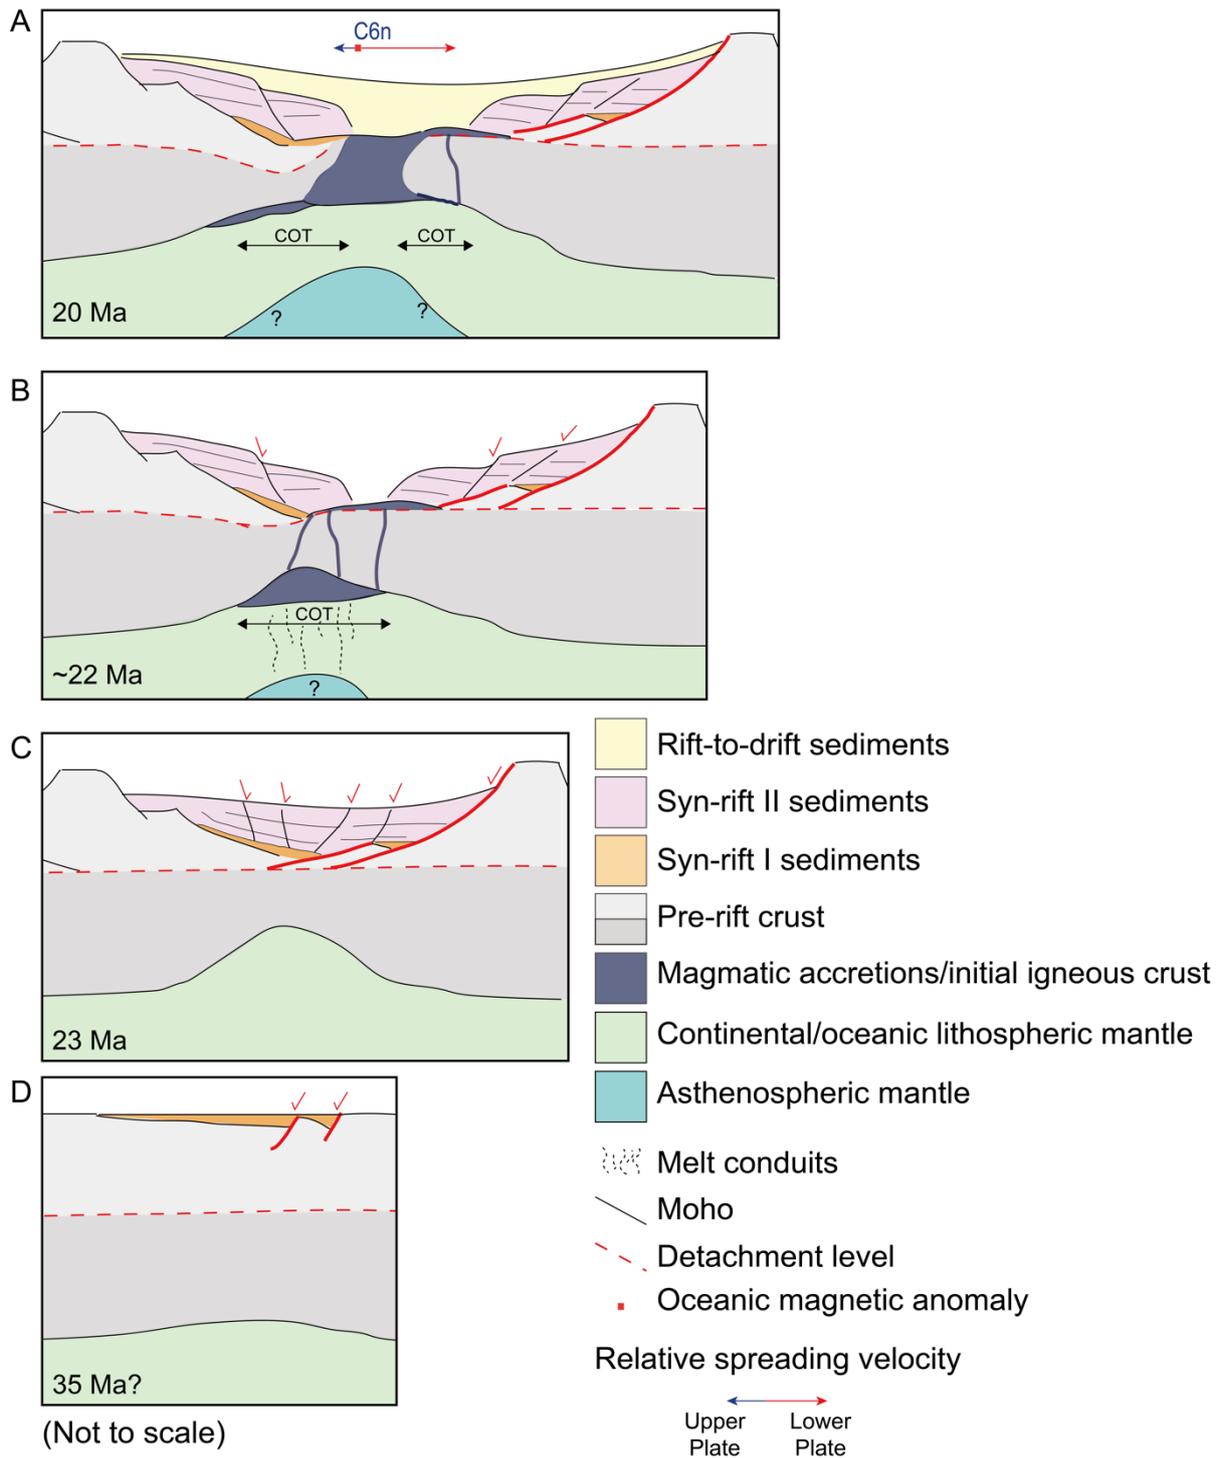

990

991 **Figure 12.** The kinematic evolution in the SCS shows that the first phase of seafloor spreading
 992 induced a series of pull-apart basins in the southwestern SCS in a N-S extension and that the
 993 second phase changed the direction of seafloor spreading and initiated breakup and subsequent
 994 NW-SE spreading.

995

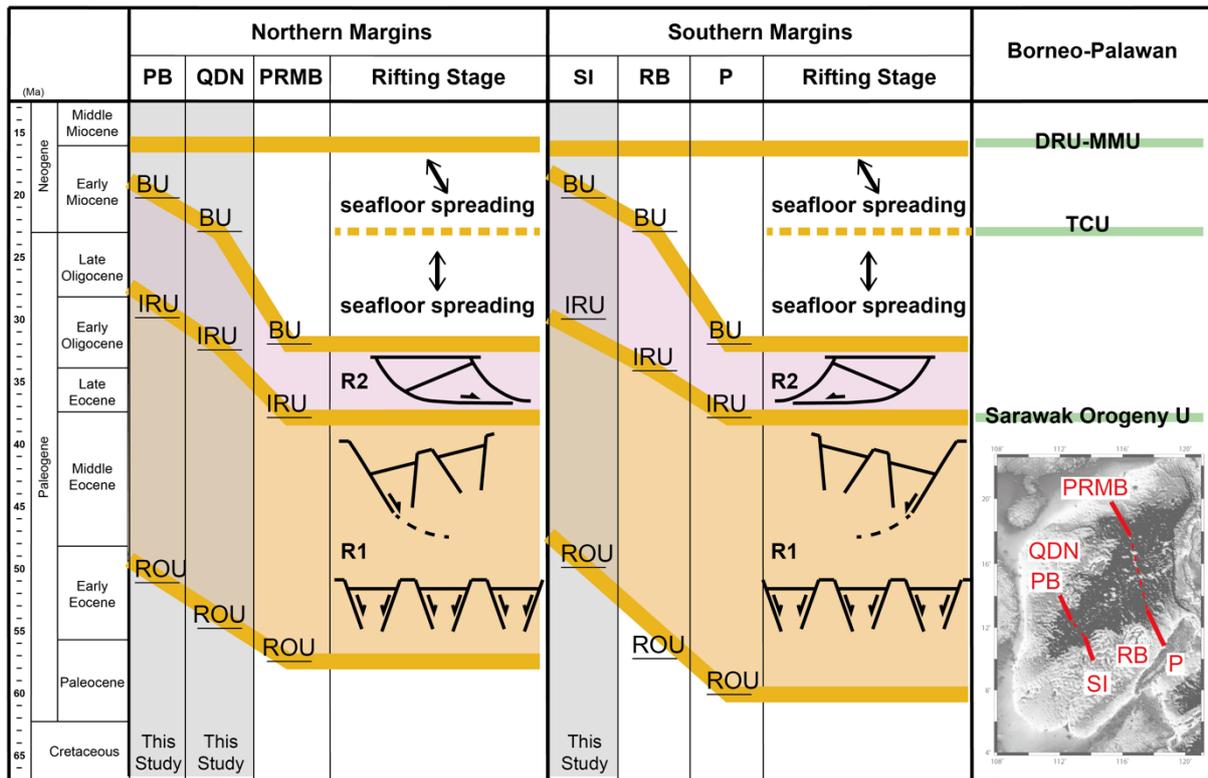

996

997

998 **Figure 13.** Conceptual model of breakup in the southwestern SCS. Detachment faults attempted
 999 to exhume lower structural levels asymmetrically, and were followed by oceanic accretion
 1000 which formed the first anomaly (C6n) in the south.

1001

1002

1003 **Figure 14.** Tectono-stratigraphic chart in diachronism along the SCS margins. Note that the
 1004 pink and orange colors correspond to the structural stages discussed in the text. In that sense,
 1005 they do not refer to specific ages of each basin. Ages of the unconformities are taken from
 1006 Cullen (2010), Yao et al. (2012), Madon et al. (2013), Savva et al. (2013), Steuer et al. (2014),
 1007 Vu et al. (2017), Xie et al. (2019). The development of detachment faults and breakup results
 1008 from the two stages of structural evolution in R1 and R2, and shows the various timing along
 1009 the margin. BU: Breakup Unconformity, IRU: Intra-rift Unconformity, ROU: Rift-onset
 1010 Unconformity, DRU: Deep-region Unconformity, MMU: Middle Miocene Unconformity,
 1011 TCU: Top Croker Unconformity.
