Abstract

Earthquakes are the most commonly cited cause of offshore slope failure, followed by high sedimentation rates and ensuing pore pressure build-up. In the South Alboran Sea, the moderate seismicity ($M_w=6.4$) of the strike-slip Al Idrissi Fault Zone does not appear to control directly the landslides distribution. To provide a preliminary geohazard assessment, we characterized the spatial distribution, the volume and the ages of the submarine landslides from multibeam and seismic reflection data in the southern part of the Alboran Sea. Since the Quaternary numerous submarine landslide processes have affected the marine sedimentary cover with volumes of the mass transport deposits (MTD) estimated between 0.01 and 15 km³. West of the Al Idrissi Fault Zone, along the South Alboran Ridge's northern flank, the distribution of the MTD follows the SW-NE bank and ridge trend that correlates with blind thrusts and folds covered by a plastered contourite drift. A pockmark field, related to fluid escape, is visible near landslide scars where the contourite drift is relatively thicker. In this area, landslide scars occur on variable slopes (2-24°) and their associated MTDs show variable decompacted volumes (0.01-10 km³). East of the Al Idrissi Fault Zone, between the Alboran Ridge and

34 the Pytheas Bank, the mapped MTDs have uneven volume. The smaller ones (<1 km³) have their slide
35 scars on steep slopes (>10°), whereas those of the largest ones (3-15 km³) occur on gentler slopes (<5°).
36 These observations and a slope stability analysis suggest that the combination of seismic shaking, blind
37 thrusts activity, relatively high sedimentation rate of contourite deposits with potential weak layers,
38 and fluid escape dynamics are likely the main controlling mechanisms. These causal factors would
39 explain the concentration of landslide head scarps at the edge of the thickest parts of the contourite
40 drifts (i.e. crest). Slides may have been controlled locally by fluid overpressures in line with blind
41 thrusts. Additionally, low to moderate seismicity potentially triggered by nearby faults might regionally
42 have played a role in destabilising the landslides since 1.12 Ma (Q2 unit), which coincides with the
43 propagation of the Al Idrissi Fault Zone in the southern Alboran Sea.

44 **1 Introduction**

45

46 Submarine landslides, encompassing all forms of submarine slope failures, may translate into the
47 destruction of seabed infrastructures and coastal areas' collapse into the sea. They can mobilize up to
48 thousands of km³ of seafloor material (e.g. Storegga Slide, 8200 years ago; Haflidason et al., 2004;
49 Calvès et al., 2015), volumes that are substantially larger than their subaerial counterparts (Dussauge
50 et al., 2003; Urgeles and Camerlenghi, 2013). Mobilization of seafloor volumes may trigger tsunamis
51 (e.g., Papua-New Guinea in 1998, Tappin et al. 2001) and submarine cable breaks (e.g., Taiwan in 2006,
52 Marle, 2007; Carter et al., 2014).

53 Mediterranean coasts have a history of tsunamis caused by submarine landslides (Nice in 1979, Dan et
54 al., 2007; Gioia Tauro in 1977, Colantoni et al., 1992; Stromboli in 2002, Chiocci et al., 2008; among
55 others). Earthquakes can generate submarine landslides and tsunamis (Messina in 1908, Valensise and
56 Pantosti, 1992; Amorgos in 1956, Okal et al., 2009; Gioia Tauro landslides in 1977, Zaniboni et al. 2014;
57 Boumerdès in 2003, Alasset et al., 2006; Cattaneo et al., 2012). A recent event of earthquakes
58 generating submarine landslide and tsunami has recently been documented on the Samos Island and
59 Izmir coast (October 2020; Triantafyllou et al., 2021). In the southern part of the Alboran Sea, two
60 studies, the ~1 km³ Alborani (Macías et al., 2015) and the ~2 km³ Xauen (Rodriguez et al., 2017)
61 submarine slides, model the tsunamigenic potential at the Moroccan coastline and suggest local run-
62 ups in the order of 1 m. These results illustrate that small submarine landslides would flood densely
63 populated coastal cities in Spain and Morocco, demonstrating a regional geohazard. These examples
64 illustrate that offshore landslides represent an important risk for the Mediterranean coastal
65 communities, industry, and offshore infrastructure. The Spanish and Moroccan Mediterranean coasts

66 hold several environmentally protected areas (UNEP/MAP, 2015), important maritime transport
67 routes, and have great potential for aquaculture zones (e.g., in the Al Hoceima area, Nada et al., 2018).
68 The increasing number of infrastructures and population (expected to grow by 75% by 2025,
69 UNEP/MAP/MED POL 2012) make the assessments of submarine landslide geohazards a key condition
70 for their safe and sustainable development.

71 In the Alboran basin, tectonics, deep water currents and sea-level changes shaped the seafloor into its
72 present-day topographic complexity with structural highs and depressions enclosed within a relatively
73 small area (~50 000 km²) (e.g. Ercilla et al., 2016; Estrada et al., 2018) (Fig. 1). Seafloor observations
74 show the occurrence of landslides that have been related to seismic faults (Estrada et al., 2018;
75 Galindo-Zaldivar et al., 2018), fluid dynamics and contourite deposition (Somoza et al., 2012). Most of
76 the recent seismicity (e.g., Gracia et al., 2019) concentrates along the NNE-SSW Al Idrissi Fault Zone
77 (AIFZ), which crosses the whole basin. In line with the seismogenic AIFZ, earthquake shaking could be
78 considered as the main potential triggering mechanism of slope failures (Galindo-Zaldívar et al., 2018).
79 However landslides are scarce in the most active area (Figs 2A, B) and localize far from the Al Idrissi
80 seismogenic zone merely along a NE-SW E-W folds and faults belt called the Alboran Ridge and the
81 South Alboran ridge (Fig. 1, AR and SAR respectively; Lafosse et al., 2020).

82 Sediment core studies reveal large variability in texture and geotechnical properties in the Alboran
83 Basin with strong variability in the grain size of the contourite deposits (Baraza et al., 1992; Ercilla et
84 al., 2021). Stability analysis suggests that the sediment is stable under static gravitational loading but
85 potentially unstable under seismic loading (Baraza et al., 1992).

86 Except in the northern part of the Alboran Basin (Casas et al., 2011; Alonso et al., 2014), most of the
87 submarine landslides' geometries and chronologies are yet to be described, and their causal factors
88 still remain poorly known. The triggering and preconditioning factors causing the submarine landslide
89 spatial distribution is still unresolved (Fig. 2A, B).

90 To provide a preliminary geohazard assessment, we characterized the spatial distribution, the volume
91 and the ages of the submarine landslides from multibeam and seismic reflection data in the southern
92 part of the Alboran Sea. We focus the discussion on the triggering and preconditioning factors, in
93 particular with regards to slope steepness, fluid escapes, tectonic features and earthquakes by
94 performing morpho-structural and slope stability analysis. Our data reveal that submarine landslides
95 occurred repetitively throughout the Quaternary, notably after a tectonic reorganization of the
96 Alboran Basin from 1.12 Ma.

97

98 **2 Geological setting**

99 The Alboran Sea was formed due to westward Tethyan slab retreat (Calvert et al., 2000; Jolivet et al.,
100 2008; Platt et al., 2003; Spakman and Wortel, 2004; Do Couto et al., 2016; d'Acremont et al. 2020)
101 within a compressive context of the African-European convergence since the end of the Oligocene
102 (Comas et al., 1999; Gutscher et al., 2002; Jolivet et al., 2009; Mauffret et al., 2007; Mauffret et al.,
103 1992). Above the metamorphic and volcanic basement, a thick Miocene depocenter is located in the
104 western basin where mud volcanoes and other shale tectonic processes affect the seafloor (Fig. 1)
105 (Pérez-Belzuz et al., 1997; Comas et al., 1999).

106 From the Tortonian onward, compressive tectonics reactivated extensional and strike-slip structures
107 (Estrada et al., 1997; Martínez García et al., 2017; d'Acremont et al., 2020). Since the start of this
108 tectonic inversion, 9 Ma ago, the topographic highs directed the water masses circulation and the
109 location and geometry of contouritic systems (Juan et al., 2016; Lafosse et al., 2020; d'Acremont et al.
110 2020). Since 5.33 Ma and the end of the Messinian Salinity Crisis, the interaction between tectonic
111 activity (i.e. thrust and fold growths, seismicity) and the formation of contourite systems and
112 seamounts explain the morphological features of the seafloor (Figs 1 and 3) (Juan et al. 2016; 2020).
113 Contourite drifts such as the 650 m thick Ceuta drift (Fig. 1) are building up in the southern Alboran
114 Sea due to the interaction of the Dense Mediterranean Waters (DMW Fig. 1; which comprise the lower
115 Tyrrhenian Dense Waters and Western Mediterranean Deep Waters), that accelerates toward the
116 Strait of Gibraltar, and of the Modified Atlantic Water current (AW Fig. 1; Ercilla et al., 2015; Juan et
117 al., 2016; Ercilla et al., 2019). Contourite systems formed when the Gibraltar Strait opened (Ercilla et
118 al. 2002, Juan et al. 2016). In response to the continuous influence of Mediterranean water masses
119 after the opening of the Strait of Gibraltar (Juan et al., 2016), contourite drifts (plastered, sheeted,
120 elongated, separated, and confined mottled drifts) and associated erosive features (terraces,
121 scarps, moats, and channels) mainly constitute the Pliocene-Quaternary sedimentary record. About
122 2.6 Ma ago, the surficial Atlantic waters and the deeper and dense Mediterranean waters favoured
123 the erosion and the sediment accumulation in all Spanish and Moroccan margins and adjacent margins
124 of the Alboran Sea (Juan et al., 2016). Contourite deposits built-up synchronously with the growth of
125 thrusts, folds, mud diapirs and volcanoes, which led to important accumulation of sediments on slopes
126 and basins (Pérez-Belzuz et al., 1997; Somoza et al., 2012; Ercilla et al., 2015; Juan et al., 2016). The
127 plastered drifts dominate the Spanish and Moroccan continental slopes whereas sheeted drifts
128 dominate the sub-basins (Juan et al. 2016; 2020). Along the Moroccan margin, the Ceuta drift (Fig. 1)
129 is mainly composed of muds with intercalated layers (50 cm) of sandy muds, bounded by sharp
130 surfaces and silty clay layers (Ercilla et al., 2002).

131 Strike-slip and reverse faults accommodated the convergence between the Eurasian and African plates
132 (Gràcia et al., 2019; d'Acremont et al. 2020; Estrada et al., 2021). In the southern part of the Alboran
133 basin, thrusts and folds form large E-W to NE-SW prominent morpho-structural highs (Fig. 2B). The

134 Xauen-Tofiño Banks and Francesc Pagès Seamount form the South Alboran compressive Ridge above
135 the thick Miocene shales (called SAR; d'Acremont et al. 2020; Lafosse et al. 2020). North of the SAR,
136 three blind thrusts limit the front of the compressional deformation (d'Acremont et al. 2020; Lafosse
137 et al. 2020; called DF1, DF2, and DF3 in Figs 2B and 3B). Recent deformations are related to the growth
138 of the anticline related to these blind thrust activities (d'Acremont et al. 2020). Eastward, the Alboran
139 Ridge is a compressive structure with blind thrusts, accommodating the African plate indentation in
140 the Alboran block (Figs 1 and 2A; Martínez-García et al., 2017, Estrada et al., 2018). Compared to the
141 SAR, the Alboran Ridge is narrower and is characterized by steeper slopes (Fig. 3). The AIFZ (Gracia et
142 al., 2019; d'Acremont et al., 2020; Lafosse et al., 2020; Figs 1 and 2) crosses these structures and
143 extends over the Alboran basin from southern Spain (Campo de Dalías/Adra region) to Morocco (Al
144 Hoceima area; d'Acremont et al. 2014; Lafosse et al. 2020) (Figs 1 and 2). The AIFZ is a Quaternary
145 NNE-SSW sinistral strike-slip structure (Gràcia et al., 2019; Lafosse et al., 2016, 2020), conjugated with
146 NW-SE dextral faults toward the northern tip of the Alboran Ridge (Yusuf Fault and Averroes Fault
147 Estrada et al., 2021; Fig 1). Most of the seismicity in the Alboran Basin is concentrated along this NNE-
148 SSW AIFZ (Fig. 2A; Grevemeyer et al., 2015; Gracia et al., 2019; Stich et al., 2020). In southern Spain,
149 the Adra 1910 earthquake has been estimated up to magnitude $M_w = 6.1$ (Stich et al., 2003), while in
150 Northern Morocco, the Al Hoceima area has been affected by three recent seismic events
151 (earthquakes, Fig. 1): May 26, 1994 ($M_w = 5.6$), February 21, 2004 ($M_w = 6.4$), January 25, 2016 ($M_w =$
152 6.4), (Medina and Cherkaoui, 2017; Galindo-Zaldívar et al., 2018; Kariche et al., 2018; Gràcia et al.,
153 2019). The February 21, 2004 event yielded 628 casualties (Stich et al., 2005). These earthquakes are
154 located along the AIFZ or related segments. Historical earthquakes are also described with intensities
155 between VIII and X (MSK Intensity; Peláez et al., 2007; Palano et al., 2015). Long recurrence periods
156 are suggested for these large earthquakes, due to the low plate convergence velocity (>1 000 years,
157 Gràcia et al., 2019).

158

159 **3 Data and methods**

160 **3.1 Geophysical dataset**

161 Two key areas, located west and east of the AIFZ, are investigated: the northern flank of the Xauen-
162 Tofiño banks and Francesc Pagès Seamount (SAR region); and the South Alboran Basin confined
163 between the Alboran Ridge and the Pytheas Bank (SAB region; Figs 1 and 2). The dataset includes
164 swath-bathymetry and sub-bottom/seismic reflection profiles acquired during academic
165 oceanographic campaigns CONTOURIBER (2010), Marlboro-1 (2011), Marlboro-2 (2012), SARAS
166 (2012), MONTERA (2012), and INCRISIS (2016) (Fig. 2C). The multibeam datasets were compiled into a

167 25 m resolution bathymetric map for the area of interest. Multibeam data were processed with the
168 Ifremer CARAIBES and QPS QINSy softwares. High- and very high-resolution seismic reflection data
169 were used for the geomorphological and stratigraphic interpretations. The seismic data originate from
170 a multi-channel airgun system yielding 5 m and 10 m vertical resolution from academic and industrial
171 acquisitions respectively, a single-channel SIG sparker system with 1 m of vertical resolution, and a
172 TOPAS full ocean depth hull-mounted parametric echosounder system of decimetric vertical resolution
173 (Fig. 2C).

174

175 3.2 Chronostratigraphy

176 The relative chronostratigraphy of submarine landslides is taken from the seismic stratigraphy of Juan
177 et al. (2016) following the correlation of ODP Sites 976 and 979 with seismic reflection profiles (Figs 2C
178 and 4). The following nine regional stratigraphic horizons are identified on the available seismic
179 reflection lines from the Messinian to late Quaternary (Fig. 4):

- 180 • Top Messinian and base Pliocene horizon: M (5.33 Ma).
- 181 • Intra-Pliocene horizons: P0 (4.5 Ma) and P1 (3.3 Ma).
- 182 • Base Quaternary horizon: BQD (2.6 Ma).
- 183 • Intra-Quaternary horizons: Q0 (1.8 Ma), Q1 (1.12 Ma), Q2 (0.7 Ma), MIS12 and MIS8 horizons.

184 Between these horizons, up to seven stratigraphic units (PL1 to PL3 and QT1 to QT4) were
185 distinguished (Juan et al. 2016; Fig. 4). Based on this chronostratigraphy obtained after correlation of
186 ODP data and available seismic data (Juan et al., 2016), we can approximate when the submarine
187 landslides were triggered (Fig. 4).

188

189 3.3 Landslides: terminology, characterization and classification

190

191 The term landslide encompasses the displacement of sediment and involves different types of
192 processes, from slides and slumps to gravity currents or mass-flows (Hampton et al., 1996; Locat and
193 Lee, 2002). Scars, evacuation areas, deposits are typically associated to a submarine landslide
194 (Hampton et al., 1996). Their deposits are named Mass Transport Deposit (MTD; Hampton et al., 1996).
195 In this study, we recognize MTDs from their seismic facies and their topography in the bathymetry.
196 Multibeam bathymetry and seismic reflection data are essential tools for identifying and characterizing
197 submarine landslides (McAdoo et al., 2000; Principaud et al., 2015; Clare et al., 2016). The vertical
198 resolution of the seismic lines presented in this study is between 30 cm and 10 m, depending on its

199 stratigraphic position and seismic source. On seismic reflection profiles, a sharp interruption of the
200 lateral continuity of well-layered deposits with top and bottom unconformity surfaces corresponds to
201 the typical seismic facies of MTDs. The facies usually displays low-amplitude chaotic reflectors (Loncke
202 et al., 2009; Moscardelli and Wood, 2008). In sub-bottom parametric profiles, the MTDs upper and
203 lower boundaries are high amplitude reflectors denoting a high impedance contrast with the
204 surrounding well-layered deposits (Fig. 5). Basal discontinuities sometimes correspond with erosional
205 surfaces. Submarine landslide deposits observed on the seismic reflection lines can result from
206 successive events with amalgamated deposits (mass transport complex) or from a single event (MTD)
207 (Moscardelli and Wood, 2008). Discriminate multistage processes with the vertical resolution of the
208 available dataset appears difficult, thus we thereby named all the mapped landslide deposits MTDs,
209 even if some of them seem to belong to mass transport complex features (Moscardelli and Wood,
210 2008).

211 The mapping procedure used follows most of the suggestions provided by the global approach of Clare
212 et al. (2019). We selected eight parameters (descriptors) to compare landslide events (Fig. 5;
213 Appendices A1 to A4):

- 214 • six quantitative morphometric parameters including deposit surface (km^2), current and
215 decompacted deposit volumes (both in km^3), runout (km), scarp height (m), and scar slope
216 (degrees)
- 217 • two qualitative parameters: the type of MTD (debris flow deposit or slide deposit) and the
218 presence of absence of an erosive base.

219 Some differences in seismic facies allow classifying them into debris flow deposit or slide deposit
220 (Appendices A1 and A2):

- 221 • Debris flow deposit: Internal structure generally lacks coherent reflectors and appears
222 acoustically transparent, semi-transparent, sometimes chaotic.
- 223 • Slide deposit: Highly disorganized sediments, locally with hyperbolic diffractions and/or
224 continuous bedding. The same landslide can display different types of facies depending on the
225 seismic source.

226 Each mapped submarine landslide has an associated volume of reworked material representing the
227 MTD (Figs. 5A and B). For some landslides, it has been possible to link this deposit (MTD) and its
228 associated scar (Fig. 5). In such cases, the runout distances between scars and deposits were
229 computed. Conversely, when scars were not recognized, the minimum runout was estimated as the
230 landslide deposit's length, as Urgeles and Camerlenghi (2013) suggested. Parameters for all mapped
231 landslides, west and east of the Al Idrissi fault zone, are provided in Appendix (Tables A1 and A2) and

232 illustrated in Figure 2B. Two deposits at equivalent stratigraphic positions are described
233 independently and interpreted as different events, although they could correspond to a unique event.
234 This limitation is not a major issue since the purpose of the article is to discuss the causal factors of
235 landslides independently of their dynamics.

236 For each mapped MTDs, we used kriging interpolation to create isopach maps. In order to convert
237 two-way travel time into metric units, P-wave velocities between 1550 m.s⁻¹ for superficial and near-
238 surface MTDs mapped with parametric records and 1650 m.s⁻¹ for buried MTDs mapped with the
239 Sparker and airgun sources have been used (Vp values from ODP sites are taken from Martinez-Garcia
240 et al., 2013; see Appendix A3). From mapped MTD surfaces (Fig. 5), present-day volumes are
241 estimated.

242 We determined decompacted MTD volume considering the following porosity law:

$$Porosity (\phi) = 73 - 9(\log_{10} d) \quad (1)$$

243 with depth (d) measured at ODP boreholes 976 and 979 (Eq. 1). The depth variation of porosity values
244 for the upper 400 m of recovered materials on ODP sites 976 and 979 is given in Appendix A4. From
245 the porosity law, the decompacted MTD volume (V₀) can be estimated using final porosity and
246 volumes (ϕ_n and V_n, respectively) using Eq. 2:

$$V_0 = \frac{(1 - \phi_n)V_n}{(1 - \phi_0)} \quad (2)$$

247

248

249 3.4. Factor of safety approach for slope stability analysis

250 Causal factors of submarine landslides are usually discussed through the interaction between
251 preconditioning factors and triggering mechanisms. Preconditioning factors are related to properties
252 of the sediments acquired during or evolved from the primary depositional process and act in longer
253 time-scales (e.g. > 0.1 ky). It can include for instance high pore (gas and water) pressure caused by
254 rapid sedimentation or gas seepage, the presence of contrasting hydro-mechanical properties within
255 sedimentary layers, or over-steepening of the slope gradient (Lee et al., 2007). This list is not
256 exhaustive but illustrates most of the causal factors that deserve to be investigated in the Alboran Sea.
257 At shorter timescales (e.g. seconds to decades), triggering mechanisms are considered initiating the
258 slope failure by exerting external forces. They are as diverse as earthquakes, consequences of eustatic
259 variations, tectonic movements or bottom currents eroding the toe of the slope (Rebesco et al., 2014).
260 According to the local context, we evaluate the role of seismicity on the stability of a range of slopes
261 by calculating the factor of safety (FOS). A slope is considered to be under stable conditions when the

262 resisting and driving forces are equal and under unstable conditions when the driving forces (stresses)
263 exceed strengths. The FOS (Eq. 3) is defined as follows:

$$\text{FOS} = \frac{\text{resisting forces}}{\text{driving forces}} \quad (3)$$

264

265 The FOS can be calculated using a range of approaches, including the one-dimensional infinite slope
266 method, the more sophisticated limit equilibrium analysis and the continuum mechanics methods in
267 two and three-dimensions (Taylor, 1948). In the absence of required in situ data to perform improved
268 slope stability analyses (i.e. in situ pore pressure conditions and mechanical properties of the
269 sediments investigated), we choose the infinite slope and the pseudo-static approaches to evaluate in
270 one dimension:

- 271 • the critical slope value based on the infinite slope approach (FOS_{is}) (Milledge et al., 2012)
- 272 • the role of earthquakes based on the pseudostatic approach (FOS_{ps}) (Kramer, 1996)

273 For a matter of simplification, the following assumptions are made:

- 274 • investigated contourites are fine-grained in agreement with stratigraphic analyses (Juan et al.,
275 2020) and present a mean sediment unit weight of $18 \text{ kN}\cdot\text{m}^{-3}$, the cohesion may vary from 0
276 to 10 kPa and mean friction angle of 30° , although at failure the critical friction angle may be
277 as low as 10° (Ouyang and Mayne, 2017).
- 278 • the sediment column investigated is not affected by pore water pressures in excess of
279 hydrostatic ($u = u_h; \Delta u = 0 \text{ kPa}$)
280 with u the pore fluid pressure, u_h the hydrostatic pressure and Δu the excess pore pressure
- 281 • sliding occurs along a pre-defined plane parallel to the face of the slope (according to the
282 infinite slope approach)
- 283 • the failure can be approached by the Mohr-Coulomb criteria (Rashid et al. 2017).

284

285 3.4.1. Infinite slope approach (FOS_{is})

286 This method postulates that a potential failure surface is parallel to the local topography and located
287 at a depth (H) smaller than the length (L) of the slope (Taylor, 1948). The slope can thus be considered
288 as being of infinite length and width so that stresses are the same on the two planes perpendicular to
289 the slope. These stresses are collinear, equal in magnitude and opposite in direction; therefor they
290 balance each other out and can be ignored. This assumption has been proved valid for landslides with
291 $H/L < 0.06$ (Milledge et al., 2012). Most of the landslides investigated show $H/L < 0.075$ (Appendices
292 A1 and A2). The expression of the FOS following the one-dimensional infinite slope approach (FOS_{is})
293 is:

$$FOS_{is} = \frac{\text{shear strength}}{\text{gravity forces}} = \frac{\tau_f}{\tau} = \frac{c' + \cos \beta \cos \beta z (\gamma_s - \gamma_w) \tan \phi'}{\gamma_{sat} \cdot z \cdot \sin \beta \cdot \cos \beta} = \frac{c'}{\gamma_{sat} \cdot z \cdot \sin \beta \cdot \cos \beta} + \frac{\tan \phi'}{\tan \beta} \quad (4)$$

294

295 Where c' is the effective soil cohesion (kPa), β is the slope inclination to the horizontal (rad), z is the
 296 depth of the sliding plane (m), ϕ' is the effective friction angle (rad), γ_{sat} the saturated sediment unit
 297 weight (kN/m^3), γ_w and γ_s the water and sediment unit weight (kN/m^3). Details about Eq. 4 are given in
 298 Appendix A5.

299

300 3.4.2. Pseudostatic approach (FOS_{ps})

301 Although submarine landslides may occur without any seismic triggering, global compilations of
 302 earthquake-induced landslides illustrate that MTD areas correlate reasonably well with earthquake-
 303 prone areas (Keefer, 1984; Rodriguez et al., 1999). According to Keefer (1984), the minimum
 304 earthquake magnitude that triggers landslides is generally $M_L = 5.5$ ($\sim M_W = 5.6$).

305 In our study, the influence of earthquakes has been attempted by using the pseudo-static FOS_{ps}
 306 approach (Kramer, 1996; Eq. 5). It represents the effects of the inertial forces F_h and F_v which act on
 307 the centroid of the failure mass during an earthquake (Appendix A5B). These two forces are dependent
 308 on pseudostatic seismic coefficients at the horizontal and vertical directions (k_h and k_v , respectively),
 309 which are linked to the recorded earthquake ground accelerations (Appendices A5 to A6). The selected
 310 expression of the pseudostatic approach, FOS_{ps} given in Eq. 6, is further detailed in Appendix (A5).

$$FOS_{ps} = \frac{\text{resisting forces}}{\text{static} + \text{pseudostatic driving forces}} \quad (5)$$

$$FOS_{ps} = \frac{c'_L + [(W - F_v) \cos \beta - F_h \sin \beta] \tan \phi}{(W - F_v) \sin \beta + F_h \cos \beta} \quad (6)$$

311

312 Where c'_L and ϕ are the Mohr-Coulomb strength parameters that describe the shear strength on the
 313 failure plane, W is the weight of the slope wedge involved in the failure and β the slope gradient. F_h
 314 and F_v are the inertial (pseudostatic) forces that act through the centroid of the failure mass. Values
 315 of k_h from 0 to 0.2 were selected to investigate the impact of earthquakes on the FOS_{ps} , with $k_h = 0.2$
 316 corresponding to violent and destructive earthquakes (Kramer, 1996). As a matter of illustration, in
 317 the study area, the maximum moment magnitude recorded during monitored earthquake crisis in
 318 2016 does not exceed 6.4 (Gracia et al. 2019), thus the potential seismicity in the study areas should
 319 not exceed $k_h > 0.2$. The ground acceleration depends on the seismic coefficient (Appendix A6) and
 320 varies according to the epicentral distance (Idriss, 1991). Epicentral distances are considered the
 321 distance between landslide scars and earthquake epicentres. The empirical correlation of Idriss (1991)
 322 relating earthquake magnitudes and the attenuation of the peak ground acceleration (PGA) with the

323 epicentral distance is used to confirm/discard whether the seismicity may trigger slope failures
324 according to Eq. 5 and 6 (Appendix A6).

325

326 3.4.3. Estimation of moment magnitude M_w

327 Based on the equations from Yen and Ma (2011) and following the framework of Stirling et al., (2013)
328 relating fault surfaces and earthquake magnitudes, the potential moment magnitudes that could be
329 expected for compressive structures can be estimated.

330 Because the Alboran Sea is a slowly deforming area with deformation rates under 10mm/y
331 (d'Acremont et al., 2020), we used the relationship of Yen and Ma (2011) for dip-slip earthquakes:

$$332 \log(\text{Surface}) = a * \log(M_0) + b;$$

$$333 a = 0.8 ; b = -12.45$$

$$334 \log(M_0) = 1.5 * M_w + 16.05$$

335 where M_0 is the seismic moment; M_w the moment magnitude; a is the intercept, b is the slope. See
336 §4.5 for the calculation of fault surface.

337

338 **4- Results**

339 4.1- Distribution of the Mass Transport Deposits

340 A total of 67 submarine landslide features, including scars, deformation fronts, and deposits (Fig. 5)
341 were described in the two SAR and SAB study areas (west and east of the AIFZ respectively, Figs 2B, 6
342 to 8; Appendices A1, A2). Twenty-eight MTDs have been determined in the SAR region (Appendix A1)
343 and thirty-eight in the SAB region (Appendix A2). MTD scars are either located along steep ($>10^\circ$) to
344 moderate ($5-9^\circ$) to gentle ($2-4^\circ$) slopes (Figs 3 and 8). Most of the MTDs are concentrated at the toe of
345 the plastered drifts (Fig. 8) where slope gradients are moderate to steep (6 to 9° ; Fig. 3B) as occurred in
346 the SAR region (Fig. 3B) or very low (2 to 5° ; Fig. 3C) as observed in the SAB region along the northern
347 Pytheas bank.

348 The SAB is a NE-SW striking synform, eastward of the AIFZ, limited northward and southward by the
349 Alboran Ridge and the Pytheas Bank, respectively (Fig. 3). In this area, MTDs are present in the SAB
350 between 760 and 1100 m. MTD scars are present on the steep ($>10^\circ$) slope of the Alboran Ridge and
351 the flatter ($2-4^\circ$) slope of the southward limb of SAB synform (Figs 2B, 3, 7). Scars found on the steep
352 slopes of the Alboran Ridge coincide with a thrust-anticline structure (Fig. 3C). Sediment failures
353 mobilize the plastered drifts from the northern flank of the Pytheas Bank, whereas the southern edge
354 of the Alboran Ridge lacks well-expressed contourite drifts.

355 In the SAR, westward of the AIFZ, MTD scars are present along moderate slopes (6-9°) between 750
356 and 1125 m (Figs 6 and 8). Those scars seem to coincide with blind thrusts and edges of contourite
357 plastered drifts (Figs. 3 and 8). The scars correspond to MTDs present in the deeper part of the basin
358 between 1300 and 1400 m, where their clear bathymetric and stratigraphic signature are visible (Fig.
359 8). They exhibit a ≤ 10 m positive topography and transparent seismic facies (Figs 3, 6, and 7). Through
360 the sedimentary sequence, historical landslide events are recognized at the foot of the SAR and AR
361 structural highs in the deep basin (Figs 2C, 6, and 7).

362 Along the AIFZ, south of the Francesc Pagès seamount and north-west of the Alboran Ridge, no
363 significant MTDs have been identified through the sedimentary record (Figs 2B and 8).

364

365 4.2. Volumes and relative ages of the MTDs

366 The decompacted volumes of the investigated MTDs (from 0.01 to ~ 15 km³; Fig. 9; Appendix A1, A2)
367 are of comparable magnitude as submarine landslides in most of the Mediterranean Sea (Urgeles and
368 Camerlenghi, 2013). In the SAR region, estimates of decompacted volumes of Pleistocene MTDs range
369 between 0.01 and 10.5 km³ (Fig. 9; Appendix A1). In the SAB region, MTDs decompacted volumes from
370 the southern flank of the Alboran Ridge range between 0.01 and 2.95 km³ (average value = 0.41 km³)
371 and between 0.02 to ~ 15 km³ MTDs (average value = 4.8 km³) for MTDs from the northern slope of
372 the Pytheas Bank (Fig. 9; Appendix A2).

373 MTDs observed on the bathymetric and seismic reflection data through the sedimentary sequence are
374 younger than the Q1 (1.12 Ma) reflector (Figs 2B and 9). In the SAR region, the twenty-eight MTDs
375 west of the AIFZ, are younger than 0.7 - 0.79 Ma (Q2 reflector to the seafloor; Fig. 9). In the SAB, the
376 thirty-eight MTDs are younger than 1.12 Ma (Q1 reflector; Fig. 9). A Messinian buried MTD is identified
377 (under the M reflector, Gorini et al., 2012) on the northern front of the SAR and in the south Alboran
378 Basin (Figs 2B, 6 and 10). With a volume of 200 km³, an area of 550 km² and a maximum thickness of
379 540 m, this giant MTD extends for over 40 km from the Xauen/Tofino banks to the deep basin floor of
380 the Western Alboran Basin (Gorini et al 2012).

381

382 4.3. Structural and fluid escape features

383 The SAR and Alboran Ridge are folded by a series of synclines and anticlines and bounded by blind E-
384 W and NE-SW thrust faults, respectively (Figs 3B, C and 8). On the edges of these highs, the slope
385 becomes steeper ($>10^\circ$) (Fig. 3). The north verging blind thrusts (DF1, DF2, DF3) affect the Messinian
386 surface and the Pliocene-Quaternary contourite drift deposits are uplifted with a northern vergence
387 (Figs 3B; 6 and 10). The sinistral AIFZ offsets the folded structural highs (Fig. 2A). MTDs described in

388 the previous section are not aligned along the NNE-SSW AIFZ but along these folded structural highs
389 (Fig. 2B).

390 In the SAR region, fluid escape features, such as pockmarks and mud volcanoes, are clearly expressed
391 on the seabed by circular depressions and mounds, respectively (Figs 1 inset; 8 and 10). All the mapped
392 pockmarks constitute two main fields oriented ENE-WSW located on the northern and southern flank
393 of the SAR into plastered drifts (Figs 8). On the southern flank of the SAR, the pockmarks are aligned
394 following the DF2 blind thrust sub-parallel to the Xauen-Tofiño banks (Fig. 8). The pockmarks are
395 imaged at the subsurface as vertical pipes with low seismic amplitudes, indicating the circulation of
396 fluids (Fig. 10). Acoustic blanking zones extends from the messinian reflector (above a buried landslide)
397 to the seabed as a set of columnar shapes (Fig. 10).

398 Almost all mapped pockmarks are concentrated west of the AIFZ, where thick contourite deposits are
399 present (600 msec TWTT since Pliocene time; Figs 6, 7, 10). The spatial relationship between fluid
400 escape features along normal faults, blind thrusts, as well as the existence of MTD scars on the steeper
401 slopes of the plastered drifts, is illustrated in Figures 3B.

402

403 4.4. Slope stability analysis

404 Calculations of the factor of safety (FOS) based on the infinite slope (FOS_s) illustrate that the
405 contourites investigated are stable for slope gradients higher than the friction angle (ϕ), independently
406 of the cohesion (Fig. 11). For the three landslide fields (LF), namely the Xauen LF, Central and Pytheas
407 LF, we found that instability may be only attained if ϕ reduces substantially, down to 10° . These results
408 illustrate that slope steepness has no negative effects if the frictional properties are high (30° , Fig. 11).
409 However, when combining both low friction angle ($< 10^\circ$) and seismic activity ($0 < K_h < 0.2$), we found
410 that the seafloor within the landslide fields (from scars to the deposits) may be affected by unstable
411 configurations (Fig. 12).

412

413 To discuss the influence of earthquakes in triggering landslides, three landslide fields are defined
414 according to their mean slope values and to their distance (from scars) to the main faults and/or to the
415 epicentral earthquake locations (Figs 2 and 13):

- 416 - the Xauen landslide field where MTD scars are located along moderate to steep slope ($6-9^\circ$),
417 where fluid escape features are present above blind thrust faults. MTD scars are at least 20
418 km west of the seismogenic AIFZ and less than 5 km from thrust faults DF1 and DF2, in the
419 western part of the SAR region (Fig. 2A-B).
- 420 - The Central landslide field, where MTD scars are located along moderate to steep slope ($6-9^\circ$)
421 is the closest to the AIFZ in the eastern part of the SAR region.

422 - The Pytheas landslide field, in the SAB region, where MTD scars are located along steep slopes
 423 (>15°) on the Alboran ridge (i.e. thrust and fold, Fig.1) and on a gentle slope (2-5°) on the
 424 northern Pytheas bank, both areas located more than 30 km from the AIFZ, Yusuf and Averroes
 425 faults.

426 For instance, $k_h > 0.1$ may destabilise the Pytheas LF whereas relatively low k_h values ($k_h \sim 0.05$) are
 427 enough to trigger landslides in the Central and Xauen LF (Fig. 12). Depending on the nature of the
 428 contourites, their friction angle (ϕ) may vary and be relatively low (10°) compared to mean values (30°)
 429 (Ouyang and Mayne, 2018), which facilitates slope failure. According to these values of ϕ , and the link
 430 between the horizontal seismic coefficient and the peak ground acceleration, the following hypotheses
 431 can be considered:

- 432 - for contourites with $\phi \sim 30^\circ$, the required seismic coefficient to trigger failure is $k_h > 0.1$, i.e. PGA
 433 ≥ 0.2 g. This PGA value is considered as the upper boundary required to destabilise sediments
 434 with classical frictional values.
- 435 - for contourites with $\phi \sim 10^\circ$, k_h values around 0.05 may trigger failure, which corresponds to
 436 PGA = 0.1 g. Accordingly, this PGA is considered the lower bound required to destabilise
 437 sediments with reduced frictional values.

438 4.5. Seismic potential of faults

439 Based on the depth converted profiles published in d'Acremont et al., (2020), we have estimated the
 440 surfaces of the thrusts DF1 and DF2 beneath the MTD's scars and the scaled moment magnitude M_w
 441 during their reactivation (Table 1, Appendix A6). Our estimate of the ruptured surface supposes that,
 442 in the SAR, thrust faults are shallow and root in a deep weak layer of under-compacted shales
 443 (d'Acremont et al., 2020). DF1 and DF2 are then approximated to faults of 4 km deep, with 30° dip and
 444 8 km length (Figs 7 and 8). Potential earthquakes have also been estimated in the Alboran Ridge
 445 according to the geometry of the reverse fault defined in Martinez-Garcia et al. (2013 and 2017) (Table
 446 1). The Alboran Ridge main thrust fault (Fig. 8) is then approximated to a fault segment of 5 km in
 447 depth and 57 km in length. A similar dip than the DF1 and DF2 thrusts was used (30°). From these
 448 rough fault characteristics, we estimate scaled moment magnitudes ranging from $M_w = 6.1$ and 6.7
 449 (Appendix A7). Considering that the entire surface of the mapped faults would break, the moment
 450 magnitude is overestimated, our values are therefore to be considered as an upper bound.

451

Faults	Length (Km)	Surface (km ²)	M_w _(W)	M_w _(YaM)
DF1a	18.71	149.69	6.50	6.49
DF2a	21.24	169.91	6.61	6.53

DF1b	16.74	133.92	6.41	6.45
DF2b	12.52	100.16	6.17	6.34
ARDF	57	285	6.17	6.72

452 Table 1: Scaled moment magnitudes (Mw) for compressive structures present on the Xauen landslide
453 field (DF1 and DF2) and the major thrust of the Alboran Ridge deformation front (ARDF). Values are
454 calculated according Wesnousky et al. (1983) (W) and Yen and Ma (2011) (YaM) approaches. See
455 Appendix A7 for the location of the faults.

456

457 5- Discussion

458

459 The fact that high numbers of MTD events can occur along low gradient slopes indicates that gravity is
460 not the main force leading the slope to fail in SAR and SAB regions as FOS values of ~ 1.1 for gradients
461 $< 30^\circ$ suggests (Fig. 11). Therefore, other processes seem to be controlling sediment failure.

462 5.1. Influence of slope gradient, sedimentation, oceanographic fluctuation and fluid
463 escape on the distribution of MTDs

464 5.1.1 Volume of MTD versus slope

465

466 In the SAB region, MTD volumes are higher when the source comes from the gently dipping ($2-5^\circ$)
467 northern Pytheas bank (average of $\sim 4.8 \text{ km}^3$), compared to those who originate from the steep ($>10^\circ$)
468 slope of the Alboran Ridge (average of 0.4 km^3 ; Figs. 3, 8, 9 and 10, Appendix A2). Since MIS 8, a
469 significant frequency of low-volume MTDs are recorded in the sediment column, they originate from
470 scars located on the steep Alboran Ridge slope (9 MTDs, Fig. 9). This demonstrates that the steeper
471 the slope is, the higher the frequency of slope failures is, the lower the volume of each MTD event are
472 (Fig. 9). Indeed, the slope gradient influences the failure frequency and sediment thickness involved in
473 the failures. In high slope area, the rupture area is limited and continuous instability can favour more
474 collapses at adjacent locations. The size of the surface available for sediment destabilization also
475 depends on the slope values. The gentler the slope at the scars area, the greater is the volume
476 potentially destabilized (e.g. Urlaub et al., 2015). On the high slope gradients of the Alboran Ridge, thin
477 packages of contourite sediments are subject to sliding (Figs. 2B,3 and 9), as demonstrated by the
478 decompacted volumes (average of 0.4 km^3) interpreted as evidences of a continuous destabilization
479 on a steep slope. In the SAB, the relatively lower slope gradients ($2-5^\circ$) of the Pytheas Bank would
480 explain less frequent (3 MTDs identified since MIS8 compared to 9 from the AR source) but more
481 voluminous events, which can be as high as 15.6 km^3 (Fig. 9; Appendix A2).

482

483 5.1.2 Overpressure versus sedimentation rates and tectonics

484

485 High sedimentation rates in the mounded part of the investigated contourites could have generated
486 pore fluid pressures as described by Rebesco and Camerlenghi (2008) and potentially fluid escapes (i.e.
487 pockmarks; Figs 8 and 10). As a consequence, the reduction of the effective stress which has a negative
488 effect on the sediments strength, can certainly impact the slope stability (Laberg and Camerlenghi,
489 2008). Previous observations from the Mediterranean Sea show that fluid escape features lower the
490 sediment strength (Blinova et al., 2011; Pérez-Belzuz et al., 1997; Somoza et al.; 2012, Lafuerza et al.,
491 2012; Urgeles and Camerlenghi, 2013).

492 The sedimentation rates recorded from ODP sites 976 and 979 for the Quaternary period are 34 cm/ky
493 and 20 cm/ky respectively (Comas et al., 1996). Based on the available stratigraphic framework (Fig. 4;
494 Appendix A3), Pliocene-Quaternary estimated sedimentation rates for the contourite drifts range
495 between 7 and 32 cm/kyr. In the mounded part of Alboran Sea contourites, Alonso et al. (2021)
496 reported sedimentation rates of 11-190 cm/ky for the Late Pleistocene to Holocene periods. Although
497 variable, they include high sedimentation rates, which supports our hypothesis. Furthermore, if
498 contourites contain permeable lenses, lateral transfer of fluids could be expected downslope and
499 explain the concentration of submarine slide scars at the edge of contourite drifts north of the SAR
500 (Fig. 3B).

501 The SAR and SAB regions are very contrasting in terms of fluids and sedimentary escape features (mud
502 volcanoes and pockmarks). West of the AIFZ, seismic data reveal that pockmarks affect uplifted
503 contourite drifts (Figs 3B, 6, 8, and 10) and these pockmarks fields are inline above the DF2 blind thrust
504 fault (Figs 2 and 6). East of the AIFZ, no major fluid and sedimentary escape features are detected at
505 the bathymetry resolution.

506 The slide scars are located between DF1 and DF2 (Figs 2 and 8) suggesting a structural control of both
507 pockmarks and MTD scar location. Differential-compaction normal faults are located at the top of blind
508 thrust faults that remobilize an old Messinian MTD (Figs 6 and 10; Gorini et al., 2012). These faults
509 allow fluids to migrate vertically from deep successions (including the Messinian landslide, Fig. 10)
510 toward the seabed. Pockmarks may develop in response to the fluid pipe propagation in
511 unconsolidated sediments in the near surface (Figs 3B, 6 and 10B). Similar spatial distribution of fluid
512 escape features controlled by buried landslides has been illustrated, for instance, in the Niger
513 submarine delta (Riboulot et al., 2013).

514 The presence of pockmarks at the top of contouritic drifts could indicate important fluid circulations
515 (Figs 3B and 10) that would precondition the slope stability as suggested by Baraza and Ercilla (1996);

516 Rebesco et al. (2014); Miramontes et al. (2018). We interpret that the distribution of MTDs east and
517 west of the AIFZ is mainly driven by the location of the structural highs (Fig. 2C).

518

519 5.1.3 Weak layer formation versus oceanographic fluctuations

520

521 Contourites are typically described in literature as sources of weak layers acting as a potential
522 preconditioning factor of slope failure (Rebesco, 2005; Laberg and Camerlenghi, 2008; Rebesco et al.
523 2014). The type of deposit, the grain size, and the thickness of contourite drift vary with the sea-level
524 fluctuations and changes in the bottom current intensity (Ercilla et al., 1994; Juan et al., 2016; Alonso
525 et al., 2021) and drive the occurrence of weak layers.

526 Coarse-grained contourites (sand-sized) may undergo more easily liquefaction in response to cyclic
527 loading, possibly inducing failure (e.g. Sultan et al., 2004). Cyclic loading could result from the high
528 frequency and high amplitude glacio-eustatic fluctuations, which profoundly modify the slope stability
529 since mid-Calabrian times (1.12 Ma) (Rohling et al., 2014, Baraza et al., 1990; Casas et al., 2011). In the
530 north and west margin of the Alboran Basin, Ercilla et al. (2002), Juan et al. (2016), Alonso et al. (2021)
531 observe successions of sandy mud deposits and silty clay intervals during sea-level lowstand and
532 highstand, respectively. Sandy contourites, related to periods of high-intensity bottom currents, are
533 interbedded within fine-grained contourites (Ercilla et al., 2002; Alonso et al., 2021; López-Gonzalez et
534 al., 2019).

535 Near the continental Moroccan margin, sandy contourites (with high liquefaction potential) are
536 identified along the Ceuta drift (Ercilla et al., 2002) (Fig. 1). In the SAB region, plastered drift seems to
537 be fine-grained at least since the last 25 ka and coarse-grained in the moat (Alonso et al., 2021). The
538 presence or absence of coarse grains depends on current intensity which is maximum in the moat part
539 whose location likely varies according to eustatic oscillations (Frigola et al., 2007). Studies in the Gulf
540 of Cadiz have shown that the classical model of contourite grain-size sequences, depending of the
541 bottom current intensity, is much more complex than expected (Mulder et al. 2013). This strong
542 variability in grain-size suggests that it is very difficult to emphasize if weak layers of coarse grains
543 sediments are likely to occur in the studied area without core analysis. Based on these arguments we
544 make the hypothesis that most of the contourite affected by the landslide scars (Fig. 8) are fine-grained
545 but sand cannot be excluded if the moat was closer in the past.

546

547 5.2. Influence of growth folds and thrust faults on the distribution of the MTD

548 We propose that the SAR and Alboran Ridge tectonic structures control the distribution of the MTDs.
549 MTDs are inline with the direction of blind thrusts and axial planes of folds (Fig. 2B). These tectonic

550 structures form topographic highs, interacting with the dense bottom current circulation, and
551 favouring local contourite drift sedimentation.

552 Along the seismogenic AIFZ, MTDs are noticeably less abundant than further east and west (Figs 2 and
553 9). The available seismic reflection coverage south of the SAR highlights this paucity of submarine
554 landslides (Fig. 2). This surprising observation can be related to “seismic strengthening” by earthquakes
555 (Sawyer and DeVore 2015; Ten Brink et al., 2016). In the AIFZ repeated exposure to earthquake energy
556 could gradually increase shear strength by shear-induced compaction (Sawyer and DeVore, 2015).

557 North of the SAR, the MTD scars (Figs 2B and 3B) are above the normal faults on top of the frontal DF1
558 blind thrust. The DF1 and DF2 blind thrusts uplift the northern wedge of the contourite drift (Figs 6
559 and 10B). The MTDs are distributed in the deep basin parallel to the headwall of the DF1 blind thrusts
560 (Figs 2B and 8). Also, thrusting results in steeper slopes than folding, as observed North of the Xauen-
561 Tofiño banks and along the Alboran Ridge (Fig. 3B, C). The northward and southward thrust vergences
562 along the Xauen- Tofiño banks and Alboran ridge respectively, control the local slopes leading to the
563 location of landslides.

564 Blind thrusts and folds are active since the late Tortonian, with a last tectonic phase starting around
565 1.8 Ma to 1.12 Ma illustrated by the DF1 to DF3 structures on the SAR (Martínez-García et al., 2013;
566 Lafosse et al., 2020 and d’Acremont et al. 2020) (Fig. 2C). The creation of the topographic barriers
567 generates an uneven seafloor on which contourite sedimentation began. However, observed MTD are
568 younger than 1.12 Ma (Fig. 9). The vertical resolution of the seismic profiles (around 5 m) in deeper
569 parts of the subsurface prevents the observation of MTDs thinner than 5 m. Increase of the MTDs
570 volume after 1.12 Ma would only reflect this limitation in seismic resolution, rather than the absence
571 of MTDs before 1.12 Ma. Despite this, the activity of these tectonic structures coincides roughly with
572 the onset of MTD from 1.12 Ma. Tectonics creates topographic highs, beneficial for contourite drift
573 growth (Juan et al., 2016) and slope failures.

574

575 5.3. What are the candidate faults triggering the submarine landslides?
576

577 To accommodate the oblique convergence between the African-Eurasian plates, strike-slip and reverse
578 fault structures are present (Martínez-García et al., 2017; Estrada et al., 2018, 2021; d’Acremont et al.
579 2020; Lafosse et al. 2020). Based on the Idriss (1991) equation relating earthquake local magnitude M_L ,
580 epicentral distance and ground accelerations (Figs 12 and 13; Appendix A6), the minimum earthquake
581 magnitude required to obtain the upper and lower bound of PGA, namely 0.1g and 0.2g in the
582 investigated landslide fields are discussed below. Since PGA varies according to the distance (D) to
583 faults, the earthquake magnitude is discussed considering the distance between the landslide field and
584 the closest tectonic structure (Figs 12 and 13, Appendix A6):

- 585 - Pytheas LF is 40 km from Yusuf fault. At this site, PGA = 0.1 g can be obtained for a MI = 6.5 of
586 both reverse and strike-slip style. Values of PGA = 0.2 g could occur only for MI = 8, which are
587 too strong according to the recorded seismicity (Gracia et al., 2019). Therefore, these
588 landslides could be explained as the result of the interaction between a moderate activity of
589 the strike-slip Yusuf fault and a contourite characterised by reduced friction angle. Seismic
590 reflection studies propose that the Averroes fault links with the Yusuf fault segment since 1.1
591 Ma (Perea et al., 2018; Martínez-García et al., 2013), suggesting generation of earthquakes up
592 to $M_w = 7.6$ (Perea et al., 2018). Then, magnitudes high enough to trigger the destabilization
593 at a regional scale and leading to an increase of the volume of the MTD could be possible.
594 Seismic events have been recorded in the South Alboran Basin, close to the Pytheas scars
595 (Fig.2A). However, those events seem too distant with too small magnitudes to generate the
596 required ground acceleration.
- 597 - Pytheas LF is located at a distance of 10-20 km from the Alboran Ridge. At this site, PGA = 0.1
598 g is obtained for a MI = 5 of reverse style and values of PGA = 0.2 g for MI = 6.5 for a reverse
599 style. Obtained values of MI suggest that active potential reverse faults along the Alboran
600 Ridge can be a better candidate to generate sufficient ground acceleration and induce slope
601 destabilization. We estimate potential earthquakes between $M_w = 6.1$ and 6.7 from these
602 structures (Table 1, Appendix A7). Recent characterization of the earthquakes occurring during
603 the 2016 crisis near the Al-Idrissi fault (Stich et al., 2020) shows that reverse foreshock
604 occurred at a depth of 12 km, indicating crustal-scale reverse faulting on similarly oriented
605 faults in the SAR and Alboran Ridge regions.
- 606 - The Central LF is 10 km west from the Al-Idrissi fault. Here, PGA = 0.1 g is attained by a MI =
607 5.5 of strike slip style and PGA = 0.2 g by a MI = 6 of strike-slip style. These results demonstrate
608 that landslides observed in this area may have been triggered by faults of at least $5.5 < MI < 6$.
609 This agrees with the average $M_w = 6.4$ earthquake on NNE-SSW structural segments reported
610 on the AIFZ (Gràcia et al., 2019; Stich et al., 2020).
- 611 - The Xauen LF is located 5 km from thrust faults DF1 et DF2. On the other hand, the Xauen LF
612 is more than 20 km west of the seismogenic AIFZ, which implies that the highest PGA expected
613 for a MI = 6.4 would be lower than 0.1 g (Fig. 13). At this site, reverse faults of MI = 4 could
614 have generated PGA = 0.1 g and of MI = 5 to generate PGA = 0.2 g. Moreover, this value is in
615 the range of $M_w \approx 6$ calculated for potential reverse faults triggered by the DF1, DF2 and
616 Alboran ridge thrusts (Figs 2C and 3B). Therefore, thrust faults DF1 and DF2 are the best
617 candidates to trigger slope instabilities in this landslide field.

618 Several faults accommodate the Quaternary deformation and trigger earthquakes near the study areas
619 (Figs 1 and 2A). The active AIFZ concentrates the seismicity (Fig. 2) with Mw=6.4 earthquakes on NNE-
620 SSW structural segments (Galindo-Zaldivar et al., 2018; Gracia et al., 2019). The strike-slip Averroes
621 and the Yusuf faults are less seismically active than the AIFZ (Estrada et al., 2021) but have an important
622 topographic expression on the seafloor (Estrada et al., 2018; 2021). Away from the AIFZ, no significant
623 earthquake has been reported during the historical and instrumental period along the SAR and Alboran
624 Ridge (Source IGN 2022; Fig. 2A) but the MTDs are in line with local blind reverse faults (Fig. 2B). Above
625 the frontal blind reverse fault (DF1) and the Alboran Ridge thrust front (AR, Fig. 1) the seafloor is
626 disturbed (Fig. 10B) showing recent activity. Some authors propose that the blind reverse faults are
627 active during Pliocene-Quaternary times to accommodate the regional shortening (Martínez-García et
628 al., 2013; Lafosse et al., 2020; d'Acremont et al., 2020). Consequently, we propose that the Pytheas,
629 Central and Xauen landslides fields could have been triggered by the AIFZ, Averroes/Yusuf fault
630 segments and blind thrust faults.

631 Moreover, MTD occurrence since ~Q2-Q1 (1.12-0.79 Ma) (Fig. 9), is consistent with the Alboran Sea
632 tectonic reorganization occurring (i) along the Averroes and Yusuf Faults since 1.1 Ma (Martinez-Garcia
633 et al. 2013, 2017, Perea et al. 2018); (ii) along the AIFZ and in the Nekor Basin after 1.12-0.8 Ma (Fig.
634 8)(Galindo-Zaldivar et al., 2018; Giacomina, et al., 2015; Lafosse et al., 2016 and 2020); (iii) along the
635 SAR and Alboran Ridge blind thrusts with their reactivation since 1.8-1.1 Ma (Martínez-García et al.,
636 2013; Lafosse et al., 2016, 2020; d'Acremont et al., 2020).

637

638 **6- Conclusions**

639

640 Morphological and seismic reflection data reveal at least sixty-seven submarine MTDs within the
641 Quaternary deposits in the southern part of the Alboran Basin. The factors resulting in slope failure in
642 the Alboran Sea are diverse, and usually a combination of several factors is needed. Despite the
643 reported effect of seismicity on slope stability, the distribution of recorded low to moderate magnitude
644 earthquakes along the AIFZ does not seem to match the investigated landslides' location. Instead, the
645 slope failures west of the AIFZ likely resulted from a combination of uplift of topographic highs,
646 contourite drift build-up and fluid flow. East of the AIFZ, slope failures are located along the SW-NE
647 trend of the Alboran Ridge. The morphological analysis reveals that most of the submarine landslides
648 with high volumes occur at low slopes (2-5°) mostly on the Pytheas Bank slopes, where active faults
649 are far. The observation of MTDs recorded only from 1.1 Ma is consistent with the formation of the
650 AIFZ around that time, supporting seismic shaking as the main triggering mechanism. Alternatively,

651 potential high sedimentation rates during the Quaternary contourite deposition may have generated
652 pore fluid overpressure and upward fluid migration, as supported by the presence of a pockmark field
653 reducing the sediment resistance. Slope stability analysis shows that if the slope stability is locally
654 preconditioned (reducing friction angles up to 10°), the required PGA to trigger a slope failure may
655 reduce (from 0.2 g to 0.1 g), and such a PGA value could be generated by the local blind thrusts in the
656 Xauen landslide field. The exact ages of these MTDs and the geotechnical properties are necessary to
657 address the link between seismicity, sedimentation, oceanographic fluctuations, tectonism, and
658 submarine landslide processes.

659

660 **Acknowledgements**

661 We thank the members of the SARAS and Marlboro cruises in 2011 and 2012. Reviews by Daniel
662 Minisini, Davide Gamboa and Aggie Georgiopolou are gratefully acknowledged. This work was funded by the
663 French program *Actions Marges, Défi Risques Naturels* CNRS-IRD (MITI-ALARM) and UPMC-Emergence (ALARM
664 project), the ALBAMAR JCJC ANR-17-03CE-0004, the EUOFLEETS program (FP7/2007-2013; n°228344), project
665 FICTS-2011-03-01. Seismic reflection data were processed using the Seismic UNIX SU and Geovecteur©
666 software. The processed seismic data were interpreted using Kingdom IHS Suite© software. This work also
667 benefited from the DAMAGE (AEI/FEDER CGL2016-80687-R) and FAUCES (Ref CTM2015-65461-C2-R;

Figure 1: Bathymetric map of the Alboran Sea showing the structural features of the area. Shaded bathymetry from compilation of ISTEP and CSIC multibeam cruises with GEBCO 2014 database, topography from SRTM database. Focal mechanism in black: 1994 main shock (El Alami et al., 1998; Biggs et al., 2006). Focal mechanism in red: 2004 main shock (van der Woerd et al., 2014). Focal mechanism in green: 2016 main shock (Kariche et al., 2017; Medina and Cherkaoui, 2017). Focal mechanism in orange: Location and moment tensor solution obtained for the 1910 Adra Earthquake from Stich et al. (2003). AF, Averroes Fault; AIFZ, Al Idrissi Fault Zone; A.Is, Alboran Island; AR, Alboran Ridge (Alboran ridge thrust front, ARTF); CSF, Carboneras Serrata Fault; EAB, East Alboran Basin; FP, Francesc Pagès Seamount; IB, Ibn-Batouta Bank; JF, Jebha Fault; NB, Nekor Basin; NF, Nekor Fault; PB, Pytheas Bank; SAB, South Alboran Basin; SAR, South Alboran Ridge; TB, Tofiño Bank; WAB, West Alboran Basin; XB, Xauen Bank; YF, Yusuf Fault. Orange dashed areas SAB and SAR correspond to the two key sites of this study (South Alboran Basin and South Alboran Ridge respectively). Offshore structural features from Estrada et al. (2017); d’Acremont et al. (2020). Inset: water currents between Mediterranean Sea and Atlantic Ocean and main features of the basement. The arrows representing water masses are from Ercilla et al. (2019); AW, Atlantic Water; LMW, Light Mediterranean intermediate Water; DMW, Dense Mediterranean Water.

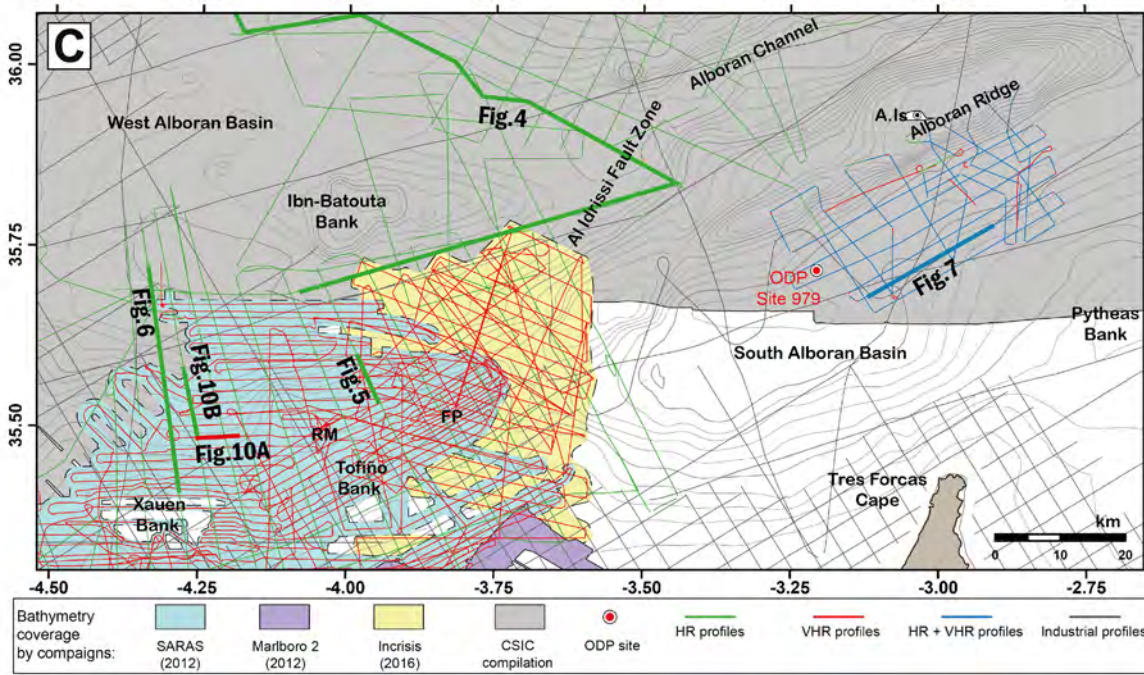

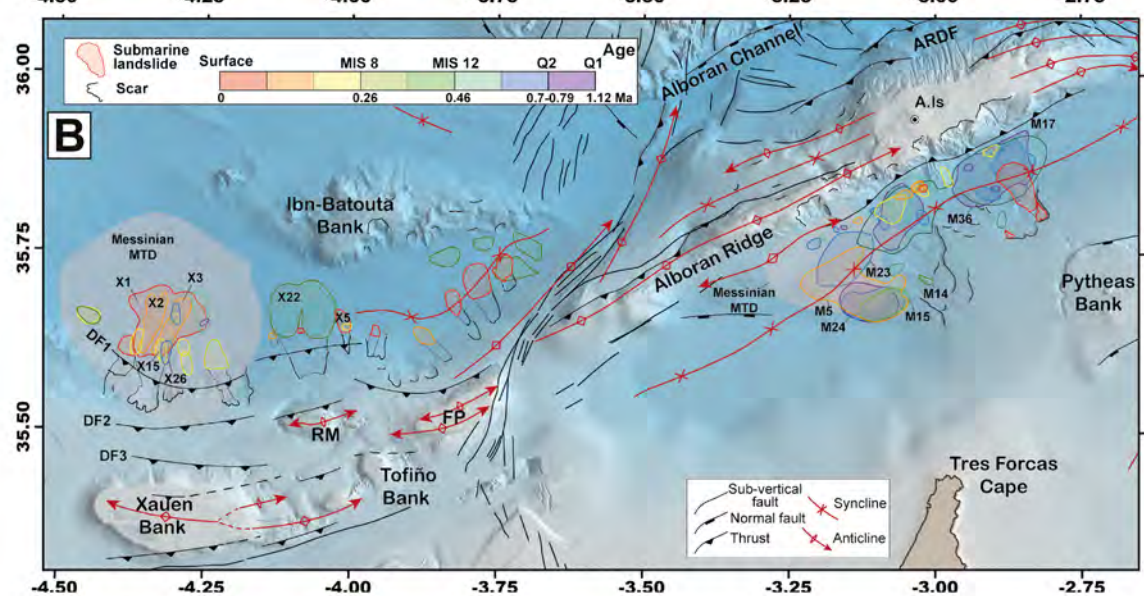

Figure 2: (A) Bathymetric and seismic epicentral map. Epicentres of the earthquakes recorded between 1964 and 2020 (Spanish Instituto Geografico Nacional (IGN) database). Landslide field location used in the text and Figure 9 (Xauen, Central and Pytheas) is represented by the white line. (B) Structural map (from d’Acremont et al. 2020; Lafosse et al. 2020) with the distribution of the submarine landslides from this study. Xx and Mx correspond to the code names of the MTDs described in this paper (see Appendix). DF1, DF2, DF3, deformation front highlighted by blind thrusts from d’Acremont et al. 2020. ARDF, Alboran Ridge Deformation Front from Martinez-Garcia et al. 2017. A.Is, Alboran Island; FP, Francesc Pagès Seamount; RM, Ramon Margalef High. (C) Swath bathymetric and seismic reflection coverage of the study area, from CONTOURIBER (2010), Marlboro-1 (2011), Marlboro-2 (2012), SARAS (2012), MONTERA (2012), and INCRISIS (2016) projects and the Fishing General Secretary (Spanish Government) (HR: high resolution; VHR: very high resolution). Thick lines correspond to seismic reflection profiles shown in this paper with the figure number.

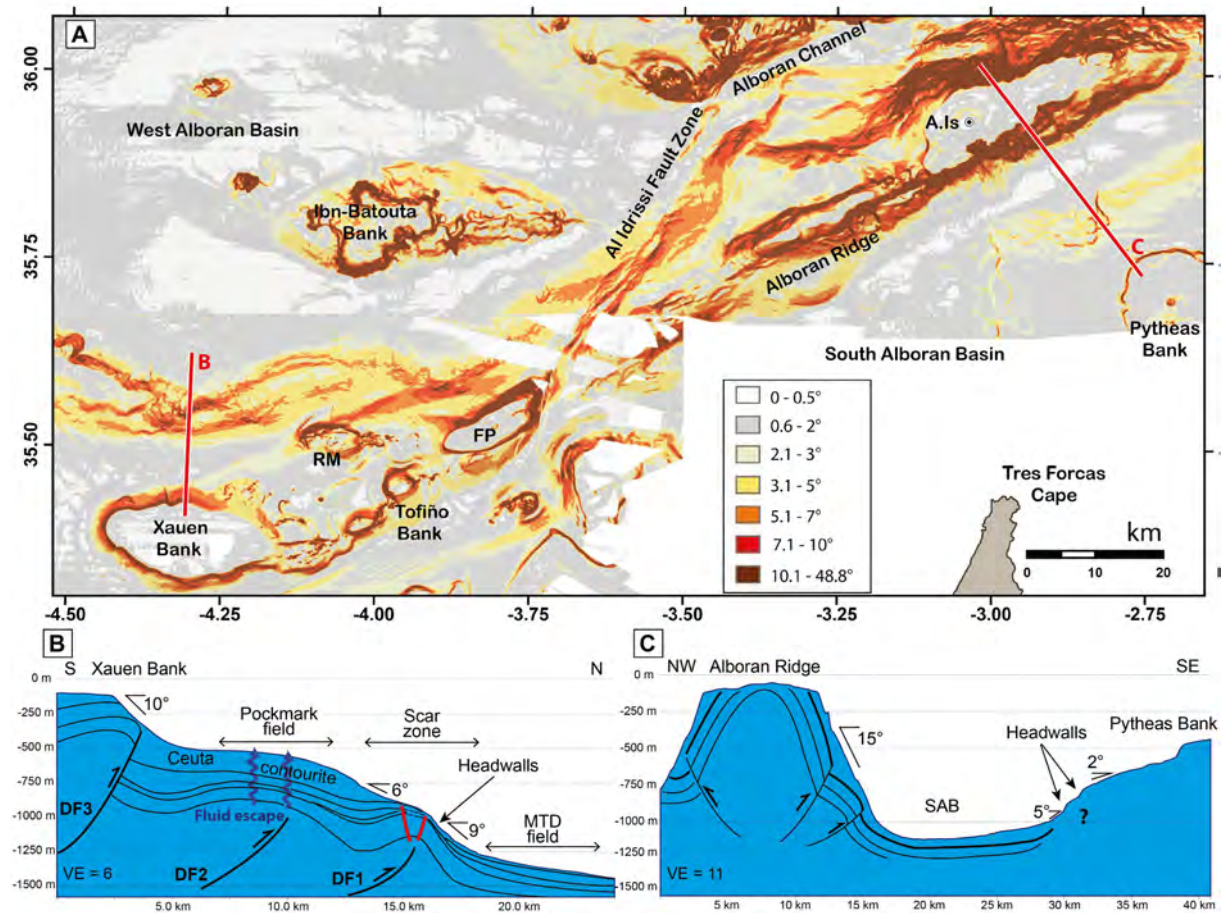

Figure 3: (A) Slope map of Southern Alboran Sea and slope failures. A.Is, Alboran Island; FP, Francesc Pagès Seamount; RM, Ramon Margalef High. (B)(C) Bathymetric profiles located in (A) with structural shape, slope values (from d’Acremont et al. 2020). VE, vertical exaggeration. DF1, DF2, DF3, deformation front highlighted by blind thrusts. MTD, Mass Transport Deposit.

Figure 4: Chronostratigraphic units and seismic horizons using ODP sites 976 (Units from Juan et al., 2016). Benthic $\delta^{18}\text{O}$ curve from Lisiecki and Raymo (2005). Composite seismic reflection profile used to follow the chronostratigraphic units from the ODP site 976 to the study area. IB, Ibn Batouta; FP, Francesc Pagès, Mioc., Miocene; Mess., Messinian; H, Holocene; U upper. MIS 12 and MIS 8 represent Marine Isotope stages, we have used this term as the name of the reflectors.

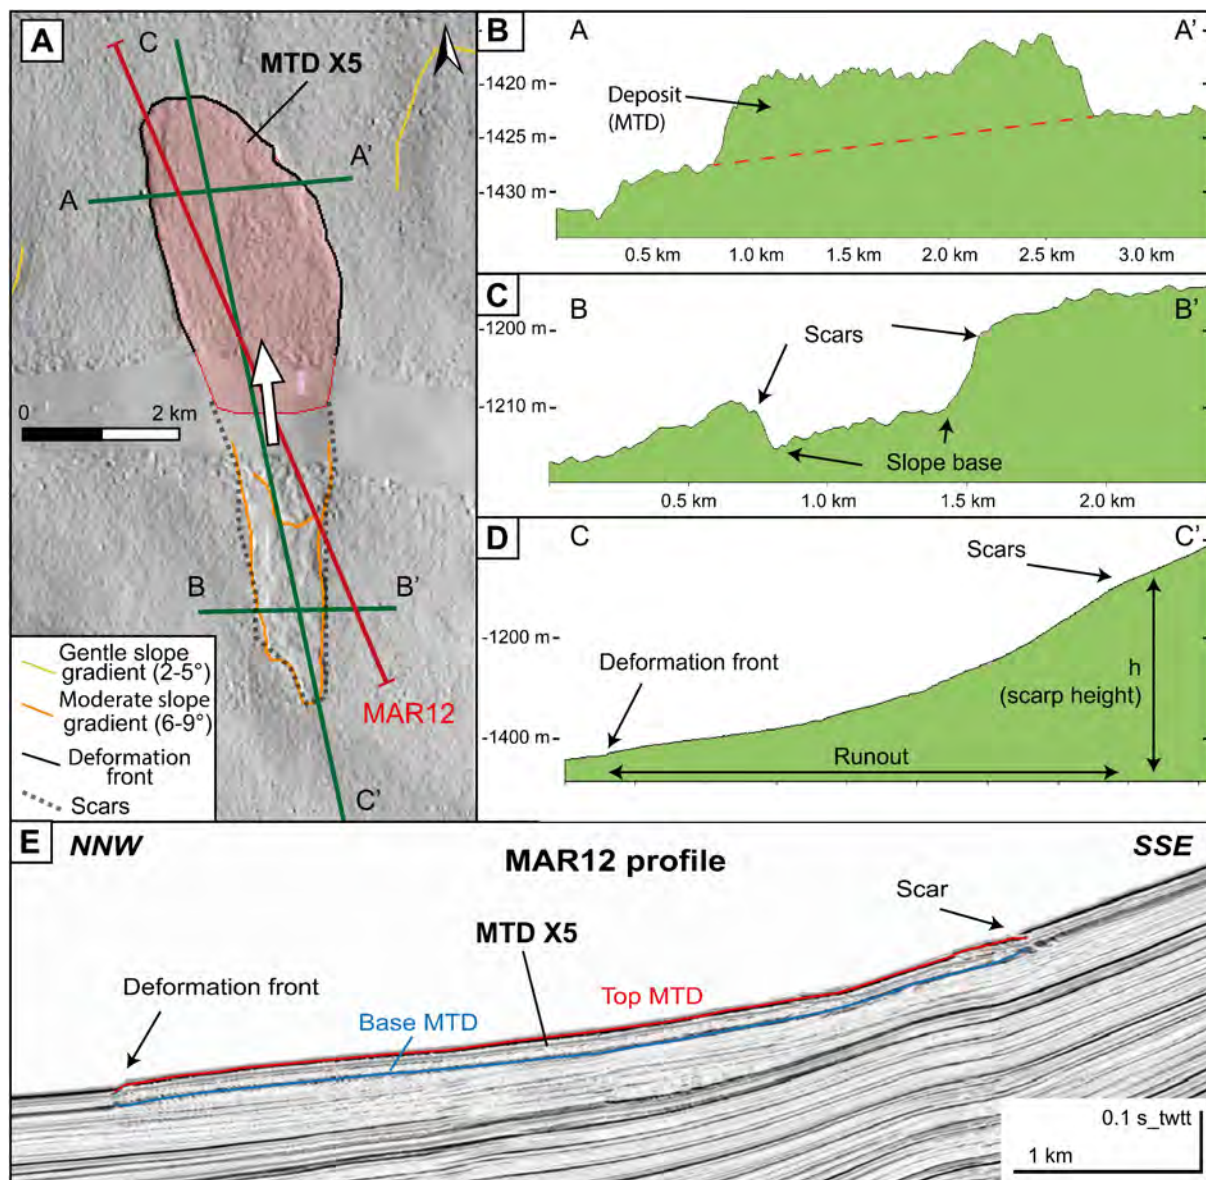

Figure 5 : Characterization of a submarine landslide using bathymetry (A), slope profiles (B, C, D) and seismic reflection profile (E): example of MTD X5 along the Xauen Bank northern flank. The white arrow indicates direction of transport of the submarine landslide.

Figure 6 : High-resolution profile from Marlboro 1 campaign (MAR02), between the Xauen Bank (XB) and the southern WAB. It shows localization of landslide scars along slopes north to the Xauen Bank, where slope gradient is affected by contouritic sedimentation (Ceuta contourite drift) and northward vergence thrusts (DF1, DF2) as well as mass transport deposits (Xx mapped in Figure 2B). TB Tofiño Bank, FP Francisc Pagès Seamount, IB Ibn Batouta seamount. P0, P1, BQD, Q0, Q1, Q2, MIS12 and MIS8 refer to seismic reflectors defined in figure 4.

Figure 7: High-resolution profile from MONTERA campaign (AL04), in the southern SAB. It highlights buried MTDs downward the slope and three decollement levels above the Q1 reflector. Mx Mass transport deposits represented in map Figure 2B. AR Alboran Ridge, PB Pytheas Bank, M, P0, P1, BQD, Q0, xx refer to seismic reflectors defined in figure 4.

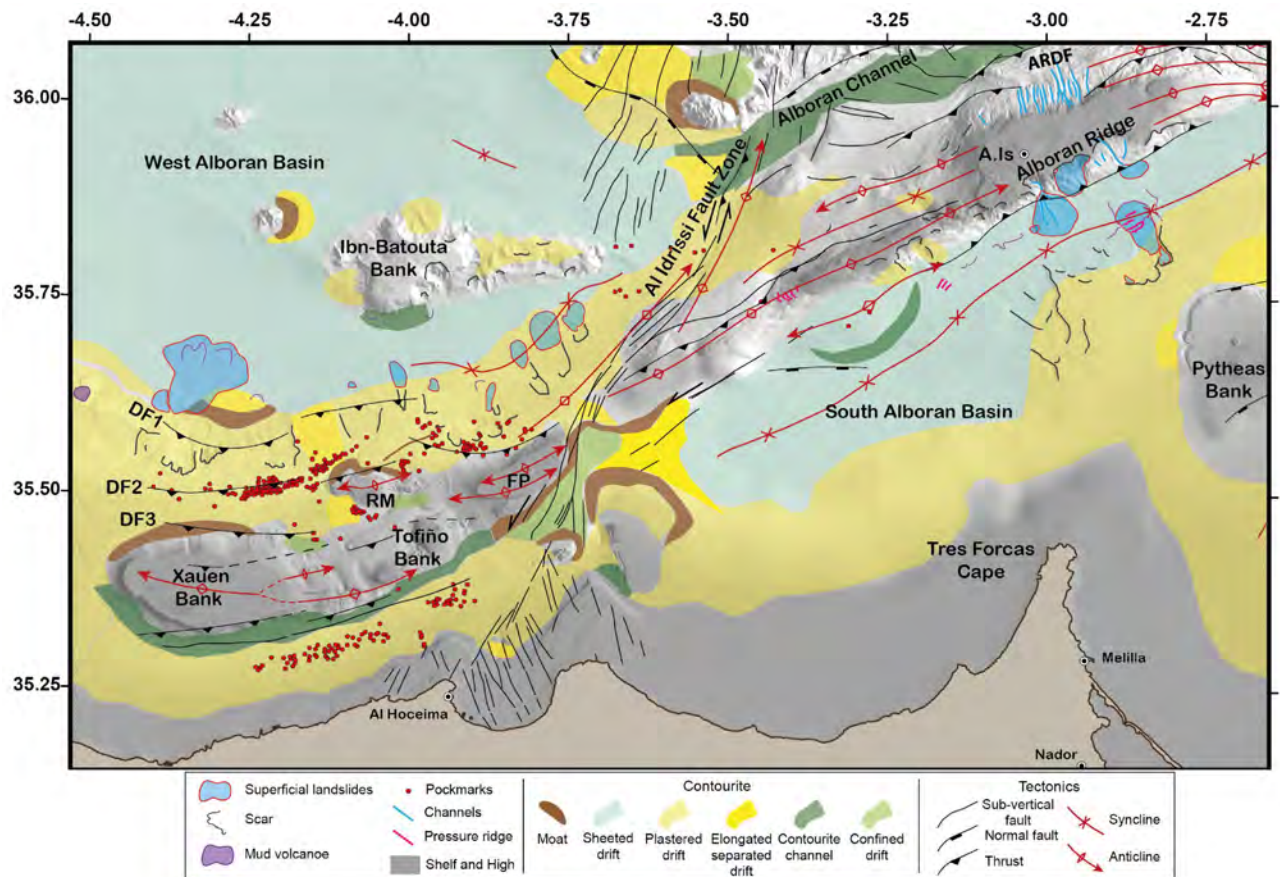

Figure 8: Morpho-structural map of the study area. Contourite deposits from Ercilla et al. 2019, structural features from d’Acremont et al. (2020) and Lafosse et al. (2020). A.Is, Alboran Island; BBFZ, Boussekkour-Bokkoya Fault Zone; FP, Francesc Pagès Seamount; RM, Ramon Margalef High. DF1, DF2, DF3, deformation front highlighted by blind thrusts.

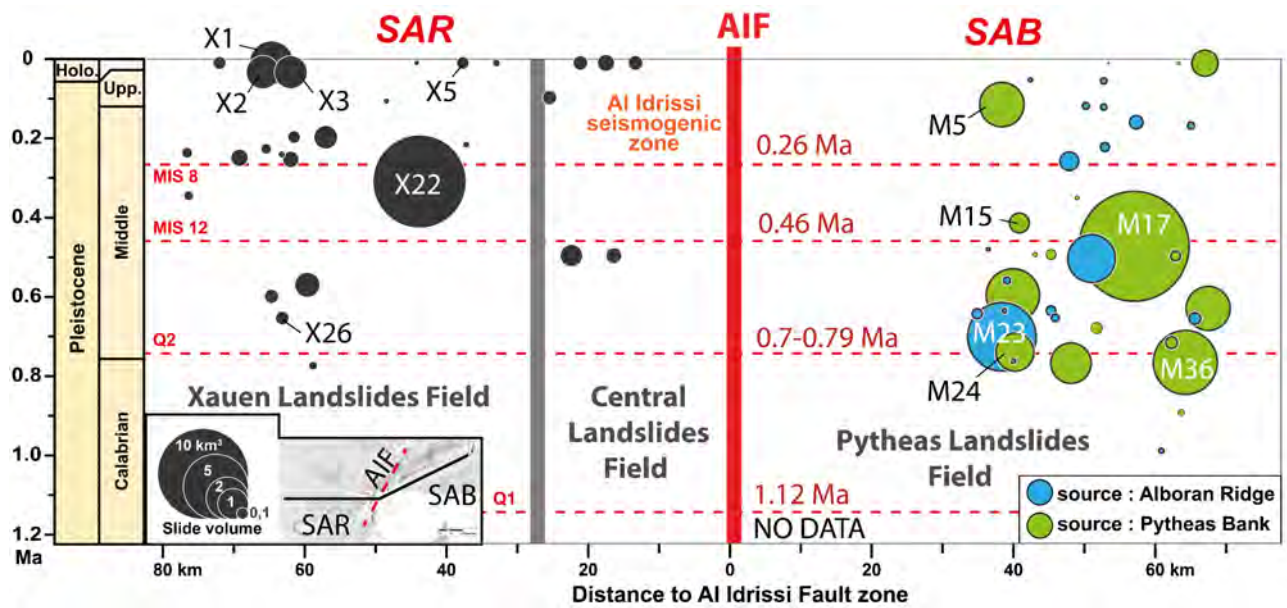

Figure 9: Distribution of MTDs observed and quantified in the southern part of the Alboran Sea, west and east of the AIFZ. The three landslide fields are localized in the Figure 2A: Xauen landslides field north to the Xauen and Tofiño Banks; Central landslides field north of the Francesc Pagès Seamount; Pytheas landslides field between the Alboran Ridge and the Pytheas bank. The MTDs are represented according to their age, volumes and for those in the east, their sources. See Appendix A1 and A2 for MTD characteristics. Xx and Mx correspond to the code names of the MTDs described and shown in Figure 2B.

Figure 10: Fluid escape and compactional fault features through contourite drift in the SAR region (north Xauen Bank). A. Sub-seabed expression of fluid escapes and pockmarks on ultra-high resolution seismic reflection data (TOPAS). Location in B. B. High-resolution seismic reflection data showing the deformation below the contourite drift, associated to faults and fluid escapes. The normal faults here are interpreted as due to fold extrados extension from blind thrusts. Inset: in red location of MAR04 and TOPAS profiles, black rectangle corresponds to bathymetric zoom C. C. Seabed expression of pockmarks and landslide scar. Bathymetric data with contours every 50m. XB, Xauen Bank; TB, Tofino Bank; RM, Ramon Margalef Seamount.

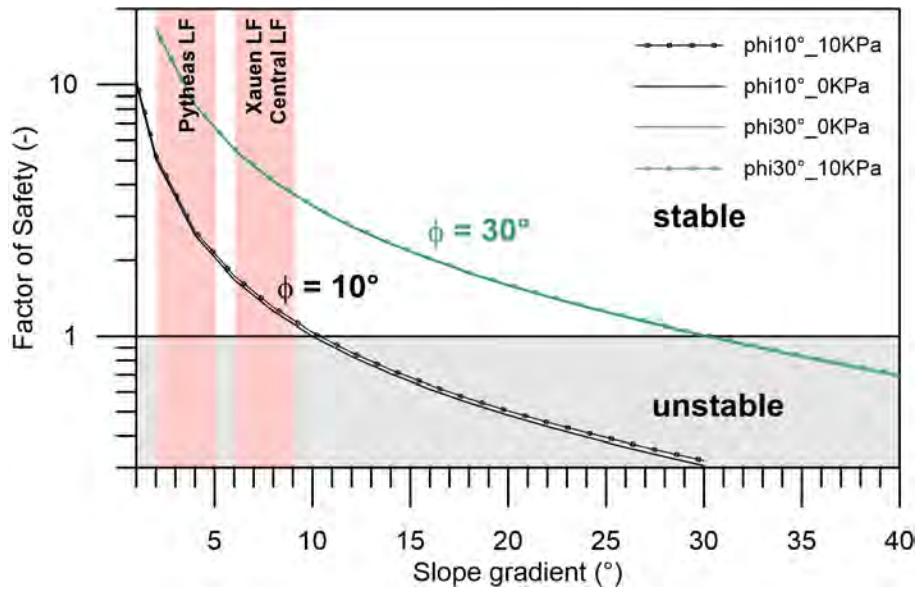

Figure 11 : Factor of safety calculations based on the infinite slope approach (FOSIS) illustrating that according to the Mohr-Coulomb criteria, the minimum slope angle required to trigger a failure is the friction angle. Calculations for three values of cohesions illustrates the restricted effects on the stability. Area of the three landslide fields (LF) according to their slope gradients are represented in pink. ϕ friction angle (ϕ); Cohesion (KPa).

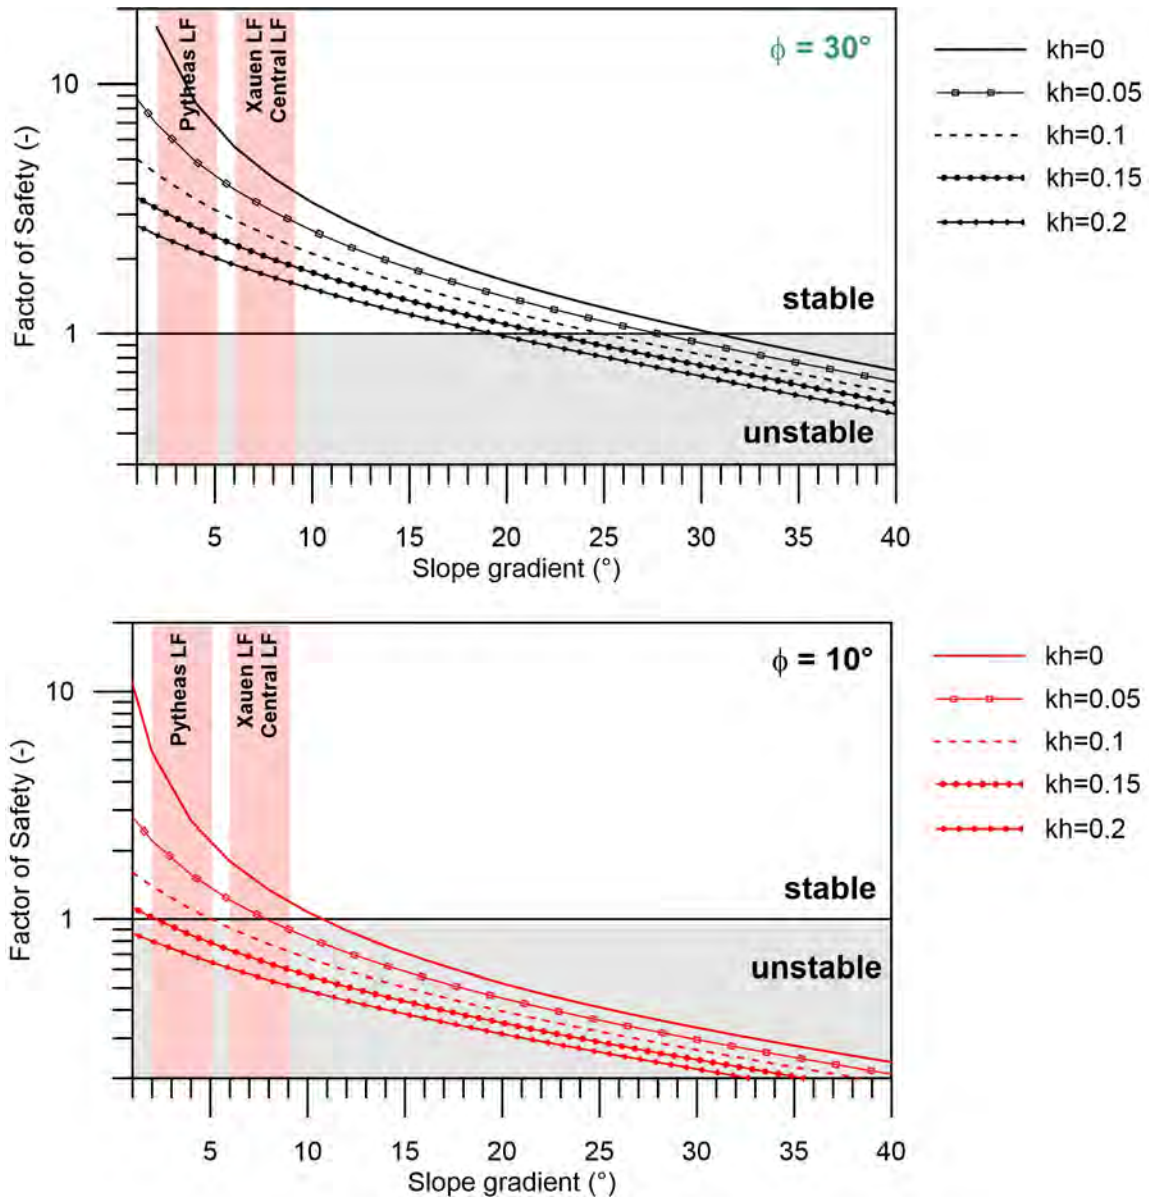

Figure 12: Factor of safety calculations based on the pseudostatic approach (FOSPS) for seismic coefficients kh from 0 to 0.2. Top: scenario of sediments with a friction angle of 30° . Bottom: scenario of sediments with a friction angle of 10° . Instability may be attained for the Xauen and Central Landslide Fields (LF) if $kh > 0.05$, and for the Pytheas LF $kh > 0.1$. ϕ friction angle; kh pseudostatic seismic coefficient.

Figure 13: Peak Ground Accelerations (PGA) obtained for reverse and strike-slip earthquakes as function of the epicentral distance. kh pseudostatic seismic coefficient. MI earthquake magnitude. D - distance between the landslide field (scar features) and the closest tectonic structure (See Appendix A6 for details).
