18 ABSTRACT

19 The human brain develops from a smooth cortical surface in early stages of fetal life to a con-
20 voluted one postnatally, creating an organized ensemble of folds. Abnormal folding patterns
21 are linked to neurodevelopmental disorders. However, the complex multi-scale interactions in-
22 volved in cortical folding are not fully known yet. Computational models of brain development
23 have contributed to better understand the process of cortical folding, but still leave several ques-
24 tions unanswered. A major limitation of the existing models is that they have basically been
25 applied to synthetic examples or simplified brain anatomies. However, the integration of patient-
26 specific longitudinal imaging data is key for improving the realism of simulations. In this work
27 we present a complete computational pipeline to build and validate patient-specific mechanical
28 models of brain development. Starting from the processing of fetal brain magnetic resonance
29 images (MRI), personalised finite-element 3D meshes were generated, in which biomechanical
30 models were run to simulate brain development. Several metrics were then employed to compare
31 simulation results with neonatal images from the same subjects, on a common reference space.
32 We applied the computational pipeline to a cohort of 29 subjects where fetal and neonatal MRI
33 were available, including controls and ventriculomegaly cases. The neonatal brain simulations
34 had several sulcal patterns similar to the ones observed in neonatal MRI data. However, the
35 pipeline also revealed some limitations of the evaluated mechanical model and the importance
36 of including patient-specific cortical thickness as well as regional and anisotropic growth to ob-
37 tain more realistic and personalised brain development models.

38 Statement of Significance:

39 Computational modelling has emerged as a powerful tool to study the complex process of brain
40 development during gestation. However, most of the studies performed so far have been car-
41 ried out in synthetic or two-dimensional geometries due to the difficulties involved in processing
42 real fetal data. Moreover, as there is no correspondence between meshes, comparing them or
43 assessing whether they are realistic or not is not a trivial task. In this work we present a com-
44 plete computational pipeline to build and validate patient-specific mechanical models of brain
45 development, mainly based on open-source tools.

46 1. Introduction

47 During brain development there is a process of folding of the cerebral cortical surface creating outward (or convex
48 hills) folds known as gyri and inward (or concave valleys) folds called sulci. The resulting cerebral cortex is highly con-
49 voluted in humans and large mammals, attaining a large surface area relative to brain volume, as analysed in [26] for 34

1 primate species. Brain/cortical folding mostly occurs during gestational ages (GA) 16-40 [57], following a hierarchical
2 organisation. Primary folds are the largest, deepest and early formed, being progressively subdivided into secondary
3 and tertiary folds [31]. Compared to the huge variations across adult brains, the location and timing of formation of
4 the first folds is remarkably stable [15]. Cortical fold wavelength is also similar between different primate species [26],
5 as it is directly related to cortical bending stiffness (thus on cortical thickness), which does not substantially change
6 across mammalian species [43].

7
8 The size and folding of the cerebral cortex have a fundamental impact on brain function [17], with abnormal
9 patterns (e.g., reduced or excessive folding that is defined as lissencephaly and polymicrogyria, respectively) leading
10 to severe intellectual disability [25]. Due to its clinical relevance, it is then essential to better understand the relation
11 between cortical malformations and neurodevelopmental disorders. Recent studies (e.g., [21, 58]) have exposed that
12 mechanical forces play an important role in the generation of characteristic folding patterns. More precisely, several
13 works [12, 68, 59] showed that differential tangential growth between different layers of the cortex (i.e., grey and
14 white matter) generates a compressive stress that is sufficient to induce buckling. Additionally, several studies have
15 demonstrated that axonal tension within fibres in the white matter plays a key role in modulating folds' shape [60, 70, 5].
16 However, the interactions between the many multi-scale developmental processes involved in the dynamics of cortical
17 folding remain to be clarified [66].

18 Several computational models of brain development have been proposed in the literature [60, 44, 4, 44, 21, 18, 72],
19 contributing to improve our knowledge about the mechanisms underlying cortical folding. They are mainly based on
20 different continuum mechanics theories. The interested reader is referred to [24, 10] for a comprehensive review of
21 brain (tissue) mechanics and its modelling. For instance, the theory of finite elasticity was used in [24] to prove that
22 growth induces elastic instability with buckling modes of different wavelengths depending on the growth parameters
23 and thickness of the shell, which naturally relates to the process of brain folding. The two most explored theories on
24 cortical folding are based on axonal tension and differential growth hypothesis. The former one, first proposed in [61],
25 is based on the assumption that axons connecting neurons in white matter mechanically pull highly interconnected
26 regions of grey matter together to form gyri. The same author recently proposed a revision of the theory that includes
27 tangential tension and sulcal zipping forces in the outer cortical margin and tension in the white matter core, together
28 competing against radially-biased tension in the cortical grey matter [62]. On the other hand, the differential growth
29 theory, proposed in [50], is based on a larger growth rate of cortical tissues compared to white matter, thus leading to
30 mechanical buckling shaping the cortex. Tallinen et al. [58, 59] extended experimental studies of differential growth
31 to 3D, using hemispheres of layered swelling gel. These authors also performed numerical simulations of growing
32 hyperelastic materials starting from an idealised smooth fetal brain 3D mesh, obtaining results reasonably matching

1 experimental observations.

2 Models only based on uniform surface growth on an elastic foundation have difficulties to reproduce the location
3 and orientation of primary folds, nor the growth of white matter. Toro et al. [60] added stress-induced growth in
4 a folding model by including radial and discrete viscoelastic fibres connected to an expanding elastic ring, which
5 represented the cortical plate. Bayly et al. [5] derived an analytical formulation of the effects of relative growth rate
6 on the folding wavelength, by representing the sub-cortical region as a continuous viscoelastic core. Budday et al.
7 [11], modelled the human brain as a morphogenetically growing outer surface and a stretch-driven growing inner core,
8 combining both axonal tension and differential growth hypotheses. The authors confirmed that the ratio between inner
9 and outer layers' growth rates influenced folding wavelength. This model was extended by Holland et al. [27] to
10 study cortical anisotropic growth, due to the preference of axons to elongate in their axial direction. As an alternative,
11 Wang et al. [64] recently proposed to link cortical growth rate to mean curvature variations, achieving distinct gyral or
12 sulcal growth. Finally, Zarzor et al. [72] are pioneering the development of multi-scale models of brain development,
13 coupling cellular processes with cortical folding, where cell properties (e.g., migration velocity, diffusivity) influence
14 cortical growth.

15 A major limitation common to all the proposed models is that they have only been applied to synthetic simplified
16 geometries (e.g., disks, ellipsoids, spheres) [60, 11, 67] or to simplified brain anatomies [58, 27, 59, 66]. Experiments
17 with synthetic data are required as part of the model validation stage to characterize the sources of errors and have bet-
18 ter control over their parameters. However, the integration of patient-specific longitudinal data of brain development
19 is key for assessing the accuracy of resulting predictions, through model validation and parameter optimisation with
20 data assimilation processes. Appropriate accuracy metrics are consequently required to compare simulation results
21 and observations. Obtaining imaging data to explore human brain development at different time-points in fetal life is
22 nonetheless challenging, unlike for other species such as ferrets, where cortical folding and white matter maturation
23 take place during the first month of life [3]. Ultrasound [69] and magnetic resonance images (MRI) [6] of the fetal brain
24 are increasingly providing insights on brain development in vivo, but still with insufficient spatial resolution (from ul-
25 trasound images) or requiring advanced image processing pipelines (in MRI) to compensate acquisition reconstruction
26 problems due to motion.

27 Another factor hampering the progress in patient-specific brain development models is the lack of openly shared
28 pipelines including all the required steps. The neuroimaging community is steadily promoting Open Science and
29 reproducible research, with numerous established tools for brain MRI data harmonization and processing (e.g., Clinica
30 [53]), some of them for the description of cortical folding in healthy and pathological human brains, as well as in other
31 species (e.g., PRIME-RE [41]). Unfortunately brain mechanical models are not integrated into the existing pipelines

1 yet, despite the availability of solvers used in some successful studies [59, 67]¹².

2 In this work we present a complete computational pipeline to build and validate patient-specific mechanical mod-
3 els of brain development, mainly based on Open Source tools. Starting from the processing of fetal brain MRI, per-
4 sonalized finite-element methods 3D meshes are generated, where biomechanical models are run to simulate brain
5 development. Several metrics are then used to compare simulation results with neonatal data from the same subjects,
6 on a common reference space built to integrate data from different individuals and time-points. The pipeline has
7 been applied to a cohort of 29 subjects where fetal and neonatal MRI were available, including controls (n = 16) and
8 ventriculomegaly (n = 13) cases.

9 **2. Materials and methods**

10 A scheme of the proposed pipeline is illustrated in Figure 1 and described in sections 2.2-2.4. The first step of the
11 pipeline is the brain tissue segmentation of fetal and neonatal MRI of the same subject. The grey matter (or cortical
12 surface) label is then the basis for building finite element method (FEM) meshes, which are later refined if required
13 to ensure model convergence. Cortical thickness maps and brain parcellation are also derived from MRI data. The
14 fetal meshes and patient-specific cortical thickness maps are subsequently set as input for the computational model
15 that simulates brain growth and folding until the GA at which neonatal real data was available for that subject. Finally,
16 neonatal simulations and observations are compared through global and local metrics.

17 **2.1. Clinical imaging database**

18 The clinical imaging database was composed of longitudinal brain MRI data from a cohort within a research
19 project on isolated non-severe ventriculomegaly (INSVM), carried out at Hospital Cl nnic in Barcelona, Spain. Ap-
20 proval was obtained for the study protocol from the Ethics Committee of the Hospital Cl nnic in Barcelona, Spain
21 (HCB/2014/0484) and all patients gave written informed consent.

22 Fetal ventriculomegaly (VM) occurs in around 1 out of 10 pregnancies [55]. It is defined as a dilation (≥ 10 mm)
23 of one or both lateral ventricles, measured in 2D in ultrasound images, being 6-8 mm the normal width in fetuses [7].
24 In the absence of other anomalies, it is called isolated ventriculomegaly. Studies [56, 33, 7] have confirmed alterations
25 in folding in fetuses with ventricular enlargement, therefore underlining the clinical relevance of understanding the
26 gyrification process.

27 We finally included 31 subjects from a larger cohort of 81 subjects (38 controls and 43 with INSVM), the ones where
28 both fetal and neonatal reconstructed MRI were available. Two subjects were excluded due to inaccurate segmentation
29 results (see Section 3.1). The demographic information of the 29 subjects included in our study is summarised in Table

Patient-specific mechanical models of brain development

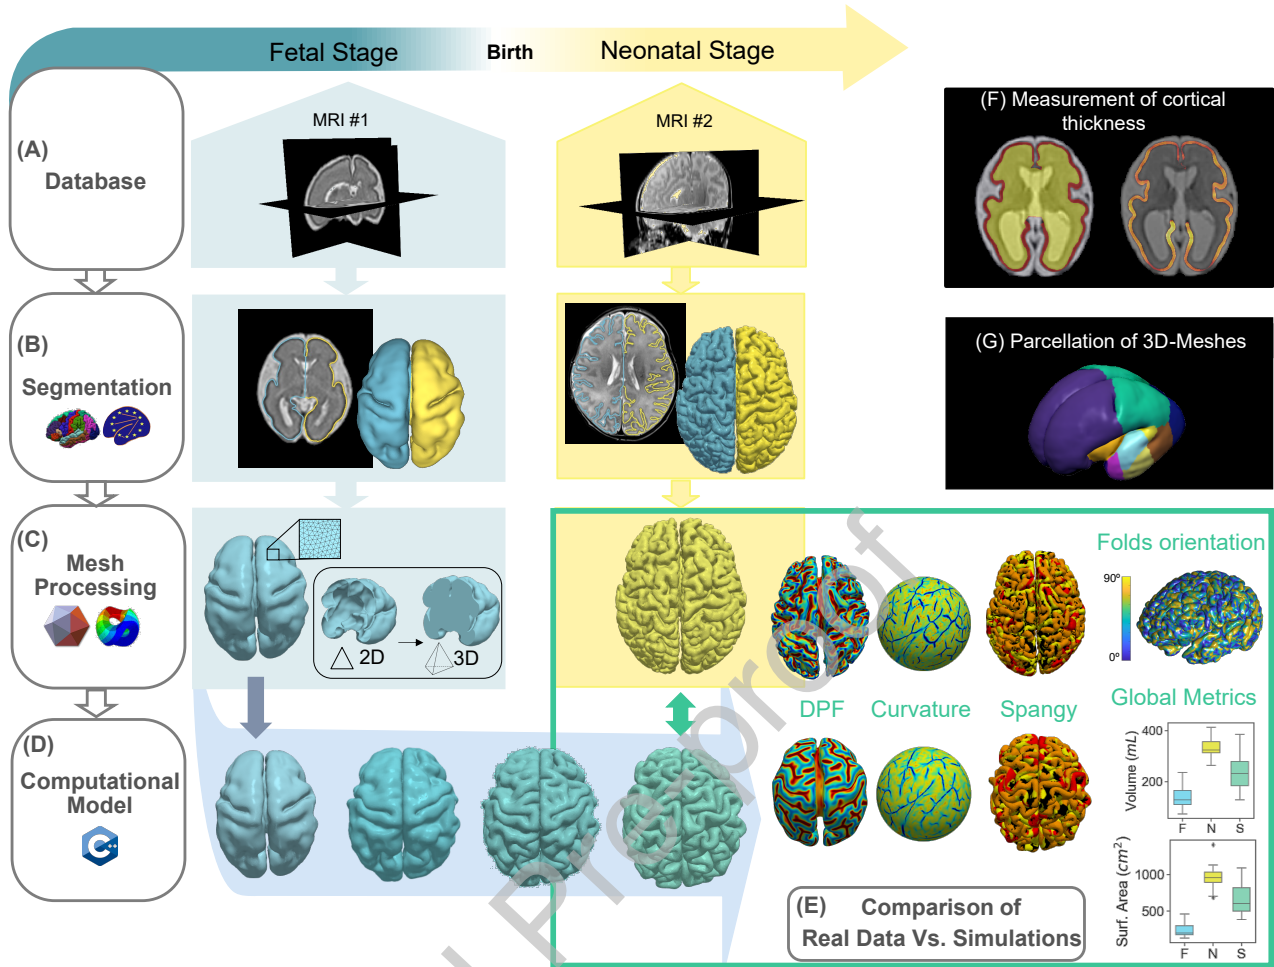

Figure 1: Scheme of the computational pipeline for patient-specific brain mechanical model generation and validation. (A) Example of fetal and neonatal magnetic resonance imaging (MRI) scans of one subject. Background of fetal and neonatal MRI processing is coloured in blue and yellow, respectively. (B) Image segmentation was performed with the Developing Human Connectome Project (dHCP) structural pipeline [40]. (C) Mesh processing was performed with Meshmixer, using Netgen to generate the 3D fetal meshes. (D) With the fetal geometry (gestational age, GA, of 28) as starting point, the computational model simulated brain development. Predicted meshes of GA 32, 36 and 40 are displayed. (E) Comparison between the neonatal real and simulated meshes using global and local metrics. DPF: Depth potential function. (F) Measurement of cortical thickness from images. (G) Parcellation of 3D meshes.

1. In addition, ground-truth segmentations performed by clinicians were provided for 13 out of those 31 fetal images.
- 2 T2-weighted MR imaging was performed on a 1.5-T scanner (Siemens Magnetom Aera syngo MR D13; Munich,
- 3 Germany) with a 8-channel body coil, resulting in images with a 2.5 mm of slice thickness, a 280Å280 mm field of
- 4 view and a voxel size of 0.5Å0.5Å2.5 mm³. Multiple orthogonal acquisitions were performed for each subject: 4
- 5 axial, 2 coronal and 2 sagittal stacks. From these 8 stacks of thick 2D slices, final 3D motion-corrected reconstructions
- 6 were obtained; subsequently, brain location and extraction were performed with the methods presented in [28]. A
- 7 high-resolution 3D volume reconstruction was then conducted using the approach proposed in [32].

Table 1

Clinical characteristics of the cohort.

Gestational / Postmenstrual Age (<i>mean ± SD</i>)	
at Birth (week)	39.73 ± 1.12
at MRI 1 (week)	29.25 ± 2.74
at MRI 2 (week)	43.51 ± 1.71
Gender n (%)	
Male	22 (75.86%)
Female	7 (24.14%)
Controls / Ventriculomegaly Cases n (%)	
Controls	16 (55.17%)
Ventriculomegaly	13 (44.83%)
Fetal MRI Onset n (%)	
Early (< 30)	20 (68.97%)
Late (> 30)	9 (31.03%)
Ethnicity n (%)	
African	2 (6.90%)
Asian	1 (3.45%)
Caucasian	23 (79.31%)
Latin American	3 (10.34%)

2.2. Medical image processing

Cortical surface geometries were obtained from neonatal images using the Developing Human Connectome Project (dHCP) structural pipeline [40]. For the fetal cases, a modified version of the dHCP pipeline was used, integrating a fetal-specific atlas [23] to permit segmentation of images taken in early gestation.

We used the ground-truth labels from 13 subjects to evaluate the accuracy of the automatic segmentation method, as illustrated on Figure 2. The obtained results were compared both visually, by displaying them using Paraview³ and 3DSlicer⁴, and quantitatively, by computing the Dice Coefficient, Hausdorff Distance (HD) and Volume Similarity (VS) measures, as follows:

$$Dice = \frac{2|GT \cap X|}{|GT| + |X|}, \quad (1)$$

where GT represented the ground-truth and X the obtained segmentation, so $GT \cap X$ corresponded to their intersection; $HD = \max(h(GT, X), h(X, GT))$, where $h(GT, X)$ was the directed Hausdorff distance, given by $h(GT, X) = \max_{gt \in X} \min_{x \in X} \|gt - x\|$, being $\|gt - x\|$ the Euclidean distance between points gt and x ;

$$VS = 1 - \frac{||GT| - |X||}{|GT| + |X|}. \quad (2)$$

³<https://www.paraview.org/>

⁴<https://www.slicer.org/>

1 As described in [39], the output of the dHCP structural pipeline included 2D meshes and associated feature maps
2 for left and right hemispheres. The different meshes corresponded to the external grey matter, the interface between
3 grey and white matter and the mid-thickness surface. In addition, an inflated, very inflated and spherical versions of
4 the surfaces were provided. These surfaces had the exact number of vertices and faces as the original mesh and were
5 used for visualisation and comparison purposes. The feature maps obtained for all subjects were: sulcal depth, cortical
6 thickness, mean curvature and brain parcellations.

7 Cortical thickness (H) was estimated on fetal MRI using the Pyezzi python library⁵, computing the thickness of
8 tissues between the internal and external borders of the grey matter segmentation (Figure 1.F) [71].

9 **2.3. Mesh processing**

10 The FreeSurfer⁶ and Meshmixer⁷ softwares were used for the format conversion and manipulation of 2D surface
11 meshes resulted from the brain segmentation. Especially to combine both brain hemispheres into one single geometry,
12 repair surface imperfections (i.e., topology correction of defects such as handles or holes, artifacts, and fix non-manifold
13 edges and self-intersecting faces) and to define an appropriate density of mesh elements (Figure 1.B). The number of
14 mesh elements was empirically defined with a minimum of 1 M tetrahedra, since folding configuration (i.e., size and
15 number) did not substantially change with more elements, following prior mesh convergence studies in [67]. Netgen⁸
16 was used to generate volumetric tetrahedral meshes through the Delaunay triangulation Method (Figure 1C). The mean
17 value and standard deviation of the mesh density was of 1.89 ± 0.25 M tetrahedra.

18 Defining point-to-point correspondence across meshes is challenging. The anatomical multimodal surface match-
19 ing (aMSM) technique [52, 51] was originally proposed as a spherical registration tool to define spatial correspondences
20 between two anatomical surfaces, each projected onto a sphere. The alignment can be driven by any feature map ex-
21 tracted from the two surfaces to match. In our pipeline, we used the mean curvature and the Depth Potential Function
22 (described below in Section 2.5.2) as the guiding feature maps. The registration process involved a resampling of the
23 meshes which induced a one-to-one correspondence across the vertices of the matched surfaces, such that each vertex
24 corresponded to the same anatomical location across the surfaces.

25 The aMSM tool was also used to generate atlases from groups of meshes, as in [21]. Cortical surfaces were re-
26 sampled to a standard 158,762-vertex mesh and averaged (with Workbench Command tools⁹) to create a preliminary
27 atlas. Original surfaces were then registered to the preliminary atlas using aMSM (with default parameters) and aver-
28 aged to obtain the final atlas. Atlases were also created for separated hemispheres by resampling meshes to a standard
29 79212-vertex mesh.

2.4. Brain mechanical model

We evaluated the finite-element model proposed by Tallinen et al. [58, 59], further modified by [66], which simulates a realistic brain folding process. The C++ codes were open-source¹⁰. The model was built on the assumption that folding appears due to the instability produced by the different growth rates in interfacing materials; if one grew faster than the other (grey and white matter, respectively), the system would become unstable and buckle.

2.4.1. Constitutive equations

The cortical tissue was modelled as a compressible neo-Hookean material, with strain energy density function:

$$W = \frac{\mu}{2} [Tr(FF^T)J^{\frac{-2}{3}} - 3] + \frac{\kappa}{2} (J - 1)^2, \quad (3)$$

μ and κ being the shear and bulk modulus, respectively, F the deformation gradient and $J = det F$. As defined in [59, 67] we assumed $\kappa = 5\mu$, which corresponded to a modestly compressible material. As the model was based on differential growth theory, the ratio between grey and white matter shear stresses was the important parameter to fix. Based on stiffness micro-indentation measurements performed on ferret brains by Xu et al. [70], we assumed the modulus ratio between cortical layer and white matter region to be $\mu/\mu_{white} = 0.86$. The Cauchy Stress was given by:

$$\sigma = \frac{1}{J} \frac{\partial W}{\partial F} F^T. \quad (4)$$

Surface traction of each tetrahedral deformed face was given by $s_i = -\sigma n_i$, with n_i being face normals. Normal forces were obtained by distributing traction of each face equally for its three vertices.

Contacts at the brain surface were modelled via penalty-based vertex-triangle contact processing [16]. If a superficial face and node were closer than a threshold and the computed elastic force would bring them even closer, a contact force would prevent nodes from penetrating element faces.

In the evaluated model, the deformation gradient equation integrated the relative tangential growth (G), being defined as: $F = A(G\hat{A})^{-1}$.

2.4.2. Growth kinetics

The relative tangential growth tensor G described the tangential expansion perpendicular to the normal vector \hat{n} of the tetrahedron. It was obtained by $G = gI + (1 - g)\hat{n} \otimes \hat{n}$, where g was the relative tangential expansion ratio of the cortical layer with respect to the white matter zone. It stepped smoothly from grey ($g = 1 + \alpha_t$) to white matter ($g = 1$)

¹⁰<http://users.jyu.fi/~tutata11/codes.html>

1 as follows:

$$g = 1 + \frac{\alpha_t}{1 + e^{10(\frac{y}{H}-1)}}, \quad (5)$$

2 where y was the distance from the top surface, H the cortical thickness and α_t the growth rate. The latter was defined
 3 as $\alpha_t = (\sqrt{8} - 1)t$ and t as the time in the model, which ranged from 0 to 1. It was experimentally parameterised,
 4 according to gyrification index values measured on real folded brains [1, 65]. The equation that related t of the model
 5 with gestational age was:

$$t = 0.987e^{-e^{-0.134(GA-29.433)}}. \quad (6)$$

6 Along simulation time-steps, the evaluated model imposed a linear increase of cortical thickness, H , with the
 7 following expression: $H = H_i + \beta t$. β was empirically defined in [66] to be equal to 0.3 and H_i was set to the chosen
 8 initial global patient-specific cortical thickness. The volumetric mesh was built to include all brain tissue inside the
 9 grey matter (GM), including the white matter (WM). Each GM and WM element of the mesh was then identified based
 10 on its distance from the top surface and H , which varies throughout the simulation, to determine the different material
 11 properties of the different brain tissues.

12 2.4.3. Kinematics of finite growth

13 As described in [58], the energy of the system was minimized by damped second-order dynamics using an explicit
 14 solver for quasi-static equilibrium of the system:

$$v_{t+dt} = v_t + \frac{f_t - \gamma v_t V_n}{m} dt, \quad (7)$$

15 where $\gamma v_t V_n$ was the damping force, γ the viscous damping of value $\gamma = 0.05$, v_t the velocity and V_n the nodal volume.
 16 f_t was the combination of the elastic and contact forces, dt the time step, $m = 10a^3$ the nodal mass and a the mesh
 17 spacing in the initial configuration. Positions of the nodes of the mesh at the next time step were computed by:

$$x_{t+dt} = x_t + v_{t+dt} dt. \quad (8)$$

2.5. Validation

2.5.1. Global metrics

Several global metrics, computed using the python package Surface anaLysis And Modeling (SLAM)¹¹, were estimated to analyse and compare fetal, neonatal and simulated grey matter meshes. First, the surface area was computed as the sum of the area of all the triangles of the 2D mesh. Second, the volume was computed as the surface integral, corresponding to the whole volume enclosed in the 2D mesh of the grey matter. Third, the 3D gyrification index (3D-GI) was computed as in [67], by dividing the area of the mesh by the area of its smooth "convex hull" generated with SLAM.

2.5.2. Local metrics

Curvature

The curvature of the analysed grey matter meshes was calculated in two different ways. First, we used the python library SLAM to obtain the curvature based on the Rusinkiewicz estimation [54], and further compute the non-dimensional curvature (K^*), as defined in [29] and [21]. The Rusinkiewicz-based method defined the mean curvature of a vertex as the average of the two principal curvatures (directions where the normal curvature reached its minimum and maximum), which were the eigenvalues of the vertex normal curvature tensor computed as:

$$II = (u', v') \begin{pmatrix} K_1 & 0 \\ 0 & K_2 \end{pmatrix} \begin{pmatrix} u' \\ v' \end{pmatrix}, \quad (9)$$

where K_1 and K_2 were the eigenvalues and (u', v') the principal directions [54, 67]. The non-dimensional mean curvature was then computed by multiplying $K^* = KL$, where $L = \sqrt{SA/4\pi}$ being SA the total cortical surface area. Second, the Workbench command tools¹² were used to compute the curvature based on [38]. This second alternative was only applied for surface registration in the aMSM and the computation of the depth potential function (see below) due to its low computational cost.

Depth potential function

The depth potential function (DPF), based on [8] and computed with SLAM, was also used to characterise grey matter meshes. DPF is a measure of the average convexity of the cortical mesh. It was defined as the scalar function that had the closest mean curvature to the original surface in a least-square sense, also being spatially regular. The DPF computation was obtained solving the time-independent Poisson's equation. The curvature metric based on [38] was used as an input for computing the DPF.

¹¹<https://github.com/brain-slam/slam>

¹²<https://www.humanconnectome.org/software/workbench-command>

1 *Spectral analysis of gyrification (SPANGY)*

2 The SPANGY [22] method performed a spectral decomposition of the mean curvature of the grey matter meshes,
 3 based on the Laplace-Beltrami operator eigenfunctions. It allowed the parcellation of the cortical surface in 7 ordered
 4 spatial frequency bands (B0-B6) according to fold-related variations in curvature. As described in [22], the bands
 5 B1-B3 were related to global brain shape, while bands B4-B6 (folding bands) were associated to primary, secondary
 6 and tertiary folds. The sum of all the power accumulated in bands B1-B6 was defined as the Analysed Folding Power
 7 (AFP). For comparison purposes the power spectrum in each band was divided by the AFP to compute the relative
 8 folding power. The SPANGY code (MATLAB) was provided by the authors.

9 *Orientation of folds*

10 As proposed in [67], we calculated the angle between the gradient of Fiedler vectors [35] and the principal directions
 11 of curvatures [47] to characterise and compare the orientation of the folds on simulated and real meshes. The Fiedler
 12 vector was defined as the first non-constant eigenfunction of the Laplace-Beltrami operator and allowed to describe the
 13 longitudinal extension of surfaces. Extrema of Fiedler vectors were the most distant points within a geometry and its
 14 contour lines were cuts on the elongation axis. The direction of elongation was defined as the gradient of the Fiedler
 15 vector that was orthogonal to the contour lines. The principal directions of the curvatures were the corresponding
 16 eigenvectors of the curvature tensor. The folding orientation angles were obtained by the scalar product between the
 17 gradient of the Fiedler vector and the principal directions of the curvatures [67].

18 To quantify the uniformity of the angular distribution of folds the Kullback-Leibler (KL) divergence or also called
 19 relative entropy was used. It was used to measure differences between two probability distributions. The KL divergence
 20 from probability distribution P to probability distribution Q was defined as:

$$D_{KL}(P||Q) = \sum_i P(i) \log \frac{P(i)}{Q(i)}. \quad (10)$$

21 In our study, P corresponded to the fold angular distributions on the folded surface while Q represented the theoretically
 22 uniform distribution of fold angles [67]. The code to compute the orientation of folds (MATLAB) was also provided
 23 by the authors.

24 **2.6. Experiments**

25 Several experiments were carried out to identify the most critical steps and relevant model parameters of the com-
 26 putational pipeline, as well as the similarity between simulations and observations. First, we assessed the accuracy of
 27 the fetal brain segmentations provided by the modified dHCP structural pipeline, comparing them with ground-truth

Table 2

Comparison between ground-truth and automatic segmentations.

	Dice Coefficient	Hausdorff Distance (mm)	Volume Similarity
Grey matter	0.78 ± 0.05	6.49 ± 1.06	0.96 ± 0.03
White matter	0.95 ± 0.01	8.80 ± 1.80	0.99 ± 0.01

1 manual annotations. Second, a sensitivity analysis on the simulations was performed, running the model with six dif-
 2 ferent initial global cortical thicknesses (H_i), ranging from 0.74 mm to 5.96 mm in a subset of 8 fetal meshes (4 VM;
 3 2 of early and 2 of late-onset; 4 controls; 2 of early and 2 of late-onset). Values were chosen as in [66], of which 0.74
 4 mm and 5.96 mm were assumed to be abnormal H_i values. An additional simulation was run for each subject with the
 5 global cortical thickness derived from its corresponding patient-specific MRI (i.e., average over the whole brain). The
 6 effect of regional growth was then assessed, using a cortical parcellation (using the DrawEM tool [39, 40]) to specify
 7 a different growth for each region in the biomechanical model.

8 3. Results

9 3.1. Data preprocessing

10 Figure 2 displays a visual comparison between ground-truth and automatic segmentation results provided by the
 11 modified dHCP pipeline. Beyond the central region in white matter (not relevant in our study) some discrepancies
 12 were found in regions with larger curvature. Quantitative results are shown in Table 2. An average Dice of 0.78 ± 0.05 ,
 13 HD of 6.49 ± 1.06 and VS of 0.96 ± 0.03 were obtained for grey matter, and of 0.95 ± 0.01 , 8.80 ± 1.80 and 0.99 ± 0.01 ,
 14 respectively, for white matter and ventricles. Snapshots of all fetal and neonatal meshes of grey matter used in this study
 15 are included in Appendix A. Two of the 31 initial cases were discarded for the final cohort because the segmentation
 16 step did not provide grey matter labels that could be used to build finite-element meshes (i.e., not continuous tissue
 17 requiring excessive manual intervention).

18 Figure 2 also provides a visual example of a cortical thickness map obtained with the Pyezzi python library. Cortical
 19 thickness in fetal MRI ranged from 1.20 mm to 1.78 mm, with mean value and standard deviation of the mean 1.53 ± 0.16
 20 mm and within-subject mean standard deviation of 0.45 mm. The cortical thickness measured in neonatal MRI was
 21 1.32 ± 0.17 mm.

22 Sets of fetal, neonatal and simulated meshes are displayed in Figures 7, 8 and 9, respectively.

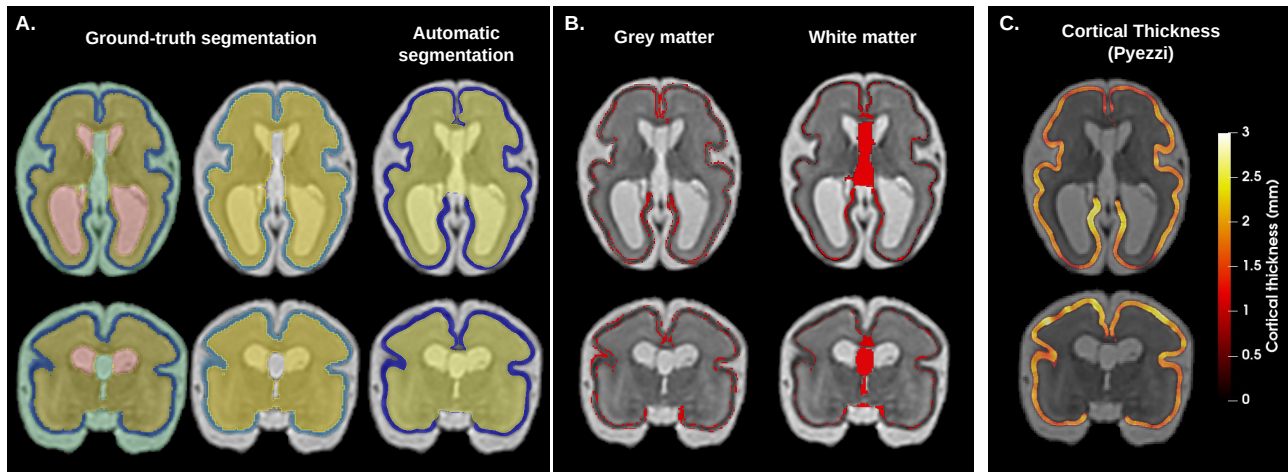

Figure 2: Comparison of ground-truth and automatic segmentations. (A) Axial and coronal views of ground-truth segmentations (all labels and only grey and white matter combined with ventricles) and automatic segmentations. (B) Differences (red) in grey (left) and white (right) matter. (C) Cortical thickness estimated from magnetic resonance images.

1 3.2. In-silico simulations

2 3.2.1. Varying global cortical thickness in brain simulations

3 The effect of having distinct initial global cortical thickness in brain simulations can be seen in Figure 3. Mean
 4 curvatures were plotted versus H_i (Figure 3.A), quantitatively showing the decrease in curvature in all meshes when
 5 increasing cortical thickness. Both mean curvature and depth potential function mapped onto cortical surfaces and
 6 spheres (Figure 3.B) clearly displayed how low values of H_i created overly convoluted cortex, while with high values
 7 gyri became fewer and wider. In terms of folding bands, SPANGY results (Figure 3.D) showed that the power spectrum
 8 of curvature was mostly of band 6 with the smaller cortical thickness value (i.e., $H_i = 0.74$ mm), mainly creating
 9 folding patterns similar to tertiary folds. As cortical thickness increased, the power in bands 5 and 6 also progressively
 10 rose, while that of band 4 decreased. Power spectrum maps plotted on the cortical surfaces (Figure 3.E) illustrate this
 11 scenario, with a greater presence of bands 5 (orange) and 6 (red) at higher values of H_i , where the nature of the folding
 12 was of first and second order.

13 3.2.2. Global vs regional growth in brain simulations

14 Results of this experiment are shown in Figure 4. With the implemented regional growth, the simulated mesh
 15 presented slightly increased volume in the parietal and occipital areas, although still far from the global shape of the
 16 real neonatal cortex (see Figure 4.A). The standard deviation between the coordinates of the vertices of the simulated
 17 and neonatal meshes was mapped on an inflated surface, as can be observed in Figure 4.B). It depicts how regional
 18 growth reduced the differences between simulations and observations in the parietal area. Box plots of global metrics
 19 also showed an increase in volume and surface area of regional simulations compared to baseline (Figure 4.C).

Patient-specific mechanical models of brain development

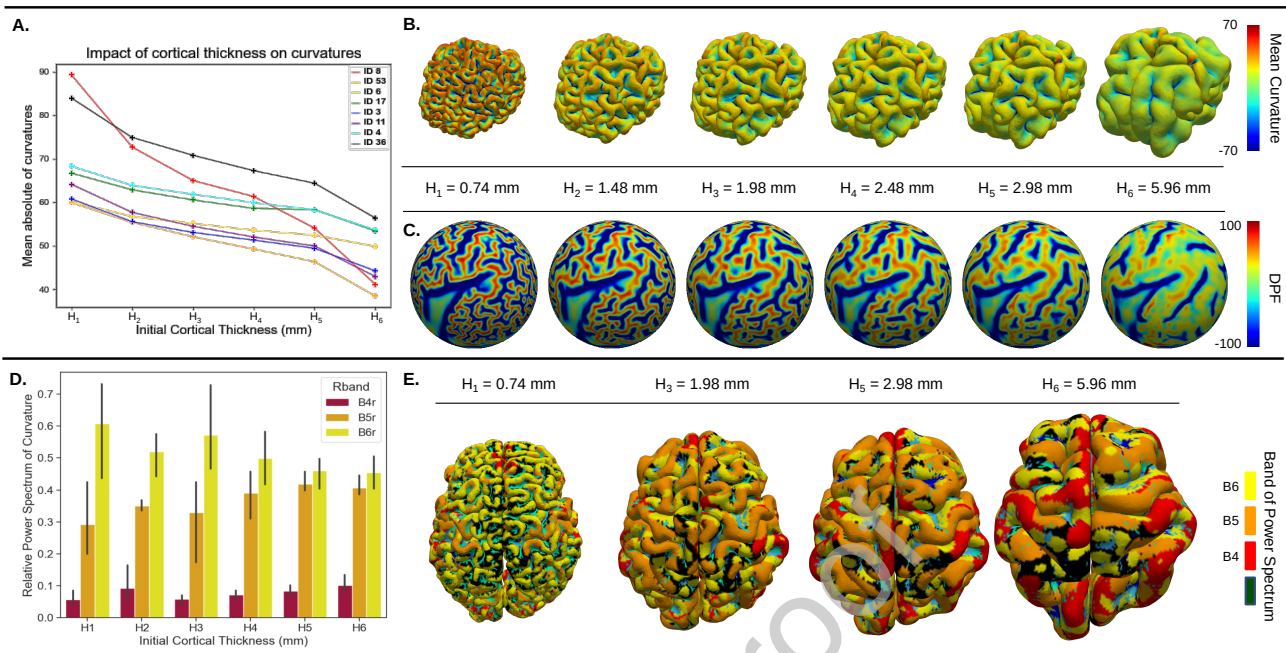

Figure 3: Impact of varying initial cortical thickness on simulated meshes. (A) Plot of mean absolute value of curvature of each mesh and level i of cortical thickness (H_i) ranging from 1 to 6. (B) Simulated cortical morphologies with curvature maps and (C) spheres coloured by the depth potential function (DPF) obtained with each initial cortical thickness. (D) Relative power spectrum of curvature in bands B4-B6 displayed as a bar plot and (E) onto cortical surfaces for four of the implemented H_i .

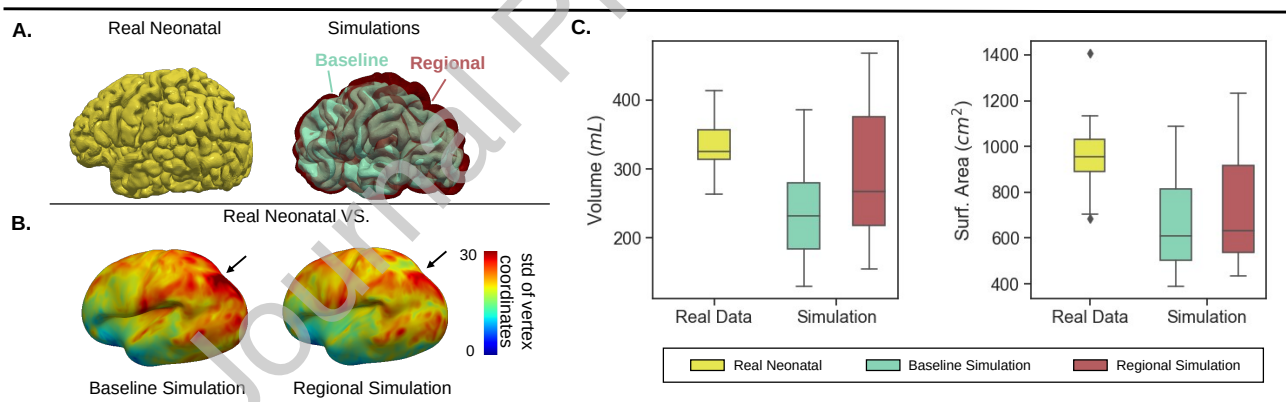

Figure 4: Comparison between simulations with global and regional growth. (A) For one subject, neonatal real cortex and both overlapped global and regional growth simulations. (B) Standard deviation of the vertex coordinates between neonatal and brain simulations plotted onto an inflated surface. Arrows point to the parietal region. (C) Box plots of volume and surface area for each group of meshes.

1 3.2.3. Neonatal data vs brain simulations

2 A comparison between neonatal real data and simulations is shown in Figure 5. Cortical surfaces and curvature
 3 maps of fetal, neonatal and simulations are displayed for two subjects (Figure 5.A): 1) a ventriculomegaly condition,
 4 with fetal MRI acquired at GA 28 (early onset); and 2) a control case, with fetal imaging available at GA 32 (late
 5 onset). Although the nature of the folding patterns was reproduced by the biomechanical model, there were notable

1 differences when comparing simulated to real neonatal meshes. The sagittal view of the cortices revealed a lack of
2 similarity in their overall shape, especially in the parietal region, which more closely resembled that observed in the
3 fetal meshes. Regarding the time (onset) at which fetal MRIs were acquired, simulations starting at advanced GA
4 were more comparable to their corresponding real neonatal meshes. Conversely, simulations of meshes starting from
5 GA 26-28 had a lower match with their corresponding neonatal real data. Fetal brains at early GA, apart from being
6 smaller in size than neonatal ones, only presented the central and lateral sulcus (Sylvian fissure); the absence of more
7 complete structural information resulted in simulations with higher variability. The identification of sulci was visually
8 performed on the DPF maps plotted onto spheres. The Sylvian fissure, central sulcus, post-central sulcus and superior
9 temporal sulcus were identified in all six meshes, thus revealing the ability of simulations to reproduce these patterns.

10 Figure 5.B shows the atlases of each group of meshes (i.e., fetal, simulation, neonatal), coloured by the depth
11 potential function estimation. It can be seen that the average cortical surface of simulations have created several gyri
12 (red colours in the figure) from the fetal stage, but not as many as observed in the neonatal atlas. Box plots of global
13 metrics are displayed in Figure 5.C to compare fetal, simulation and neonatal brains. The simulations underestimated
14 the surface area, volume and 3D-GI observed in neonatal meshes, by a 30.9%, 26.9% and 14.4%, respectively.

15 3.2.4. Controls vs ventriculomegaly cases

16 Figure 6 displays differences between control and VM cases, for both simulations and real data. Surface area and
17 volume were underestimated by simulations when compared to values of neonatal meshes. The increase in fetal surface
18 area and volume in the simulations was of 64% and 42%, respectively, whilst real neonatal meshes had an increase of
19 75% and 58%. No significant differences were observed in mean surface values between controls and VM, but controls
20 presented lower volume (6%) than VM in both simulated and real meshes ($p < 0.05$). 3D-GI was lower in simulations
21 than in real neonatal meshes; values for controls (simulations: 2.68 ± 0.31 , neonatal: 3.20 ± 0.32) were higher than
22 for VM (2.63 ± 0.27 , 2.99 ± 0.37).

23 Results in depth potential function and mean curvature were similar for both groups: fetal cases, 12.75 ± 6.64
24 (controls) and 11.11 ± 4.53 (VM); neonatal cases 33.29 ± 4.62 (controls) and 33.62 ± 4.37 (VM); and simulations,
25 45.12 ± 6.57 (controls) and 42.81 ± 7.65 (VM). Statistically significant differences ($p < 0.05$) were obtained between
26 simulations and neonatal data but not between VM and controls. In addition, fetal meshes showed bigger mean and
27 dispersion of the KL divergence, i.e., more isotropy in their surface orientation: controls: $6.34 \pm 4.57 \times 10^{-3}$; VM,
28 $4.96 \pm 5.16 \times 10^{-3}$. Simulations presented larger KL divergence values than neonatal meshes (26% in controls and
29 35% in VM), which suggested less anisotropy in their fold orientation.

30 SPANGY results are shown in Figure 6.B. No significant differences were observed between controls and VM
31 in none of the three groups (fetal, neonatal, simulations). Fetal meshes presented higher values of relative folding

Patient-specific mechanical models of brain development

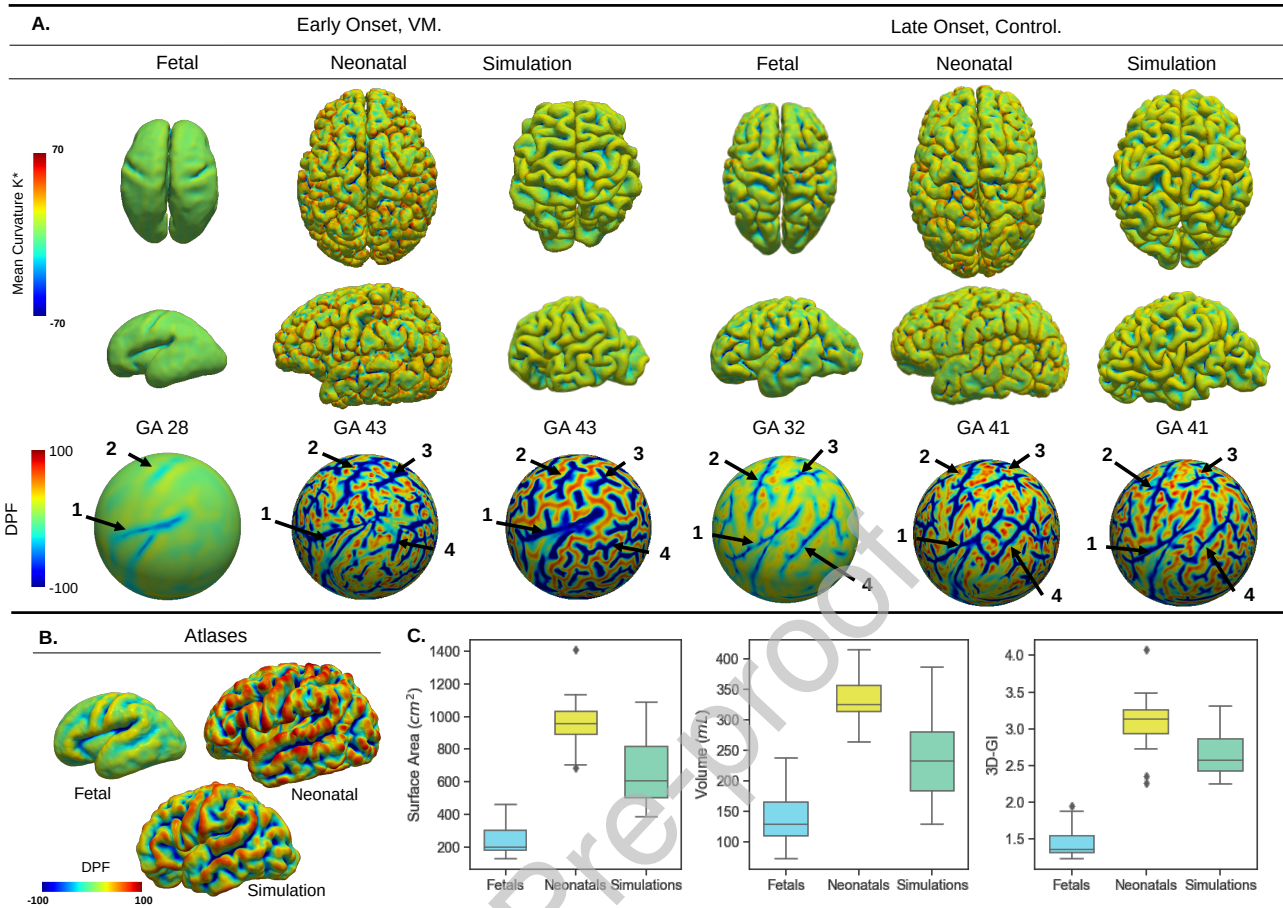

Figure 5: (A) Cortical morphologies and curvature maps of fetal and neonatal meshes of two subjects (a ventriculomegaly, VM, fetal brain at early gestation and a control one of late onset), together with the resulting brain simulations. Depth potential function (DPF) maps are mapped onto spheres with arrows pointing at the following: 1 = Sylvian fissure; 2 = Central sulcus; 3 = Post-Central sulcus; 4 = Superior Temporal sulcus. (B) Atlases of real fetal and neonatal and simulated meshes. (C) Global metrics of surface area, volume and 3D gyrification index (3D-GI) for the whole cohort.

1 power in band 4 (0.154 ± 0.057) than neonatal ones (0.048 ± 0.01) and simulations (0.079 ± 0.019). For neonatal
 2 real data, power spectrum in band 6 (0.628 ± 0.023) roughly doubled the power in band 5 (0.285 ± 0.025), while for
 3 simulations they were of 0.440 ± 0.081 in band 5 and 0.431 ± 0.111 in band 6. Atlases and inflated surfaces with DPF
 4 (Figure 6.C), qualitatively showed how, although minor discrepancies in folding were present between controls and
 5 VM, major differences in size, shape and folding were prominent between groups. Overall, results showed that the
 6 differences between simulations and real data were much larger than those observed between pathological and healthy
 7 conditions.

8 3.2.5. Computational times

9 Table 3 shows a breakdown of the tasks performed at each step of the pipeline along with an estimate of the
 10 computational time required to complete them. Segmentation with the dHCP structural pipeline took 15-20' for each

Patient-specific mechanical models of brain development

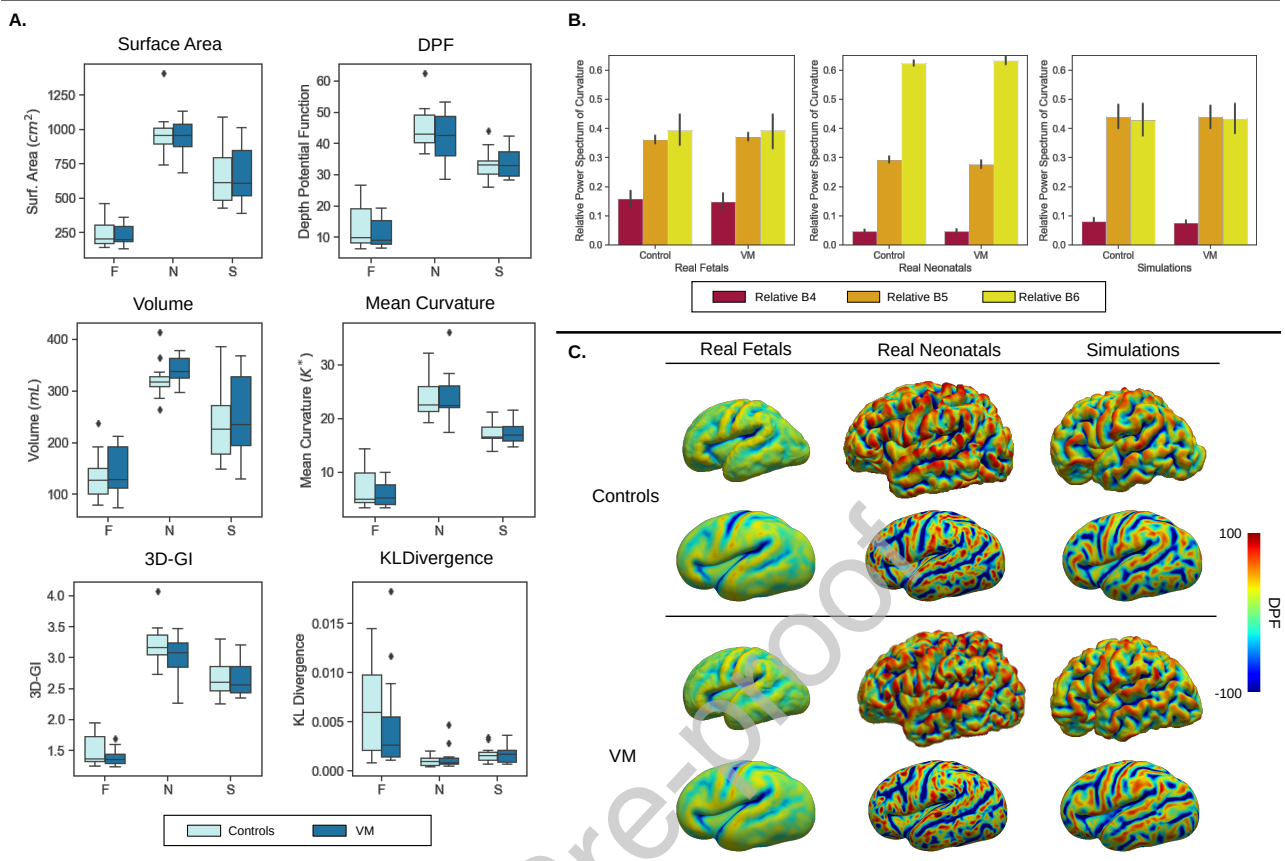

Figure 6: Comparison of real data and simulations for control and ventriculomegaly (VM) cases. (A) Box plots for global metrics and mean values of depth potential function (DPF), mean curvature and Kullback-Leibler (KL) divergence. (B) Bar plots of relative power spectrum of curvature in folding bands. (C) Atlases of cortical surfaces for each group of meshes (control and VM, simulations (S), real fetal (F) and neonatal (N)), coloured by DPF distribution. Below each atlas, inflated versions of the surfaces are included.

- 1 MRI dataset. Mesh processing took around 20-30' but it could vary depending on the nature of meshes, since this
- 2 step was highly manual. The computational model was the longest process, in particular when the solver did not
- 3 converge the first time it was run. In that case, in an iterative manner the mesh was re-processed (by repairing the
- 4 problematic area or re-meshing the whole mesh), the volumetric mesh was generated again and the model was re-run.
- 5 The calculation of the evaluation metrics required different times. For instance, SPANGY is time-consuming because
- 6 it requires to solve a generalized eigenvalue problem with thousand of eigenvectors in a very large dimension.

Table 3
Computational time required to run the whole pipeline.

Pipeline Stage	Task (software)	Computational time (min)
Segmentation	Segmentation (dHCP structural pipeline)	15-20'
Mesh Processing	Mesh Processing (Meshmixer)	20-30'
	Volumetric mesh generation (Netgen)	3-5'
Computational Model	C++ Solver (HPC Cluster)	25-35 h
Evaluation metrics	Global metrics (Slam, Python)	<1'
	Mean curvature (Slam, Python)	5-8'
	SPANGY (Matlab)	15-30h
	Depth potential function (Slam, Python)	3-5'
	Folds orientation (Matlab)	20-30'
	aMSM	10-15'

4. Discussion

Personalised computational models are progressively being more used in medical fields such as cardiology [45], to support diagnosis [14], therapy optimisation and risk prediction [42]. Together with statistical (e.g., machine learning) models, they are the foundations of digital twins for improved patient-specific clinical decisions and precision medicine [13]. However, mechanical models of brain development are not that mature yet, basically been tested on synthetic or idealised geometries due to the difficulties of obtaining longitudinal imaging data. However, recent advances in imaging acquisition and processing techniques are leading to better quality images of the fetal and neonatal brain. In this work, we present a computational pipeline, based on open-source tools, that allowed to successfully process fetal MR images of 29 subjects, building patient-specific meshes to simulate brain growth/folding, and comparing the resulting simulations with neonatal data from the same subjects with several global and local metrics in a common reference space. The different steps in the pipeline for geometrical model building and the brain mechanical modelling influenced the final simulation results and its comparison with neonatal data, as described in the following.

4.1. Geometrical model building

4.1.1. Brain segmentation

Brain segmentation was the initial step of the pipeline since fetal MRI 3D reconstruction was already performed in the standard imaging protocol in the hospital. Inaccuracies to reconstruct fetal MR images would obviously affect the whole modelling pipeline; it is then necessary to apply motion correction algorithms (see [6] for options) to provide high-resolution 3D data to process.

Patient-specific brain modelling of several cases requires the automatization of 3D fetal brain MR data segmentation. In our work, we were able to compare brain tissue segmentations provided by the modified dHCP pipeline with manual labels in 13 fetal MR images. Overall, automatically obtained grey matter labels were similar to the ground-truth after visual inspection of the results (see Figure 2, with more differences in the area between the hemispheres and systematically over-estimating sulcal depth. The estimated quantitative metrics (e.g., Dice) were good enough (0.78, above inter-rater variability recently measured in [46]), considering the complexity of cortical morphology. However, two cases (out of 31) were discarded due to inaccurate GM segmentation that would require almost fully manual labelling. Improved fetal brain segmentation techniques, using deep learning techniques, are already appearing (e.g., [36]) thanks to the availability of Open Access data in initiatives such as the Fetal Tissue Annotation (FETA) challenge [46]¹³. Regarding neonatal brain segmentation, we made use of the standard dHCP pipeline [40] (Dice of around 0.80 for cortical GM, reported in [39]) but its accuracy in our data could not be quantified due to the lack of ground-truth data at this stage.

¹³<https://feta-2021.grand-challenge.org/>

1 **4.1.2. Cortical thickness estimation**

2 In the implemented brain mechanical model, the initial cortical thickness (width of grey matter layer) is a key
3 parameter for the simulated folding [66]. Cortical thickness estimation directly depends on the brain segmentation
4 accuracy. Using a well-known tissue thickness method [71], the cortical thickness values for fetal MRI (average of
5 1.53 ± 0.16 mm) were larger than the ones reported in [9] (average of 1.05 mm) but within the range of the ones
6 published in Vasung et al. [63] (1-2 mm from GA 26 until 42). On the other hand, we found cortical thickness
7 estimated in neonatal data less reliable. In a counter-intuitive way, the average value of cortical thickness was lower in
8 neonatal than in fetal data. Neonatal cortical thickness was estimated from the dHCP-based segmentations, from which
9 values of 1.04 mm at 36 weeks to 1.10 mm at 44 weeks have been reported [40], in concordance with our results. The
10 main reason for this discrepancy was the topological differences in GM segmentations in the two stages, with neonatal
11 segmentations being too thin and discontinuous comparing to fetal ones, having a large influence on cortical thickness
12 values.

13 **4.1.3. Meshing**

14 Building patient-specific meshes of human organs with complex morphologies is one of the main bottlenecks that
15 has prevented a more widespread clinical translation of computational models, due to the difficulties on automatis-
16 ing the process. Tetrahedral meshes were chosen to build patient-specific brain meshes since they usually can better
17 discretise complex geometries than hexahedral representations. Still, the building of 29 patient-specific brain meshes
18 was a labour-intensive process that should be better streamlined in the future. Mechanically evolving a fetal, relatively
19 smooth, brain into the highly convoluted cortical surface post-natally is a numerical problem pushing FEM techniques
20 to the limit. For instance, large deformations may be needed but they may lead to negative Jacobian or overlapping ele-
21 ments impeding finding correct solutions. Sophisticated meshing and solver methodologies are required, often asking
22 for manual intervention in an iterative framework. In our experiments, 10 cases out of 29 needed several re-meshing
23 iterations (i.e., removing or smoothing elements, correcting topological defects such as handles or holes) to ensure
24 convergence of the solutions. The contact penalty force implemented in [59] was key to avoid non-negative Jacobian
25 mesh elements through simulation time-steps. Meshless techniques such as the ones based on smooth particle hydro-
26 dynamics, already successfully applied for electromechanical simulations of the heart [37], or based on the material
27 point method to study live human brain dynamics [19], should be explored for brain development modelling since they
28 are suitable when meshing is challenging.

29 **4.2. Brain mechanical modelling**

30 Initially, the available open-source brain mechanics solver was adapted to have as input any fetal brain geometrical
31 mesh, at any initial GA and delivery week, since several routines were hard-coded to only work on particular idealised

1 geometries. Starting from patient-specific fetal brain geometries, the model was able to reproduce the convoluted
2 nature of brain folding patterns in neonatal stages described in [59, 20]. Spherical representations of metrics (e.g.,
3 DPF in Figure 5) were effective to identify the resemblance of certain sulcal patterns (e.g., central and post-central
4 sulcus, 2 and 3 in Figure 5, respectively) between neonatal simulations and observations, even in cases starting from
5 an early GA fetal mesh. It is remarkable the stability of the central and temporal sulci through the simulation process,
6 as it was earlier demonstrated in spheres [34], likely due to their presence in fetal meshes (range between 26 to 34 GA).
7 Nevertheless, it is evident that the simulated meshes still present large differences with real neonatal data in terms of
8 global shape and folding patterns (see results in Figure 5 and Figure 6). Mechanical simulations consistently generated
9 smaller (as seen by the surface area and volume metrics) and less convoluted (from 3D-GI and curvature metrics)
10 brains than neonatal real ones. The detailed characterisation of folds with SPANGY, DPF and orientation-based metrics
11 showed that simulations created, compared to neonatal real patterns: 1) less convex folds in average and with a smaller
12 range of different values (from DPF); 2) less uniform (i.e., isotropic) fold orientation (from KL divergence); and 3) an
13 insufficient percentage of secondary folds (see orange bars in Figure 6 corresponding to B5), slightly overestimating
14 primary folds. The more isotropic orientation of the folds in the simulations was due to the model assumption of
15 uniform and isotropic growth across the entire grey matter geometry, which is an over-simplification of brain growth
16 dynamics during fetal brain development. Comparing simulated neonatal brains of controls and ventriculomegaly
17 cases, we observed the same subtle differences than in real data in all metrics: slightly less convoluted brain (from
18 3D-GI) and reduced volumes in ventriculomegaly cases, in agreement with literature [56, 33, 7]. To complement the
19 evaluation of the simulations, future studies will also include the computation and analysis of the sulcal depth, sulci
20 identification and number of folds.

21 It is important to point out the relevance of the initial fetal brain gestational age, as can be seen in Figure 5:
22 with initial smoother meshes (i.e., earlier GA such as in Figure 5.A), the brain mechanical model generates simulated
23 neonatal brains further from data than with initial meshes where more folds are present (i.e., later fetal GA, such as in
24 Figure 5.B). This is in agreement with conclusions found in the literature [30, 49, 17], stating that first order folds are
25 thought to be regulated by genetic and cellular pre-patterning processes. These were not included in our experiments
26 since initial fetal brain meshes in our study were from 26 weeks on, with primary folds already formed. Recent
27 pioneering work on multi-scale modelling of brain development [72], including cellular dynamics, has the potential to
28 better simulate the generation of folds that have not appeared yet. Additionally, it would be interesting to incorporate
29 axonal tension forces to the current model of Tallinen et al. [58, 59] since it is only based on the differential growth
30 between cortical and white matter regions. As seen in [20], although it has been demonstrated that axonal tension does
31 not drive gyrification, it does have a relevant role in the modulation of folding patterns.

32 Two additional parameters were important to obtain different brain simulation patterns: cortical thickness and

1 brain growth characteristics. When modifying the initial global cortical thickness, the resulting simulations were
2 in agreement with literature [17, 66], with a thinner cortex leading to more folded brains and vice versa (such as
3 in polymicrogyria and lissencephalic brains, respectively). In our sensitivity analysis, imposing an initial cortical
4 thickness of 1.48 mm or 1.98 mm (H_2 and H_3 in Figure 3) provided the closer simulations to neonatal data. However,
5 we finally tailored the initial global cortical thickness for each simulation to the one extracted from the MRI of each
6 individual, further personalising the model. In this context, it is also worth mentioning that differences in the order
7 of the resolution of the acquired magnetic resonance images (0.5 mm) should not be relevant. In the future, different
8 cortical thickness values will be imposed locally to different regions based on MRI estimations, which should lead to
9 less homogeneous and more realistic behaviour of the simulated folding patterns.

10 For simplicity, cortical growth was initially assumed uniform and isotropic in the initial experiments. However, pre-
11 vious studies have demonstrated inter-hemisphere gyrification differences [48] and non-homogeneous shape changes
12 between fetal and neonatal cortical surfaces [21]. A simple implementation of regional growth was then implemented,
13 showing qualitative and quantitative improvements in certain areas such as the parietal region. Refined spatio-temporal
14 local growth patterns based on prior observations (e.g., from Garcia et al. [21]), already partially tested on atlas fe-
15 tal brains [65], will improve the realism of the presented brain simulations. In parallel, anisotropic growth could be
16 incorporated, as in [64], dependent on the mean curvature of the cortex to achieve preferential growth in either gyri
17 or sulci. Local constraints based on the particular characteristics of individual sulci and related cytoarchitecture, in
18 particular the primary folds (e.g., central sulcus), would help to better control the folding pattern evolution in the
19 simulations. Additionally, the equations of the biomechanical model accounted for a stress-independent growth, with
20 values being imposed throughout the simulation. For more realistic simulations, the model must be modified to allow
21 for biomechanical feedback, so that growth is readjusted according to the stress fields generated at each point in the
22 process.

23 Material properties of both grey and white matter were defined globally by the bulk and shear modulus. However,
24 there is evidence that they vary significantly not only across regions of the brain [11], but also throughout the fetal
25 development, when the brain constantly adapts to new functional demands. A better characterization of brain tissue
26 mechanical properties is becoming possible with recent advanced experimental set-ups [10] and should definitively be
27 integrated into the existing brain development models. Sensitivity analysis studies should then be carried out to assess
28 the influence of material properties on the simulation results.

29 5. Conclusions

30 Computational models of brain development are arguably in its infancy, comparing to the ones in other human or-
31 gans such as the heart. One of the main causes is the absence of validation studies confronting simulation results with

1 observations, due to the difficulty of having longitudinal brain data from the same subject. More multi-disciplinary
2 efforts between data scientists, modellers and clinicians would also be beneficial for improving the realism of existing
3 simulations. In this work we have presented a complete pipeline for creating and validating patient-specific mechani-
4 cal models of brain development, which has been applied to 29 fetal brain MRI data. Simulations of neonatal brains
5 remarkably mimicked folding patterns observed in MR images. However, the developed pipeline allowed to quantify
6 important differences between model results and observations at different time-points or subjects, both globally and
7 locally, with the employed metrics and the building of a common reference system. In consequence, some of these
8 metrics could be used for model parameter optimisation within data assimilation processes such as for determining
9 the optimal cortical growth in each region to better match neonatal data. The different open-source tools used in the
10 presented pipeline also facilitate joint multi-institutional efforts, necessary to bring the field of brain mechanical mod-
11 elling forward. Initiatives such as the dHCP¹⁴, releasing tools and data for fetal and neonatal imaging research, will
12 soon allow the creation of benchmark studies to compare models based on different hypothesis (i.e., axonal tension,
13 differential growth, stress-dependent growth) and integrate them, together with other statistical or phenomenologi-
14 cal approaches such as disease progression models [2]. Brain mechanical model researchers should then follow the
15 example of neuroimaging researchers, pioneers in Open Science, and jointly work in multi-disciplinary teams with
16 neurologists to better understand the wonders of brain development.
