HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Accelerated Convergence of Error Quantiles using Robust Randomized Quasi Monte Carlo Methods ^{*}

Emmanuel Gobet[†] Matthieu Lerasle[‡] David Métivier[§]

September 14, 2024

ABSTRACT: We aim to calculate an expectation $\mu(F) = \mathbb{E}(F(\mathbf{U}))$ for functions $F : [0, 1]^d \mapsto \mathbb{R}$ using a family of estimators $(\widehat{\mu}_B)_B$ with a budget of B evaluation points. The standard Monte Carlo method achieves a root mean squared risk of order $1/\sqrt{B}$, both for a fixed square integrable function F and for the worst-case risk over the class \mathcal{F} of functions with $\|F\|_{L_2} \leq 1$. Using a sequence of Randomized Quasi Monte Carlo (RQMC) methods, in contrast, we have a faster convergence $\sigma_B \ll 1/\sqrt{B}$ for the risk $\sigma_B = \sigma_B(F)$ when fixing a function F , as a difference with the worst-case risk which is still of order $1/\sqrt{B}$. We address the convergence of quantiles of the absolute error, namely, for a given confidence level $1 - \delta$ this is the minimal ε such that $\mathbb{P}(|\widehat{\mu}_B(F) - \mu(F)| > \varepsilon) \leq \delta$ holds. We show that a judicious choice of a robust aggregation method coupled with RQMC methods allows reaching improved convergence rates for ε depending on δ and B , while fixing a function F . This study includes a review on concentration bounds for the empirical mean as well as sub-Gaussian mean estimates and is supported by numerical experiments, ranging from bounded F to heavy-tailed $F(\mathbf{U})$, the latter being well suited to functions F with a singularity. The different methods we have tested are available in a Julia package.

integral of the form

$$\mu(F) = \int_{[0,1]^d} F(\mathbf{x})d\mathbf{x} = \mathbb{E}(F(\mathbf{U})), \quad (1.1)$$

with $F : [0, 1]^d \mapsto \mathbb{R}$ and $\mathbf{U} \sim \mathcal{U}([0, 1]^d)$. The above is written under a generic form of expectation with respect to (w.r.t.) the uniform distribution over the unit cube: it is not really a restriction since even in the case where the Quantity of Interest (QoI) is an expectation w.r.t. a more complex distribution, in practice we usually generate uniform samples and after some transformations specific to the sampling scheme, we are back to Eq. (1.1) with some F related to the QoI and to the sampling scheme.

The current work is devoted to the use of Randomized Quasi Monte Carlo Sequences (RQMCS) to evaluate $\mu(F)$ and, specifically, how to derive some confidence intervals that are provably better than those obtained with usual independent random sequences (standard Monte Carlo method). Let us be more specific on the objectives. Given an estimator $\hat{\mu}(F)$ of $\mu(F)$, while it is standard to assess the accuracy using the Mean Squared Error (MSE) given by $\mathbb{E}(|\hat{\mu}(F) - \mu(F)|^2)$, we alternatively focus on the $(1 - \delta)$ -quantile of the absolute error:

$$e(\hat{\mu}, \delta, F) := \inf\{\varepsilon > 0 : \mathbb{P}(|\hat{\mu}(F) - \mu(F)| > \varepsilon) \leq \delta\}. \quad (1.2)$$

Our aim is to design some estimators $\hat{\mu}$, combining RQMCS and robust statistics, that achieve efficient upper bounds for the above quantile, for a given $\delta \in (0, 1)$ and a given F , and to compare these estimators on various examples. Robust statistics refer to various statistical methods that are robust to tail assumptions on the data and to data outliers, see [24] for an overview. Monte Carlo and Quasi Monte Carlo methods are discussed in several monographs [44, 59] and review articles [62, 5, 21]. For RQMCS, see [31], [14], [30] for reviews. From now on, we will use the term Monte Carlo alone when referring to the standard Monte Carlo method, i.e. i.i.d. uniform sampling. We fix a few notations:

- we make use of n independent mini-batches, each providing an estimate $(\bar{\mu}_N^{(i)}(F), i = 1, \dots, n)$ of $\mu(F)$;
- the i -th mini-batch estimate is computed as an average of F along a sequence of N points $(\mathbf{R}_1^{(i)}, \dots, \mathbf{R}_N^{(i)})$ so that

$$\bar{\mu}_N^{(i)}(F) := \frac{1}{N} \sum_{j=1}^N F(\mathbf{R}_j^{(i)}). \quad (1.3)$$

The RQMCS $(\mathbf{R}_1^{(i)}, \dots, \mathbf{R}_N^{(i)})$ are usually generated using a low-discrepancy deterministic sequence including an appropriate randomization: for such techniques, see the Cranley-Patterson rotation [10], scrambled nets [46][15, Chapter 13]. Usually the size N being given (as a power of an integer in the case of (t, m, d) -nets), one has to choose a RQMCS of that size; for extensible sequence, see [22][15, Chapter 4]. The key properties of the RQMCS are that each $\mathbf{R}_j^{(i)}$ is distributed as $\mathcal{U}([0, 1]^d)$, while having the N points fill more regularly the unit cube than usual independent random points so that

$$(\sigma_N(F))^2 := \text{Var}\left(\bar{\mu}_N^{(i)}(F)\right) = o(N^{-1}) \quad \text{as } N \rightarrow +\infty, \quad (1.4)$$

for appropriate functions F and RQMCS. See [48, Theorem 1] or [17, Corollary 1] showing the above estimate under the sole assumption that F is square integrable and when the RQMCS is based on a (t, m, d) scrambled net. For strong law of large numbers for $F(U) \in L^p$ ($p > 1$), see the recent work [56]. In [53, Theorem 3], it is proved that $\sigma_N(F) = \mathcal{O}(N^{-3/2}[\log(N)]^{(d-1)/2})$ for smooth functions and scrambled nets. We refer to Section 4.3 for quantitative results. Unless specified explicitly all the convergence results will be meant for a given F in some functional space \mathcal{F} , as opposed to uniformly over all F in \mathcal{F} as in [28]. However, we will compare our results (for a given F) with those in the latter reference.

All in all, as a first estimator of $\mu(F)$, we can consider the Empirical Mean (EM) over the n mini-batches:

$$\bar{\mu}_{N,n}(F) := \frac{1}{n} \sum_{i=1}^n \bar{\mu}_N^{(i)}(F). \quad (1.5)$$

Because $\mathbf{R}_j^{(i)}$ is uniformly distributed, $\bar{\mu}_{N,n}(F)$ is advantageously an unbiased estimator of $\mu(F)$. The MSE of $\bar{\mu}_{N,n}(F)$ equals its variance:

$$\mathbb{E}(|\bar{\mu}_{N,n}(F) - \mu(F)|^2) = \text{Var}(\bar{\mu}_{N,n}(F)) = \frac{(\sigma_N(F))^2}{n} = o(N^{-1}) n^{-1},$$

as $N \rightarrow \infty$, showing that the distribution of $\bar{\mu}_{N,n}(F)$ concentrates much around its mean. We aim at designing non-asymptotic confidence intervals (CIs) of $\mu(F)$ for estimators (possibly different from $\bar{\mu}_{N,n}(F)$) which would efficiently leverage the fast convergence rate Eq. (1.4). One of our main results (see Theorem 5.1 for a precise statement) states that, for any uncertainty level $\delta \in (0, 1)$, for some specific estimator $\hat{\mu}_{B,\delta}(F) := \hat{\mu}_{B,\delta}(\bar{\mu}_N^{(i)}(F) : 1 \leq i \leq n)$ based on a budget of $B \geq n \times N$ points (both n and N depending on the budget B and δ , see later for details), the $(1 - \delta)$ -quantile of the absolute error is bounded as follows:

$$e(\hat{\mu}_{B,\delta}, \delta, F) \leq (\sigma_N(F)\sqrt{N})L_{\delta,n}\sqrt{\frac{\log(2/\delta)}{B}} \quad (1.6)$$

where $L_{\delta,n} \approx \sqrt{2}$, $\sigma_N(F)\sqrt{N} \rightarrow 0$ for any square integrable F (with some fast rates to 0 when F satisfies some regularity/singularity estimates – see Theorem 4.4). Our results complement lower bound results of [28] by providing explicit estimators matching their worst-case lower bounds (up to log terms) and by establishing convergence rates in new situations. See Section 5 for a detailed discussion. Note that the above theoretical bound can be turned into a practical bound using an empirical estimation of $\sigma_N(F)$ based on the same samples $(\bar{\mu}_N^{(i)}(F))_{i=1,\dots,n}$.

To achieve this program, we will first analyze in Section 2 that the usual empirical mean Eq. (1.5) can not – in general – achieve the above bounds Eq. (1.6), thus we have to propose new estimators of $\mu(F)$ based on different aggregations of $\bar{\mu}_N^{(i)}(F)$. Combining robust mean estimator with established randomized algorithms for achieving better confidence properties has been done in the past with the median trick (or probability amplification) [26]. It is similar to what is called median-of-means (see Section 3.3). Here we investigate, in a more generic framework, robust mean estimators that have better theoretical guarantees and perform better numerically. In particular, these estimators should satisfy finite sample risk bounds like Eq. (1.6) that

- are proportional to the optimal rate $\sigma_N(F)/\sqrt{n}$ with respect to n, N , thus fully benefiting from the low discrepancy property of RQMCS;
- are proportional to the optimal $\sqrt{\log 1/\delta}$ rate with respect to δ , to be relevant even for very small uncertainty levels δ .

Interestingly, this question is related to the work of Catoni [6]. In this paper, the author wondered if one can design an estimator of the expectation $\mu_X = \mathbb{E}(X)$ of a random variable X from an independent identically distributed (i.i.d.) sample X_1, \dots, X_n with sub-Gaussian deviation tails, assuming only a finite second moment of each variable X_i . He proved that it is possible to build estimators $\hat{\mu}_{\delta, \sigma_X}$ depending on the uncertainty level δ and the standard deviation $\sigma_X = \sqrt{\text{Var}(X)}$ such that

$$\mathbb{P} \left(|\hat{\mu}_{\delta, \sigma_X} - \mu_X| > C_n \sigma_X \sqrt{\frac{\log(1/\delta)}{n}} \right) \leq \delta, \quad (1.7)$$

with leading constant C_n asymptotically as $n \rightarrow \infty$ not larger than the optimal value $\sqrt{2}$ and independent of the law of X , level $\delta \geq \exp(-cn)$ for some absolute constant c (see Remark 3.1 about the optimality of $\sqrt{2}$ as a lower bound for C_n). Notice that the bound Eq. (1.7) exhibits precisely the behavior we are seeking for our estimators (see Eq. (1.2)-(1.6)) when applied to the random variables $X_i = \bar{\mu}_N^{(i)}(F)$. Let us pause for a second to stress important points regarding this result: Compared to the empirical mean, there are indeed important restrictions to this result, that may be undesirable in our application.

- i) First, the Catoni estimator depends on the standard deviation parameter σ_X , which is typically unknown in applications.
- ii) Second, it also depends on the uncertainty level δ .
- iii) Third, the uncertainty level δ has to be sufficiently large (at least of order $\exp(-cn)$).

The biggest problem to apply this result is the dependency of the estimator on σ_X (although we can follow Catoni's strategy by replacing σ_X by an appropriate estimator). However, Catoni's work was followed by [11] that showed that the median-of-means principle can be used to build estimators achieving similar theoretical results (although with worse leading constants $C_n > \sqrt{2}$). Compared with Catoni's estimators, median-of-means estimators *do not depend on* σ_X and are robust to the presence of a few outliers. In Section 3 we will present three other robust mean estimators that do not depend on σ_X . This proves that the first restriction i) can be easily overcome. The paper [11] also showed, however, that the dependency in the confidence level $1 - \delta$ is mandatory without further information on the distribution of X and that the third restriction always holds unless X is sub-Gaussian with a link between its variance and its ψ_2 -norm. Table 6.1 reports the minimal number n for usual values of δ and it turns out that these restrictions on n are quite mild. Among all robust mean estimators that will be discussed in this work, we will see that, in our experiments, the Lee-Valiant estimator [33] often provides the most accurate result.

Asymptotic error assessment. Last but not least, to complete the state-of-the-art picture, let us mention some references about evaluating RQMC error asymptotically (although our focus is on non-asymptotic estimates). In numerical software packages, stopping criteria are sometimes proposed [2, 8] as approximate error assessment methods. Besides, in some cases, the distribution of $\bar{\mu}_N^{(i)}(F)$ for N large can be close to a normal distribution: if so, $\bar{\mu}_{N,n}(F)$ is also (approximately) normally distributed, so the Empirical Mean is exactly a (sub)-Gaussian estimators (and thus optimal); then, robust mean estimators are not expected to yield much improvement against EM. These cases of asymptotic normality are known for $(0, m, d)$ -scrambled nets and for F with Lipschitz continuous first derivatives, see [35]; sufficient conditions are, furthermore, studied in [42]. However, the approximate normality of $\bar{\mu}_N^{(i)}(F)$ may not hold, as exemplified by [32]. All in all, non-asymptotic approaches keep all its advantages compared to the asymptotic point of view. Last, we refer to the work [28] by Kunsch and Rudolf, which has been pointed out to us by the authors when our work was finalized and presented in conference: their work deals with theoretical asymptotic minimal error bounds for confidence intervals. In Section 5, we discuss how our approach fits in their framework by achieving the minimal error bounds.

Our contributions. This paper combines Robust (sub-Gaussian) Estimators with Quasi Monte Carlo method to exhibit Robust Randomized Quasi Monte Carlo (Robust RQMC) estimates that can be provably highly accurate with a large probability, in the sense of the quantile Eq. (1.2) of the absolute error. To the best of our knowledge, this combination is original. We show that as long as F is squared integrable, the Robust RQMC method converges still faster than the usual Monte Carlo method, and robust methods allow a high concentration of the statistical error around 0. We exhibit, in Theorem 5.1, the associated non-asymptotic confidence interval, and show that for square integrable integrands F or for smoother functional spaces, it matches, in the limit $N \rightarrow +\infty$, the worst-case lower bound (up to a logarithmic term) proved in [28].

As a side contribution, we show in Theorem 4.4, how quick the Mean Square Error $(\sigma_N(F))^2$ decreases for integrands with corner singularities. This extends the previous result of [52] on the expected integration error (L_1 -error) of these functions. Robust statistics are particularly relevant for this kind of singular function mimicking heavy-tailed distributions. Combining Theorems 5.1 and 4.4 together provides confidence intervals for this case, in the form of a bound like Eq. (1.6), and the estimates of Theorem 4.4 support the interest of RQMC method by quantifying the convergence rate (as $N \rightarrow +\infty$) of the factor $\sigma_N(F)\sqrt{N}$ occurring in Eq. (1.6).

Numerical experiments in Section 6 confirm how beneficial the combination of RQMCS and robust mean estimators is, even in the case of smooth and bounded F .

Outline. Section 2 investigates various theoretical concentration-of-measure inequalities for the empirical mean, in the perspective of arguing for variance reduction effect when deriving non-asymptotic confidence intervals. This brief overview is interesting on its own and serves as a warm-up before moving to robust mean estimators. In Section 3 we review the Robust Mean estimators existing in the literature and the best confidence bounds available. In addition, this review is important for understanding the numerical experiments, that can be easily reproduced using a software package that we make accessible online. Section 4 is devoted to present some (Robust) Quasi Monte Carlo

methods with their properties. In the last theoretical Section 5, we derive results combining the two previous approaches. In Section 6, we test these various methods numerically.

2 Are there theoretical guarantees that the empirical mean has improved confidence intervals when using a variance reduction method?

The discussion of this section goes beyond the framework of Randomized Quasi Monte Carlo method, and it actually encompasses any variance reduction method: it is aimed at advocating for the use of robust mean methods for benefiting from variance reduction, instead of simple empirical means (EM).

Namely, consider a variance reduction scheme from which we sample n i.i.d. copies $(\bar{\mu}_N^{(i)}(F))_{i=1, \dots, n}$ of an unbiased estimate of $\mu(F)$, and let us study the accuracy of the empirical mean $\bar{\mu}_{N,n}(F)$ defined in Eq. (1.5) in term of the supposedly reduced variance $(\sigma_N(F))^2 = \text{Var}(\bar{\mu}_N^{(i)}(F))$. The parameter N here should be interpreted as a variance reduction cost equivalent to a sampling effort, that is we should have small $N(\sigma_N(F))^2$. We focus on the measure of accuracy given by error quantiles whose sizes are proportional to $\sigma_N(F)$, in particular by computing the $(1 - \delta)$ -quantile of the absolute error under the form

$$e(\bar{\mu}_{N,n}, \delta, F) \leq \sigma_N(F)g(n, \delta). \quad (2.1)$$

The parameter δ is the so-called *uncertainty*. We retrieve a full variance reduction effect on the error quantile if g does only depend on n and δ , but not on the distribution of $F(U)$.

Concentration-of-measure inequalities are the crux for quantile bounds such as Eq. (2.1). The aim of the following discussion is to show that none of the available concentration-of-measure inequalities is able to fit Eq. (2.1).

Asymptotic bounds ($n \rightarrow +\infty$). The Central Limit Theorem gives, for fixed N, δ and as $n \rightarrow +\infty$,

$$e(\bar{\mu}_{N,n}, \delta, F) \approx \sigma_N(F) \frac{\Phi^{-1}(1 - \delta/2)}{\sqrt{n}}, \quad (2.2)$$

where $\Phi^{-1}(q)$ is the quantile function of the standard Normal distribution. Observe that the above holds for a fixed function F . For a 95% CI, we have $\Phi(0.975) \simeq 1.96$. For later reference, note that $\Phi^{-1}(1 - \delta/2) \sim \sqrt{2 \log(1/\delta)}$ as $\delta \rightarrow 0$, so that Eq. (2.2) writes (as $n \rightarrow \infty$ for fixed small δ):

$$e(\bar{\mu}_{N,n}, \delta, F) \approx \sigma_N(F) \sqrt{\frac{2 \log(1/\delta)}{n}} = \sqrt{2} \frac{\sigma_N(F) \sqrt{N}}{\sqrt{B}} \sqrt{\log(1/\delta)}, \quad (2.3)$$

the right hand side being written in terms of budget $B = n \cdot N$. At first sight, Eq. (2.3) is a nice bound which shows well the interest of variance reduction scheme for which $\sigma_N(F)$ is small compared to $1/\sqrt{N}$ (as for some RQMC methods, see Theorem 4.1). However, a careful

look at the above bound shows that for a given budget B , one has better to take $N \rightarrow +\infty$ with n fixed, which is in contradiction with the applicability of the CLT.

In other words, to capture the benefit of variance reduction, we need to state bounds valid for finite n , with the hope that a small $\sigma_N(F)$ improves the probable bound on $|\bar{\mu}_{N,n}(F) - \mu(F)|$. The theory of concentration of inequalities (see [4] for a broad overview) is dedicated to derive such finite sample bounds. However, these are never as good as the asymptotic ones, even under strong assumptions such as boundedness of $\bar{\mu}_N^{(i)}(F)$, and they are deteriorating rapidly when these assumptions are relaxed to allow for unbounded $\bar{\mu}_N^{(i)}(F)$. Before moving to other aggregation procedures of the $(\bar{\mu}_N^{(i)}(F))_{i=1,\dots,n}$ in Section 3, let us briefly review classical bounds that can be proved for the empirical mean.

Finite sample bounds (n fixed) under sub α -exponential moments for $\bar{\mu}_N^{(i)}(F)$. We now discuss bounds available for fixed n : they depend on extra assumptions available for $\bar{\mu}_N^{(i)}(F)$. Under bounded assumption, see Hoeffding and Bennett inequalities; under sub-Gaussian or sub-exponential tail assumptions, see Bernstein inequalities; for a detailed presentation, we refer to the first version of this work [18]. Here, for the sake of efficiency in the argumentation, we adopt a single setting encompassing various cases where $\bar{\mu}_N^{(i)}(F)$ has some exponential moments: we do not pretend that our presentation leads to sharp constants in the upper bounds, however it has the advantage to convey the main ideas. The assumption of sub-exponential tail can be stated using Orlicz norms $\|\cdot\|_{\psi_\alpha}$ as the ones considered in [64]: for $\alpha > 0$, for a random variable X define its ψ_α -norm by

$$\|X\|_{\psi_\alpha} = \inf \left\{ c > 0 : \mathbb{E} \left(e^{|X|/c} \right) \leq 2 \right\}. \quad (2.4)$$

Assume for the discussion that $\|\bar{\mu}_N^{(i)}(F)\|_{\psi_\alpha} < \infty$ for some $\alpha \in (0, 1]$ (which covers usual sub-exponential tails for $\bar{\mu}_N^{(i)}(F)$). Using ψ_α -deviation inequality [7, Section 4-(vii)], we get, for any $\varepsilon > 0$ and $\delta > 0$

$$\begin{aligned} \mathbb{P} \left(|\bar{\mu}_{N,n}(F) - \mu(F)| > \varepsilon \right) &\leq 2 \exp \left(- \frac{\varepsilon^\alpha}{\|\bar{\mu}_{N,n}(F) - \mu(F)\|_{\psi_\alpha}^\alpha} \right), \\ e(\bar{\mu}_{N,n}, \delta, F) &\leq \|\bar{\mu}_{N,n}(F) - \mu(F)\|_{\psi_\alpha} (\log(2/\delta))^{1/\alpha}. \end{aligned}$$

Using the Talagrand inequality [64, Theorem 3] and the maximal inequality [7, Section 4-(viii)] for ψ_α -Orlicz norm, we get

$$\|\bar{\mu}_{N,n}(F) - \mu(F)\|_{\psi_\alpha} \leq K_\alpha^{\text{Tal.}} \left(\frac{\sigma_N(F)}{\sqrt{n}} + \frac{\|\bar{\mu}_N^{(1)}(F) - \mu(F)\|_{\psi_\alpha}}{n} \left(\frac{\log(1+n)}{\log(3/2)} \right)^{1/\alpha} \right).$$

All in all, the $(1 - \delta)$ -quantile of the absolute error is bounded as follows:

$$e(\bar{\mu}_{N,n}, \delta, F) \leq K_\alpha^{\text{Tal.}} \frac{\sigma_N(F)}{\sqrt{n}} (\log(2/\delta))^{1/\alpha} \left(1 + \frac{\|\bar{\mu}_N^{(1)}(F) - \mu(F)\|_{\psi_\alpha}}{\sigma_N(F)} \frac{(\log(1+n))^{1/\alpha}}{\sqrt{n}(\log(3/2))^{1/\alpha}} \right). \quad (2.5)$$

The good news is to have $\sigma_N(F)$ in factor, so that the quantile can benefit from the variance reduction of the RQMC method. The lesser good news comes from the ratio

$$r_N := \frac{\|\bar{\mu}_N^{(1)}(F) - \mu(F)\|_{\psi_\alpha}}{\sigma_N(F)};$$

although it is down-weighted by $1/\sqrt{n}$ there are two issues: a) as $N \rightarrow +\infty$, does it remain bounded? b) is there any explicit bound for this ratio? Both questions are open to our knowledge. What can be established, from the definition of the Orlicz norm ψ_α , is that r_N is bounded from below by a positive quantity independent on N (to see this, expand $e^{(|x|/c)^\alpha}$ in a series of $|x|^\alpha$). Moreover, deriving an upper bound on r_N reduces to prove that $\|\bar{\mu}_N^{(1)}(F) - \mu(F)\|_{\psi_\alpha}$ converges to 0 at the *same* rate as $\sigma_N(F)$: this is a difficult problem, much harder than quantifying an upper bound for the rate at which $\sigma_N(F) \rightarrow 0$ (delicate on its own as we can check from our analysis in Theorem 4.4). As a side-remark, note that the dependence of Eq. (2.5) w.r.t. $\log(\delta)$ is via a α -root and not the square-root, which gives a worse bound for small δ . Similar bounds can be derived for the case $\alpha \in (1, 2]$ (which covers sub-Gaussian tails for $\bar{\mu}_N^{(i)}(F)$), using the Talagrand inequality [64, Theorem 4].

The final conclusion is the same: for the EM, it is extremely delicate (if not impossible in general) to get a bound like

$$e(\bar{\mu}_{N,n}, \delta, F) \leq \frac{\sigma_N(F)\sqrt{N}}{\sqrt{B}}(\log(2/\delta))^{1/\alpha} \times [\dots]$$

with a factor $[\dots]$ that can be bounded explicitly (independent on N), so to mathematically demonstrate the gain of accuracy (in the sense of error quantile) when using RQMC in combination with EM.

Finite sample bounds under finite second moment for $\bar{\mu}_N^{(i)}(F)$. In the extreme (heavy-tail) case where only the second moment of $\bar{\mu}_N^{(i)}(F)$ is finite, then Chebyshev-Cantelli's inequality implies

$$e(\bar{\mu}_{N,n}, \delta, F) \leq \frac{\sigma_N(F)\sqrt{N}}{\sqrt{B}} \frac{1}{\sqrt{\delta}}.$$

Here, the dependency of $\frac{\sigma_N(F)\sqrt{N}}{\sqrt{B}}$ with respect to n, N, B is the targeted order of magnitude. On the other hand, the dependency on the uncertainty level $1/\sqrt{\delta}$ is significantly deteriorated compared with the previous results, of order $(\log(1/\delta))^{1/\alpha}$ for some $\alpha \in (0, 2]$ in Eq. (2.5), or even $\sqrt{\log(1/\delta)}$ in the asymptotic case Eq. (2.2): for $\delta = 5\%$ (resp. $\delta = 0.1\%$), we have $1/\sqrt{\delta} = 4.47$ (resp. 31.62), while $\sqrt{\log(1/\delta)} = 1.73$ (resp. in 2.63).

To summarize, none of the finite sample concentration inequalities yield the desired bound like Eq. (2.3) for the empirical mean, showing that we cannot guarantee that the latter fully benefits from the variance reduction effect in terms of the deviation probability. The rest of this work consists in designing aggregation procedures of $(\bar{\mu}_N^{(i)}(F))_{i=1, \dots, n}$ that achieve accuracy bounds like Eq. (1.6), and then to discuss their theoretical and numerical efficiency.

3 Theory of Robust Mean estimators

We present some standard robust mean estimators as well as some recent ones. In this whole section, we denote by X_1, \dots, X_n a sequence of i.i.d. real random variables with expectation $\mu_X = \mathbb{E}(X_1)$ and finite variance $\sigma_X^2 = \text{Var}(X_1)$. The quantity $\bar{\mu}_n$ is the empirical mean estimator of the X_1, \dots, X_n sample. These results will be applied to our problem by considering $X_i = \bar{\mu}_N^{(i)}(F)$, so $\sigma_X = \sigma_N(F)$ and $\bar{\mu}_n = \bar{\mu}_{N,n}(F)$. Let also $\hat{\mu}_n$ denote a generic mean estimator built from X_1, \dots, X_n .

The accuracy of this estimator $\hat{\mu}_n$ is assessed via the $(1 - \delta)$ -quantile of the absolute error, in a consistent manner with the definition Eq. (1.2) given in introduction, but adapted to the current section:

$$e(\hat{\mu}_n, \delta, X) := \inf\{\varepsilon > 0 : \mathbb{P}(|\hat{\mu}_n - \mu_X| > \varepsilon) \leq \delta\}.$$

3.1 Sub-Gaussian distributions

Using

$$\Phi^{-1}(1 - \delta/2) \leq \sqrt{2 \log(2/\delta)}$$

and the Central Limit theorem, we have

$$\lim_{n \rightarrow \infty} \mathbb{P}\left(|\bar{\mu}_n - \mu_X| \leq \sigma_X \sqrt{\frac{2 \log(2/\delta)}{n}}\right) \geq 1 - \delta$$

for $\delta \in (0, 1)$, that is $e(\bar{\mu}_n, \delta, X) \lesssim \sigma_X \sqrt{\frac{2 \log(2/\delta)}{n}}$ as $n \rightarrow +\infty$.

Definition 3.1. A random variable X is called sub-Gaussian if it satisfies for all $\lambda \in \mathbb{R}$

$$\mathbb{E}(\exp(\lambda(X - \mu_X))) \leq \exp\left(\tilde{\sigma}_X^2 \lambda^2 / 2\right)$$

where $\tilde{\sigma}_X$ is proportional to the ψ_2 -norm of $X - \mu_X$ (as defined in Eq. (2.4)).

It is easy to show using Chernoff's bound that sub-Gaussian random variables satisfy, for any $\delta \in (0, 1)$,

$$e(\bar{\mu}_n, \delta, X) \leq \tilde{\sigma}_X \sqrt{\frac{2 \log(2/\delta)}{n}}.$$

Actually, it can be shown that the empirical mean only achieves this bound (w.r.t. n and δ , for all δ) if X is sub-Gaussian. In particular, thus, if the distribution of X_1 has a finite variance only, the empirical mean does not have sub-Gaussian tails. [6] shows that, under this assumption, Chebyshev's inequality is tight. In the following sections, we present several robust alternatives to the empirical mean. As explained in the introduction, these estimators typically depend on the uncertainty level δ that has therefore to be set by the statistician. This and our ultimate goal motivate the following definition.

Definition 3.2. Given $\delta \in (0, 1)$, we say that an estimator of the mean μ_X is a δ -Sub-Gaussian mean estimator (SGME) $\hat{\mu}_n := \hat{\mu}_n(X_1, \dots, X_n)$ (with some parameter $0 < L < +\infty$), if it satisfies

$$e(\hat{\mu}_n, \delta, X) \leq L\sigma_X \sqrt{\frac{\log(2/\delta)}{n}} \quad (3.1)$$

for any i.i.d. sample X_1, \dots, X_n with mean μ_X and variance σ_X^2 .

Informally, δ -sub-Gaussian estimators are those we are interested in as they exhibit provable risk bounds of optimal order both with respect to n, σ_X and δ . It turns out that such estimators exist even under weak finite second moment assumptions on data, but they have to depend on the confidence level.

Remark 3.1 (Optimality of sub-Gaussian Mean Estimator). *SGME are optimal in the sense that for any estimator of the mean $\hat{\mu}_n$ and uncertainty level $\delta \in (0, 1)$, we must have (see [6, Proposition 6.1])*

$$e(\hat{\mu}_n, \delta, X) \geq \sigma_X \frac{\Phi^{-1}(1 - \delta/2)}{\sqrt{n}}.$$

Since $\Phi^{-1}(1 - \delta/2) \sim \sqrt{2 \log(2/\delta)}$ for small δ , we must have $L \geq L_{\text{optimal}} = \sqrt{2}$ for any mean estimator working for all finite variance distributions. An estimator satisfying $L = \sqrt{2} + o(1)$ is referred to as "nearly optimal".

3.2 Trimmed Mean

Perhaps the most intuitive robust mean estimator is the trimmed mean, which removes the most extreme samples and takes the empirical mean on the remaining samples. The asymptotic behavior of this estimator is well known, see for example [63]. However, the non-asymptotic deviation bounds have only recently been investigated. We present here a result from [36, Theorem 6] attributed to [45] (work unpublished at the date of our work).

For $\alpha \leq \beta$, define the truncation function

$$\varphi_{\alpha, \beta}(x) = \begin{cases} \beta & \text{if } x > \beta, \\ x & \text{if } x \in [\alpha, \beta], \\ \alpha & \text{if } x < \alpha. \end{cases}$$

For $y_1, \dots, y_m \in \mathbb{R}$, let $y_1^* \leq y_2^* \leq \dots \leq y_m^*$ be a non-decreasing rearrangement.

Theorem 3.1 ([36, Theorem 6]). *Let n be an even integer. Let $X_1, \dots, X_{n/2}, Y_1, \dots, Y_{n/2}$ be i.i.d. random variables with mean μ_X and variance σ_X^2 .*

1. Let $\delta \in (0, 1)$ be such that $n > (32/3) \log(8/\delta)$ and

$$\varepsilon = \frac{32 \log(8/\delta)}{3n}.$$

2. Assume for simplicity that $\varepsilon n/2$ is an integer.

3. Let $\alpha = Y_{\varepsilon n/2}^*$ and $\beta = Y_{(1-\varepsilon)n/2}^*$ and set the trimmed mean estimator as

$$\widehat{\mu}_n = \frac{2}{n} \sum_{i=1}^{n/2} \varphi_{\alpha, \beta}(X_i).$$

Then

$$e(\widehat{\mu}_n, \delta, X) \leq 19\sigma_X \sqrt{\frac{2 \log(8/\delta)}{n}}.$$

In words, the trimmed mean is a δ -sub-Gaussian estimator. It does not depend on σ_X but it is "structurally not" nearly optimal as a trimmed mean is based essentially on only half of the sample (the other half being used to compute the trimming levels α and β). The constant $L = 19$ appearing in the bound can probably be optimized, it differs from the constant $L = 9$ given in [36, Theorem 6] which is the result of a typo.

3.3 Median-of-means

An alternative to trimmed mean, that has theoretically the same kind of properties, is given by median-of-means. The idea is to partition the dataset into batches, take the mean on each batch, and then aggregate these estimators by taking their median. These estimators are structurally robust to the presence of a few outliers due to the median step, but they can also easily be shown to be δ -sub-Gaussian when the number of blocks is of order $\log(1/\delta)$. We present these estimators and this property formally in this section.

Definition 3.3. *The median-of-means estimator $\widehat{\mu}_n$ of a sample X_1, \dots, X_n is defined as*

$$\widehat{\mu}_n = \text{median}(\bar{X}_{J_1}, \dots, \bar{X}_{J_k}) \tag{3.2}$$

where $\bar{X}_{J_l} = |J_l|^{-1} \sum_{i \in J_l} X_i$ and J_l is a partition of $\{1, \dots, n\}$, that is $\{1, \dots, n\} = \bigcup_{l=1}^k J_l$ and $J_l \cap J_{l'} = \emptyset$ for $l \neq l'$, each batch J_l has roughly the same size. In the following, we denote by $m = |J_l|$ assuming $n = km$.

We used the notation $|J| := \text{Card}(J)$ to denote the cardinality of an ensemble. Note that the result depends on the arrangements of the sample.

Median-of-means estimators appeared independently in various communities, see for example [43, 1]. Their sub-Gaussian property was established in [11]. We present here a slightly tighter result.

Theorem 3.2 ([11, Theorem 4.1]). *Let X_1, \dots, X_n be i.i.d. random variables with mean μ_X and variance σ_X^2 . Let m, k be positive integers, assume that $n = mk$. Then the median-of-means estimator $\widehat{\mu}_n$ introduced in Definition 3.3, is a δ -sub-Gaussian estimator with $k = \lceil 8 \log(1/\delta) \rceil \leq n$, that is*

$$e(\widehat{\mu}_n, \delta, X) \leq \sigma_X \sqrt{\frac{32 \log(1/\delta)}{n}}.$$

A permutation-invariant version of median-of-means estimators exists (also related to a higher order Hodges-Lehmann estimator), see the discussion in [41, Section 3.4]. There, the median is taken over all possible equi-partitions of the samples, $\text{median}(\bar{X}_J, J \in \mathcal{A}_n^{(k)})$, $\mathcal{A}_n^{(k)} = \{J : J \subseteq \{1, \dots, n\}, |J| = k\}$. In this case, it is not clear how the deviation bounds are modified, but we expect a better estimate. Of course, $|\mathcal{A}_n^{(k)}| = \binom{n}{k}$ so this estimator is not tractable in practice.

3.4 Z-estimators

Parameter estimation often relies on minimization (or maximization) criteria, such as the Maximum Likelihood estimator. Another classical example is the problem of estimating a location parameter θ by minimizing the mean square error $\sum_i (X_i - \theta)^2$. The minimum is reached at the empirical mean $\theta^* = \bar{\mu}_n$. Generalizing that idea, M-estimators were introduced [25] to minimize the expression of the type $\sum_i \rho(X_i - \theta)$ for some well-chosen function ρ . Similarly, Z-estimators are defined as the zero of the expression $\sum_i \psi(X_i - \theta)$ where $\psi = \rho'$ is called the influence function. Here we consider Z-estimators, $\hat{\mu}_n$, defined as the zero of the following equation

$$\mathcal{R}_{n,\psi}(\theta) = \sum_{i=1}^n \psi(\alpha(X_i - \theta)), \quad (3.3)$$

where the influence function $\psi : \mathbb{R} \rightarrow \mathbb{R}$ is an antisymmetric non-decreasing function and $\alpha \in \mathbb{R}$ is a tuning parameter. Different choices of an influence function yield different estimators. For example, $\psi(x) = x$ gives the empirical mean, while $\psi(x) = \text{sign}(x)$ gives a median estimator. The behavior at large $|x|$ determines the outliers' importance.

3.4.1 Huber's influence function

The Huber's influence function [25] is defined as

$$\psi(x) = \begin{cases} 1 & \text{if } x > 1, \\ x & \text{if } |x| \leq 1, \\ -1 & \text{if } x < -1. \end{cases} \quad (3.4)$$

Essentially all large values above some threshold dictated by α are treated with the same weight. In this case, the following result shows that the Huber M-estimator is sub-Gaussian.

Theorem 3.3 (See for example [38, Section 3]). *Let X_1, \dots, X_n be i.i.d. random variables with mean μ_X and variance σ_X^2 . Let $\delta \in (0, 1)$ be such that $n > 2 \log(2/\delta)$. Define the Huber's mean estimator $\hat{\mu}_n$ as the zero of Eq. (3.3) with influence function Eq. (3.4) and parameter*

$$\alpha = \sqrt{\frac{2 \log(4/\delta)}{n \sigma_X^2}}. \quad (3.5)$$

Then Huber's mean estimator is a δ -sub-Gaussian estimator, that is

$$e(\hat{\mu}_n, \delta, X) \leq 8\sigma_X \sqrt{\frac{2 \log(4/\delta)}{n}}.$$

Notice that, contrary to the previously introduced estimators, Huber’s estimator depends on the variance σ_X^2 through the tuning parameter α . In practice, this undesirable feature can be partially overcome by taking an estimator of σ_X^2 .

3.4.2 Catoni’s influence function

Catoni in [6] proposes the following influence function

$$\psi(x) = \begin{cases} \log(1 + x + x^2/2) & \text{if } x \leq 0, \\ -\log(1 - x + x^2/2) & \text{if } x > 0. \end{cases} \quad (3.6)$$

This function is not bounded, and the resulting estimators are therefore still sensitive to very large outliers. However, the logarithmic growth at infinity allows reducing the importance of “reasonable outliers” arising in i.i.d. samples from finite two moments distributions, as shown by the following result.

Theorem 3.4 ([6]). *Let X_1, \dots, X_n be i.i.d. random variables with mean μ_X and variance σ_X^2 . Let $\delta \in (0, 1)$ be such that $n > 2 \log(2/\delta)$. Define Catoni’s mean estimator $\hat{\mu}_n$ as the zero of Eq. (3.3) with the influence function Eq. (3.6) and the parameter*

$$\alpha = \sqrt{\frac{2 \log(2/\delta)}{n \sigma_X^2 \left(1 + \frac{2 \log(2/\delta)}{n - 2 \log(2/\delta)}\right)}}. \quad (3.7)$$

Then

$$e(\hat{\mu}_n, \delta, X) \leq \sigma_X \sqrt{\frac{2 \log(2/\delta)}{n - 2 \log(2/\delta)}}. \quad (3.8)$$

The sub-Gaussian bound satisfied by Catoni’s estimator is therefore tight up to a $\frac{1}{1 - \frac{2 \log(2/\delta)}{n}}$ = $1 + o(1)$ term when $\log(1/\delta)/n \rightarrow 0$. As Huber’s estimators, the tuning parameter defining Catoni’s estimators depends on the variance σ_X^2 which is usually unknown. When an interval $[\sigma_1, \sigma_2]$ is known such that $\sigma_X \in [\sigma_1, \sigma_2]$, Catoni [6, Section 3] showed that this dependency can be removed using Lepski’s method. However, the bounds are only tight when the ratio σ_2/σ_1 is bounded and this extra step makes the leading constant in the risk bound bigger than its optimal value $\sqrt{2}$.

3.4.3 Lee-Valiant estimator

In a recent work, Lee and Valiant [33] propose a tight SGME up to a term going to zero, that does not require any knowledge on the variance.

Definition 3.4. *For a given δ , define the median-of-means estimator Eq. (3.2) $\kappa := \kappa(X_1, \dots, X_n)$ computed on $k = \log(\frac{1}{\delta}) \leq n$ groups with $\delta \geq e^{-n}$ and k an integer. The Lee-Valiant estimator is then defined as*

$$\hat{\mu}_n = \kappa + \frac{1}{n} \sum_{i=1}^n (X_i - \kappa)(1 - \min(\alpha(X_i - \kappa)^2, 1)) \quad (3.9)$$

where the parameter α is the solution of the monotonic, piecewise-linear equation

$$\sum_{i=1}^n \min(\alpha(X_i - \kappa)^2, 1) = \frac{1}{3} \log\left(\frac{1}{\delta}\right). \quad (3.10)$$

Theorem 3.5 ([33]). *Let X_1, \dots, X_n be i.i.d. random variables with mean μ_X and variance σ_X^2 . Let $\delta \in (0, 1)$ be such that $\delta \geq e^{-n}$ and assume that $k = \log(\frac{1}{\delta})$ is an integer. Then, Lee-Valiant's estimator $\hat{\mu}_n$ introduced in Definition 3.4, satisfies*

$$e(\hat{\mu}_n, \delta, X) \leq \sigma_X(1 + o(1))\sqrt{\frac{2 \log(1/\delta)}{n}}, \quad (3.11)$$

where the $o(1)$ term goes to zero when $(\delta, \log(1/\delta)/n) \rightarrow (0, 0)$.

In this result, the $o(1)$ term is not explicit, this is also the case in the proof of this theorem in [33]. This means that the risk bound cannot be used directly to derive confidence intervals in applications. When $\kappa = 0$, Lee-Valiant's estimator can be reformulated as an M-estimator. The condition Eq. (3.10) guarantees that " $\frac{1}{3} \log\left(\frac{1}{\delta}\right)$ of the samples are discarded".

3.4.4 Minsker-Ndaoud's Estimator

In an even more recent work, Minsker and Ndaoud [41] propose another SGME that does not require any information on the variance and describe its properties in detail. The idea is, as for median-of-means, to divide the sample X_1, \dots, X_n into k blocks of similar size and take the empirical mean \bar{X}_l of each block J_l . However, instead of computing the median of the block, they propose a weighted mean where each weight is inversely proportional to the empirical standard deviation $\bar{\sigma}_l$.

Definition 3.5. *Let $p_{\text{MN}} \geq 1$. Minsker-Ndaoud's estimator $\hat{\mu}_n$ of a sample X_1, \dots, X_n is defined as*

$$\hat{\mu}_n = \frac{\sum_{l=1}^k \bar{X}_l / \bar{\sigma}_l^{p_{\text{MN}}}}{\sum_{l=1}^k 1 / \bar{\sigma}_l^{p_{\text{MN}}}}, \quad (3.12)$$

where $\bar{X}_l = |J_l|^{-1} \sum_{i \in J_l} X_i$ is the empirical mean over the block J_l , and $\bar{\sigma}_l$ denotes the empirical

standard deviation. The sample $\{1, \dots, n\} = \bigcup_{l=1}^k J_l$ is divided into k blocks, $J_l \cap J_{l'} = \emptyset$ for $l \neq l'$, of size $m = |J_l|$ assuming $n = km$.

The weights give less importance to the block with large variance (and possibly outliers). Note that for $p_{\text{MN}} = 0$, it corresponds to the empirical mean, while for $p_{\text{MN}} \rightarrow \infty$ only the block with the smallest variance is considered. In [41] the authors consider the case $p_{\text{MN}} = 1$ and $p_{\text{MN}} = 2$. We state a simplified δ dependent version of their main theorem, showing that the estimator Eq. (3.12) is an SGME.

Theorem 3.6 ([41, Theorem 3.1 with Lemma 3.2]). *Let X_1, \dots, X_n be i.i.d. random variables with mean μ_X and variance σ_X^2 . Let $\delta \in (0, 1)$ be such that $\delta \gtrsim e^{-\sqrt{n/\log(n)}}$. Then, Minsker-Ndaoud’s estimator $\hat{\mu}_n$ introduced in Definition 3.5 with $k = \log(3/\delta)$ blocks of size $m = n/k$ satisfies for $p_{\text{MN}} \geq 1$*

$$e(\hat{\mu}_n, \delta, X) \leq \sigma_X C_{p_{\text{MN}}} \sqrt{\frac{1 + \log(3/\delta)}{n}},$$

for some $C_{p_{\text{MN}}} > 0$ constant depending only on p_{MN} .

Notice that the range of δ for which this result applies is more restrictive than in the other results. The constant $C_{p_{\text{MN}}} > 0$ is sub-optimal in this result, but it is proved in the paper that the estimator is also asymptotically normal [41], with optimal variance (i.e., $\sqrt{n}(\hat{\mu}_n - \mu_X) \xrightarrow[n \rightarrow \infty]{d} \mathcal{N}(0, \sigma_X^2)$), which is an interesting feature that suggests a good practical behavior.

3.4.5 Discussion

We have defined five “robust” estimators, all satisfying sub-Gaussian bounds with different L . Up to recently, Catoni’s estimators had the best theoretical guarantees (see Eq. (3.8)) given some information on the variance σ_X^2 because $L = \sqrt{2}(1 + o(1)) \approx L_{\text{optimal}}$. In practice, this yields important improvements over other SGME like median-of-means and Trimmed Mean that do not request knowledge of the variance but have larger L . However, recent results like Lee-Valiant [33] show that the best of both worlds is possible: they obtain quasi optimal bound (see Eq. (3.11)) without any knowledge on the variance. In our practical experiments in Section 6, we confirm this impression: the estimators from Lee-Valiant and Minsker-Ndaoud look like they have the best practical performances. The theoretical non-asymptotic deviation bound obtained by Minsker and Ndaoud, see Theorem 3.6, does not express explicitly the leading constant. However, as suggested by their asymptotic result, it seems like this constant can be proved to be very close to optimal, even for reasonable p_{MN} .

4 Theory of Quasi Monte Carlo methods

Say that we wish to approximate the QoI Eq.(1.1) by a quadrature rule, i.e., an expression of the form

$$\mu(F) \simeq \sum_{j=1}^N w_j F(\mathbf{x}_j) =: \bar{\mu}_N(F)$$

for a given sequence of point $(\mathbf{x}_1, \dots, \mathbf{x}_N)$ and weights (w_1, \dots, w_N) . Common examples of deterministic quadrature rules are tensorized one-dimensional rules (of Newton, Gauss, Clenshaw-Curtis, etc. types) or sparse grids (Smolyack’s quadrature rules). Generally speaking, the error convergence rate depends on the dimension d and on the regularity of the function F , see [65] and references therein for an overview. The purpose of Monte Carlo, Quasi Monte Carlo and Randomized Quasi Monte Carlo methods is to obtain convergence rates that are completely or almost independent of the dimension d . The quasi Monte Carlo approach is to use equal weights $w_j = 1/N$.

4.1 Classical Monte Carlo

Let $\mathbf{U}_1, \dots, \mathbf{U}_N$ be N independent vectors uniformly distributed over $[0, 1]^d$. For square integrable functions F , set $(\sigma(F))^2 = \text{Var}(F(\mathbf{U}))$ where $\mathbf{U} \sim \mathcal{U}([0, 1]^d)$: we have $\text{Var}(\bar{\mu}_N(F)) = \frac{(\sigma(F))^2}{N}$, i.e., randomly choosing the quadrature point $\mathbf{U}_1, \dots, \mathbf{U}_N$ leads to an RMSE of order $\mathcal{O}(N^{-1/2})$. This result is usually worse than the deterministic quadrature rules in small dimensions, but it is both independent of the dimension d and the integrand regularity.

4.2 Quasi Monte Carlo

Instead of using N independent uniformly distributed random variables, quasi Monte Carlo methods use deterministic sequences $(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)$ that asymptotically fills well the unit hypercube (like random sequences), thus the name quasi Monte Carlo (QMC) methods. We review briefly the basic properties of these QMC methods. Let us define the multidimensional interval

$$[\mathbf{a}, \mathbf{b}] = \prod_{k=1}^d [a_k, b_k] := \{\mathbf{x} \in \mathbb{R}^d \mid a_k \leq x_k < b_k, k = 1, \dots, d\},$$

assuming $a_k < b_k$ for any k . To measure how well a point sequence $(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)$ fills the d -dimensional cube $[0, 1]^d$, following [44, Section 2.1], we introduce the star discrepancy defined as

$$D_N^*(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N) := \sup_{\mathbf{x} \in [0, 1]^d} |\Delta(\mathbf{x}; \boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)|, \quad \text{where} \quad \Delta(\mathbf{x}; \boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N) := \frac{1}{N} \sum_{j=1}^N \mathbb{1}_{\boldsymbol{\xi}_j \in [0, \mathbf{x}]} - \prod_{k=1}^d x_k.$$

If the d -dimensional cube was filled homogeneously, the proportion $N^{-1} \sum_{j=1}^N \mathbb{1}_{\boldsymbol{\xi}_j \in [0, \mathbf{x}]}$ of points inside the multidimensional interval $[0, \mathbf{x}]$ would exactly be equal to its Lebesgue measure, thus $\Delta(\mathbf{x}; \boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N) = 0$. The perfect homogeneity is out of reach, but the error can be made quite small.

Definition 4.1. A d -dimensional infinite sequence $\boldsymbol{\xi}_1, \boldsymbol{\xi}_2, \dots$ is said to have Low Discrepancy (LD) if

$$D_N^*(\boldsymbol{\xi}_1, \boldsymbol{\xi}_2, \dots, \boldsymbol{\xi}_N) = \mathcal{O}\left(N^{-1}(\log N)^d\right)$$

as $N \rightarrow \infty$.

4.2.1 Koksma-Hlawka error bound

The Koksma-Hlawka inequality [27, 23] provides an error bound for the finite N estimate of any sequence $(\mathbf{u}_1, \dots, \mathbf{u}_N)$,

$$\left| \frac{1}{N} \sum_{j=1}^N F(\mathbf{u}_j) - \mu(F) \right| \leq V_{\text{HK}}(F) D_N^*(\mathbf{u}_1, \dots, \mathbf{u}_N), \quad (4.1)$$

where $V_{\text{HK}}(F)$ is the Hardy-Krause variation of the function F . In words, $V_{\text{HK}}(F)$ is defined as the supremum over all multidimensional intervals partitions of the variations of F between intervals'

vertices (see [44, p.19] for details). If $V_{\text{HK}}(F) < +\infty$, we write $F \in \text{BVHK}([0, 1]^d)$ or simply $F \in \text{BVHK}$. Observe that if F is unbounded then $F \notin \text{BVHK}$; this means that for a heavy-tailed random variable $F(U)$, the above Eq. (4.1) is not informative since the right-hand side is infinite.

If F is smooth with continuous mixed partial derivatives, then $F \in \text{BVHK}$ and we have

$$V_{\text{HK}}(F) = \sum_{\emptyset \neq u \subseteq \{1, \dots, d\}} \int_{[0, 1]^{|u|}} \left| \frac{\partial^{|u|} F}{\partial \mathbf{x}_u}(\mathbf{x}_u : \mathbf{1}_{-u}) \right| d\mathbf{x}_u,$$

where for a non-empty set of coordinates u and for $\mathbf{x} = (x_1, \dots, x_d) \in [0, 1]^d$, \mathbf{x}_u stands for the components x_j such that $j \in u$, $\mathbf{x}_u : \mathbf{1}_{-u}$ denotes the point $\mathbf{y} \in [0, 1]^d$ with $y_j = x_j$ for $j \in u$ and $y_j = 1$ for $j \notin u$, see [14, p.176]. It is known that the inequality Eq. (4.1) is tight for smooth functions, see [44, Theorem 2.12]. Besides, extension of Eq. (4.1) to functions F satisfying fractional regularity conditions is achieved in [12].

All in all, for any LD sequence as in Definition 4.1 and $F \in \text{BVHK}$ we have

$$\left| \frac{1}{N} \sum_{j=1}^N F(\boldsymbol{\xi}_j) - \mu(F) \right| = \mathcal{O}\left(N^{-1}(\log N)^d\right),$$

which is asymptotically better than MC. However, this estimate is completely deterministic, necessarily biased, and error bounds are difficult to evaluate in practice since the bounding terms $V_{\text{HK}}(F)$ and $D_N^*(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)$ are not easily tractable. In contrast, the Robust RQMC method of Section 5 leads to computable error bounds in the sense of Eq. (5.1) (where the unknown $\sigma_N(F)$ can be easily estimated empirically).

4.2.2 Digital nets and sequence

The construction of LD sequences satisfying Definition 4.1 with good properties is an active research area. Ideally, one wants both the LD sequence to have good theoretical guarantees and efficient algorithms to generate large N sequences in large dimensions d . Moreover, as we will discuss in Section 4.3, we will be interested in a sequence that can be randomized while preserving their LD characteristics. For detailed reviews on LD sequence, see [44, 14]. Here, we only focus on digital net/sequence [15] because of their well-studied properties (see Section 4.3).

Let us define (t, m, d) -nets and (t, d) -sequences, also referred to as digital nets and sequences. Let $b \geq 2$ an integer base in which to represent real numbers. Consider the elementary intervals $E_{\mathbf{k}}(\mathbf{c})$ in base b which are subintervals of $[0, 1]^d$ of the form

$$E_{\mathbf{k}}(\mathbf{c}) = \prod_{j=1}^d \left[\frac{c_j}{b^{k_j}}, \frac{c_j + 1}{b^{k_j}} \right),$$

for integers k_j and c_j , with $k_j \geq 0$ and $0 \leq c_j < b^{k_j}$.

Definition 4.2. Let m and t be integers with $0 \leq t \leq m$. A sequence $(\mathbf{x}_1, \dots, \mathbf{x}_N)$ of $N = b^m$ points in $[0, 1]^d$ is called a (t, m, d) -net in base b if every elementary interval $E_{\mathbf{k}}(\mathbf{c})$ in base b of volume b^{t-m} contains precisely b^t points of the sequence.

The parameter t defines the quality of the net, with smaller values implying better equidistribution. From [44, Theorem 4.10], it is known that a (t, m, d) -net in base b satisfies the LD property of Definition 4.1.

Definition 4.3. *The infinite sequence $\mathbf{x}_1, \mathbf{x}_2, \dots, \in [0, 1]^d$ is a (t, d) -sequence in base b if for all $k \geq 0$ and $m \geq t$ the sequence $\mathbf{x}_{kb^m+1}, \dots, \mathbf{x}_{(k+1)b^m}$ is a (t, m, d) -net in base b .*

Digital nets are “closed” sequences of points (with a fixed number of points $N = b^m$) whereas digital sequence are “open” infinite sequences, which has the advantage of providing as many points as desired by the user.

4.3 Randomized Quasi Monte Carlo

One drawback with QMC estimation is that it provides a (deterministic) error estimate (Koksma-Hlawka inequality Eq. (4.1)) which can be very loose and is as hard as the QoI to compute. Randomized low discrepancy sequences have been introduced to allow easier error estimation. The deterministic LD sequence $(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)$ is transformed into a random $(\mathbf{R}_1, \dots, \mathbf{R}_N)$ that is still LD (with probability 1) with $\mathbf{R}_j \sim \mathcal{U}([0, 1]^d)$ for all $j \in \{1, \dots, N\}$. This new sequence is called a Randomized Quasi Monte Carlo Sequence (RQMCS). Hence, the RQMCS is composed of identically distributed uniform random variables which are *not* independent. The dependency is the key difference with Monte Carlo sampling. Given a RQMCS of N points $\mathbf{R}_1, \dots, \mathbf{R}_N \in [0, 1]^d$, the estimator of the QoI is

$$\bar{\mu}_N(F) = \frac{1}{N} \sum_{j=1}^N F(\mathbf{R}_j). \quad (4.2)$$

Due to the uniform distribution of each point, the RQMC estimate is unbiased.

4.3.1 Nested Uniform Scrambling (NUS)

There are several ways to randomize a LD sequence $(\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_N)$ which can affect the convergence rates, see [31, 14, 30] for reviews. Scrambling is a randomization method that is typically applied to (t, m, d) -net (sequence) by shuffling each digit of each coordinate of the \mathbf{R}_j . Among the different class of scrambling, there is the nested uniform scramble [46] (sometimes referred to as Owen scrambling). It preserves their (t, m, d) -net (sequence) character [46, Proposition 1] with probability 1 and each point is uniformly distributed [46, Proposition 2] (independently of the digital net/sequence nature of the sequence). The Nested Uniform Scrambling (NUS) has strong theoretical guarantees, we will expose some of them in the following. We will from now on refer to QMC sequences scrambled as in [46] simply as scrambled sequences. Recently, it has been proved in [56] that for any $F \in L^p$ with $p > 1$, the estimator Eq. (4.2) based on a scrambled (t, d) -sequence follows a strong law of large numbers.

4.3.2 Variance of scrambled nets

In view of the discussion in the introduction, the standard deviation $\sigma_N(F)$ given by

$$(\sigma_N(F))^2 := \text{Var} \left(\frac{1}{N} \sum_{j=1}^N F(\mathbf{R}_j) \right)$$

plays an important role. We expect that for an RQMCS, it goes to 0 faster than N^{-1} (the case of MC method).

General bounds. In a series of works [46, 47], Owen has shown that for nested uniform scrambling, the above variance is bounded by N^{-1} up to a multiplicative factor, for any value of N , see Theorem 4.1. Moreover, in [48, Theorem 1], it is shown that $N(\sigma_N(F))^2 \rightarrow 0$ under the sole assumption of square integrable F . We summarize these results in the following statement, which definitely justifies to use RQMC as a variance reduction technique.

Theorem 4.1. *Let $\mathbf{R}_1, \dots, \mathbf{R}_N$ be the points of nested uniform scrambling of a (t, m, d) -net in base b where $N = b^m$. Assume that F is such that $(\sigma(F))^2 := \text{Var}(F(\mathbf{U})) < \infty$. Then*

$$\lim_{N \rightarrow +\infty} N(\sigma_N(F))^2 = 0 \tag{4.3}$$

and we have

$$(\sigma_N(F))^2 \leq b^t \left(\frac{b+1}{b-1} \right)^d \frac{(\sigma(F))^2}{N}. \tag{4.4}$$

The limit Eq. (4.3) is valid for each given F , whereas Eq. (4.4) ensures an uniform bound

$$\sup_{F: \text{Var}(F(\mathbf{U})) \leq 1} N(\sigma_N(F))^2 \leq b^t \left(\frac{b+1}{b-1} \right)^d.$$

The proof relies on an ANOVA Haar wavelet decomposition of the variance using the structure of (t, m, d) scrambled net. The above non-asymptotic bound should be seen as a worst-case variance estimate, showing that the RQMC variance cannot be worse than the Monte Carlo variance up to a factor, given a budget of N points; this is cheering. The factor grows exponentially fast with the dimension d . This does not contradict Eq. (4.3), it just says that for a fixed N , there might exist a worst-case function F reaching this bound.

The first asymptotic result is really appealing, and states that RQMC based on an NUS is asymptotically always better than MC. It will be of main importance when combined with robust mean estimators of Section 3.

Bounds for $F \in \text{BVHK}$. When the integrand F satisfies some regularity properties (typically $F \in \text{BVHK}$), the previous variance reduction can be improved. It directly stems from the Koksma-Hlawka bound Eq. (4.1), assuming that the convergence in Definition 4.1 is valid with a deterministic

upper-bound:

$$(\sigma_N(F))^2 = \mathbb{E}((\bar{\mu}_N(F) - \mu)^2) \leq \mathbb{E}\left((D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N) V_{\text{HK}}(F))^2\right) = \mathcal{O}\left(\frac{\log(N)^{2d}}{N^2}\right).$$

For the scrambling of a digital net, the above can be refined as follows. The result is due to [53, Theorem 3].

Theorem 4.2. *Assume that the function F is smooth¹, in the sense that $\frac{\partial^{|u|}}{\partial \mathbf{x}_u} F(\mathbf{x})$ is continuous on $[0, 1]^d$ for all possible $u \subseteq \{1, \dots, d\}$. If the \mathbf{R}_i 's are a nested uniform scramble of (t, m, d) -net in base b , then*

$$(\sigma_N(F))^2 = \mathcal{O}\left(\frac{\log(N)^{d-1}}{N^3}\right).$$

as $N \rightarrow +\infty$.

The logarithmic factor can be avoided by using the randomized Frolov quadrature rule, see [66], which is however less easy to implement than the scrambled nets.

Bounds when $F \notin \text{BVHK}$. Because $F \in \text{BVHK}$ implies that F is bounded (discarding heavy-tailed $F(\mathbf{U})$), the previous assumption does not cover many practical situations. However, the case of bounded and fractional smooth functions can be covered by the extension of the Koksma Hlawka inequality by [12]. The case of discontinuous F is studied in [20, 19]. Therefore, we now focus our subsequent discussion on unbounded F , to handle heavy-tailed $F(\mathbf{U})$, which is to us a primary challenge.

To obtain more precise scaling of the variance $(\sigma_N(F))^2$, one needs assumptions on singularities of F .

Definition 4.4. *The function F on $[0, 1]^d$ has corner singularities no worse than $\prod_{k=1}^d x_k^{-A_k}$ if*

$$\left| \frac{\partial^{|u|} F(\mathbf{x})}{\partial \mathbf{x}_u} \right| \leq C \prod_{k=1}^d x_k^{-A_k - \mathbb{1}_{\{k \in u\}}}$$

holds for all $u \subseteq \{1, 2, \dots, d\}$, some $A_k \in (0, 1)$, and some $0 < C < \infty$. Here x_k is the k -th component of the vector \mathbf{x} .

Setting $p^* = (\max_k A_k)^{-1}$, observe that $F(\mathbf{U})$ is in L^p for any $p < p^*$. Thus, the condition $0 < A_k < 1$ ensures just that F is at least integrable (but potentially singular).

In the case of such an F , the integration error can be estimated, see [51, Theorem 5.7].

Theorem 4.3. *Let $\mathbf{R}_1, \dots, \mathbf{R}_N \sim \mathcal{U}([0, 1]^d)$ with $\mathbb{E}(D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N)) = \mathcal{O}(N^{-1+\varepsilon})$ for all $\varepsilon > 0$. If F satisfies Definition 4.4, then for any $\varepsilon > 0$,*

$$\mathbb{E}(|\bar{\mu}_N(F) - \mu(F)|) = \mathcal{O}(N^{-1+\varepsilon+\max_k A_k}).$$

¹mixed smooth in the terminology of [53].

Appendix A includes a proof of this result. The result in [51] is in fact slightly more generic, as it considers singularities possibly both at the origin and $\mathbf{1} = (1, \dots, 1)$. The result is extended to arbitrary singularity point [52, Theorem 1] and arbitrary RQMC sequence (not only scrambled nets).

We provide the analog theorem for the variance: note that in the perspective of using aggregation methods for mean estimation and leveraging quantile bounds like Eq. (3.1), it is not enough to bound the L_1 -error $\mathbb{E}(|\bar{\mu}_N(F) - \mu(F)|)$ as in Theorem 4.3, we need to control the variance $(\sigma_N(F))^2$. This is one of our contributions.

Before, we introduce the useful concept of joint density between random pairs of sequence points.

Definition 4.5. Let $(\mathbf{R}_1, \dots, \mathbf{R}_N)$ be a sequence of random points such that for each $\mathbf{R}_i \sim \mathcal{U}([0, 1]^d)$ and $\mathbb{E}(F(\mathbf{U})) = \mu(F)$ and $\text{Var}(F(\mathbf{U})) = (\sigma(F))^2 < \infty$. Let I, J be two different integers valued in $\{1, \dots, N\}$ picked with uniform distribution (independent of $(\mathbf{R}_1, \dots, \mathbf{R}_N)$). Define by $\Psi(d\mathbf{x}, d\mathbf{y})$ the joint distribution of $(\mathbf{R}_I, \mathbf{R}_J)$: for any measurable function $\ell : [0, 1]^d \times [0, 1]^d \mapsto \mathbb{R}^+$,

$$\mathbb{E}(\ell(\mathbf{R}_I, \mathbf{R}_J)) := \int_{[0,1]^d \times [0,1]^d} \ell(\mathbf{x}, \mathbf{y}) \Psi(d\mathbf{x}, d\mathbf{y}).$$

With this definition at hand, we have, for any square integrable function G ,

$$\begin{aligned} \frac{1}{N(N-1)} \sum_{i \neq j} \mathbb{E}(G(\mathbf{R}_i)G(\mathbf{R}_j)) &= \mathbb{E}(G(\mathbf{R}_I)G(\mathbf{R}_J)) \\ &= \int_{[0,1]^d \times [0,1]^d} G(\mathbf{x})G(\mathbf{y}) \Psi(d\mathbf{x}, d\mathbf{y}). \end{aligned} \quad (4.5)$$

We are now in a position to state a new variance bound, whose proof is postponed to Appendix A.

Theorem 4.4. Let $\mathbf{R}_1, \dots, \mathbf{R}_N$ be a RQMCS: each $\mathbf{R}_i \sim \mathcal{U}([0, 1]^d)$ and for any $\varepsilon > 0$, there exists (deterministic) $D_\varepsilon < \infty$ with $\mathbb{P}(D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N) \leq D_\varepsilon N^{-1+\varepsilon}) = 1$ for all N large enough.

Assume that F satisfies Definition 4.4 (with $\max_k A_k < \frac{1}{2}$) and that the joint distribution $\Psi(d\mathbf{x}, d\mathbf{y})$ has a density (w.r.t. Lebesgue's measure on $[0, 1]^d \times [0, 1]^d$) uniformly bounded (in N), then for any $\varepsilon > 0$,

$$(\sigma_N(F))^2 = \mathcal{O}(N^{-2+\varepsilon+2\max_k A_k}).$$

As a consequence of Theorem 4.4, for a function with corner singularity (as in Definition 4.4) and square integrable (i.e., the condition $\max_k A_k < 1/2$), RQMC is asymptotically better than MC: this is consistent with Theorem 4.1. In addition, the smaller $\max_k A_k$, the faster the convergence.

We shall mention that without the condition on the joint distribution $\Psi(d\mathbf{x}, d\mathbf{y})$, one can still get that $(\sigma_N(F))^2 = \mathcal{O}(N^{-1+\varepsilon+2\max_k A_k})$ (see Remark Eq. (A.1) in Appendix A) which is better than MC whenever $\max_k A_k < 1/4$ (the random variable $F(\mathbf{U})$ has four finite polynomial moments).

By leveraging [69, Theorem 3.6], we additionally prove that the property of bounded density is satisfied for a $(0, m, d)$ -net in base $b \geq 2$. See Appendix B for the proof.

Note that the hypothesis on the existence of deterministic D_ε is satisfied for the scrambled (t, m, d) -net, as it is a (t, m, d) -net to which we can apply the deterministic bound from [44, Theorem 4.6 and Theorem 4.10] on the discrepancy.

5 Error bounds for Robust Quasi Monte Carlo

Combining the previous results of robust mean estimation (Section 3) and RQMCS with scrambled nets (Section 4.3), one obtains the following ‘‘Robust Quasi Monte Carlo’’ finite sample result.

Theorem 5.1. *Let $F : [0, 1]^d \mapsto \mathbf{R}$ such that $F(\mathbf{U})$ (with $\mathbf{U} \sim \mathcal{U}([0, 1]^d)$) has mean $\mu(F)$ and finite variance $(\sigma(F))^2$. Consider a (t, m, d) -net in base b where $N = b^m$, and n independent replicas of the related nested uniform scramble, which we denote $(\mathbf{R}_j^{(i)} : 1 \leq j \leq N)_{1 \leq i \leq n}$. Set the i -th RQMC-empirical mean $\bar{\mu}_N^{(i)}(F)$ as in Eq. (1.3).*

Then, for a given $\delta > 0$, define a sub δ -Gaussian estimator

$$\hat{\mu}_{B,\delta}(F) := \hat{\mu}_n(\bar{\mu}_N^{(1)}(F), \dots, \bar{\mu}_N^{(n)}(F))$$

as defined in Definition 3.2 (with some $L_{\delta,n} \in [\sqrt{2}, \infty)$), assuming that the restriction condition between δ and n is satisfied: the above estimator has an evaluation budget equal to $B = N \times n$. Then, the $(1 - \delta)$ -quantile of the absolute error (see Eq. (1.2)) of $\hat{\mu}_{B,\delta}(F)$ is bounded as follows:

$$e(\hat{\mu}_{B,\delta}, \delta, F) \leq (\sigma_N(F)\sqrt{N})L_{\delta,n}\sqrt{\frac{\log(2/\delta)}{B}}, \quad (5.1)$$

where the factor $\sigma_N(F)\sqrt{N}$ can be analyzed in conjunction with Theorems 4.1, 4.2 and 4.4 under different assumptions on F .

The above Theorem requires several important comments. To alleviate the discussion, we assume that $L_{\delta,n}$ depends neither on δ nor on n , which is merely the case for all the estimators proposed in Section 3.

- Theorem 5.1 is to the best of our knowledge, the first result stating a non-asymptotic error bound for RQMC making explicit the advantage of variance reduction (since $\sigma_N(F)\sqrt{N} \rightarrow 0$ as $N \rightarrow +\infty$) owing to RQMCS, under the sole assumption of square integrable $F(\mathbf{U})$.
- This estimate, with the upper bound $\sigma_N(F)\sqrt{N} \leq \sigma b^{t/2} \left(\frac{b+1}{b-1}\right)^{d/2}$ of Eq. (4.4), is consistent with the worst-case lower bound result by [28, Theorem 2.3] in the case of non-smooth F (in their notation, it corresponds to $r = 0$, $p = q = 2$). The latter reference states that the B -th minimal probabilistic Monte Carlo error at uncertainty δ , uniformly over the square integrable functions F (with second moment at most equal to 1) is asymptotically (in B) equal to

$$\sqrt{\frac{\log(1/\delta)}{B}},$$

up to constant². Observe that since the latter reference considers the rate uniformly with respect to the function F , it is not aimed at catching the improvement $\sigma_N(F)\sqrt{N}$ for each specific function F as we do. Besides, our bound is valid for any given B (provided that the

²in this statement, we omit to recall the usual condition that $B \geq c \log(1/\delta)$ which is often required both in [28] and the definition of sub δ -Gaussian estimators in Section 3

explicit restriction between n and δ is met - see Table 6.1 for a summary of these restrictions) and in a way, our formulation is slightly more precise than the one in [28], where their bounds are stated for asymptotic budget (constants in factor of the convergence rates are ignored). As a consequence, scrambled (t, m, d) -nets coupled with robust mean techniques match the rates of the worst-case lower bounds of [28, Theorem 2.3], for functions F under the sole assumption $\mathbb{E}(F^2(U)) < +\infty$.

- Furthermore, the above bound Eq. (5.1) highlights well the effect of variance reduction due to $\sigma_N(F)\sqrt{N} \rightarrow 0$ as $N \rightarrow +\infty$ in general, with some quantitative rate under some assumptions on F as those studied in Theorem 4.2 or Theorem 4.3.
 - For a function F with mixed smoothness, i.e. $\frac{\partial^{|u|}}{\partial \mathbf{x}_u} F(\cdot)$ is continuous on $[0, 1]^d$ for all possible $u \subseteq \{1, \dots, d\}$, combining the Theorems 4.2 and 5.1 and by taking n fixed, it readily follows that the probabilistic Monte Carlo error at uncertainty δ is equal to $c \frac{\log(B)^{(d-1)/2}}{B} \sqrt{\frac{\log(2/\delta)}{B}}$. Up to the logarithm $\log(B)$ factor, this rate matches the worst-case lower bound of [28, Section 4 on Mixed Smoothness Space, Equation (28)]. On the one hand, it does not mean that our bound can not be improved for such a specific F ; on the other hand, this result is an argument in favor of the use of scrambled (t, m, d) -net in this context of Robust RQMC approach. Last, it may happen that for a given F , a RQMC scheme gives a more accurate result than another, but changing the F may change the ranking of RQMC scheme. Our results guarantee upper bounds on the accuracy when certain RQMC schemes are used with Sub-Gaussian mean estimators.
 - The generalization of this estimator for more regular functions in the mixed smoothness sense of order $r \in \mathbb{N}^*$ [28, Section 4] can be made using higher order scrambling methods: it includes smooth functions with continuous partial derivatives $\frac{\partial^{r_1+\dots+r_d}}{\partial \mathbf{x}_1^{r_1} \dots \partial \mathbf{x}_d^{r_d}} F(\cdot)$ for all $(r_1, \dots, r_d) \in \{0, \dots, r\}^d$ [13, Section 3.2.2]. According to [13, Theorem 10], the variance of quasi Monte Carlo integration with sufficiently high-order scrambled nets (generalization of Owen scrambling) yields $\sigma_N(F) = O(N^{-r-1/2}(\log N)^{d(r+1)/2})$. This combined with a robust mean estimator at uncertainty δ produces an asymptotic error bound as $c \frac{\log(B)^{d(r+1)/2}}{B^r} \sqrt{\frac{\log(2/\delta)}{B}}$. This upper bound is once again aligned with the worst-case lower bound of [28, Section 4 on Mixed Smoothness Space, Equation (28)] up to a logarithmic term. Note that for $f \in \mathcal{C}^r([0, 1]^d)$, the convergence rate is $B^{-1/2-r/d}$, see [9] for a recent computationally tractable implementation. In this case, there are no log terms, and it can also be combined with a robust mean estimator at uncertainty δ .
 - The function with corner singularities like in Theorem 4.3 is not covered by the optimality results in [28]. Our Theorem 5.1 shows that the probabilistic Monte Carlo error at uncertainty δ is equal to $\frac{c}{B^{\frac{1}{2}-\max_k A_k - \varepsilon}} \sqrt{\frac{\log(2/\delta)}{B}}$ for any $\varepsilon > 0$. Knowing whether this rate can be improved is an open question.
- The rate of the form $\sigma_N(F)\sqrt{N}L\sqrt{\frac{\log(2/\delta)}{B}}$ shows that, to improve the probabilistic Monte Carlo error at uncertainty δ , it is theoretically better to increase N than to increase n , under

the constraint of a fixed budget B . This heuristic will be confirmed in our next numerical experiments, see Figure 6.6.

- While working on the revision of this article, the authors have been aware of another approach combining median-of-means and RQMC [58, 57]. In their work, they focus on Linear Matrix Scrambling (LMS) [39] which is a weaker form of scrambling than the nested uniform scrambling considered in this paper, but LMS is numerically more memory efficient. They show that with high probability, LMS provides an estimation with a small variance; however, with low probability, it gives a very wrong estimation. Using the robust median-of-means mitigates these extreme cases, which can be seen as outliers or contaminated samples. It is interesting to note that the outlier does not come from an extreme distribution or singular integrand but from the randomization method. A strong smoothness assumption on F is required for their result.

6 Numerical Experiments

We compare the Monte Carlo (MC) approach and Randomized Quasi Monte Carlo (RQMC) for mean estimator. We will use the following abbreviations: EM: Empirical Mean, MoM: median-of-means, LV: Lee-Valiant, MN: Minsker-Ndaoud, CA: Catoni and HU: Huber. Often we report results for LV and not for MoM since LV is an improved version of MoM. We do not report results for the Trimmed Mean estimator because its theoretical and numerical performance is worse than other robust mean estimators, in addition, the condition $n > (32/3) \log(8/\delta)$ in Theorem 3.1 is not satisfied for our simulations where $n = 56$. In all the following, for the Minsker-Ndaoud estimator (Definition 3.5) we use $p_{MN} = 1$. The number of realizations used to obtain the distributions of $\hat{\mu}_n$ is denoted by M .

6.1 Illustration of Robust Mean Estimators

We illustrate the robustness of the estimator presented in Section 3 in the “most extreme case” where the sample X_1, \dots, X_n comes from a Pareto distribution whose density function is $f_X(x) = \theta/x^{1+\theta} \mathbb{1}_{x \geq 1}$ with finite second moment, i.e., $\theta > 2$. For these examples, we use the α parameter of the Catoni Eq. (3.7) and Huber Eq. (3.5) estimators based on the exact standard deviation σ_X of the Pareto distribution. Figure 6.1 shows the distribution of different (standardized) estimators $\hat{\mu}_n$ for different θ compared with the Gaussian distribution. Because of the relatively small number of samples $n = 56$ and the heavy tail character of the distribution, the behavior of all estimators (including EM) is far from normality. However, if EM estimator distribution suffers from heavy tails, other robust mean estimators are much less affected. It is clear that the robust mean estimators HU, CA, LV, MN and especially MoM trade robustness against bias. CA and HU seem like the robust mean estimator with the smallest bias. However, these two estimators are both computed using the exact standard deviation σ_X , which is unknown in general. Visually, by examining how concentrated the distributions are, the best estimators requiring no knowledge about the variance σ_X^2 seem to be LV and MN. It will be confirmed by the subsequent experiments using RQMC.

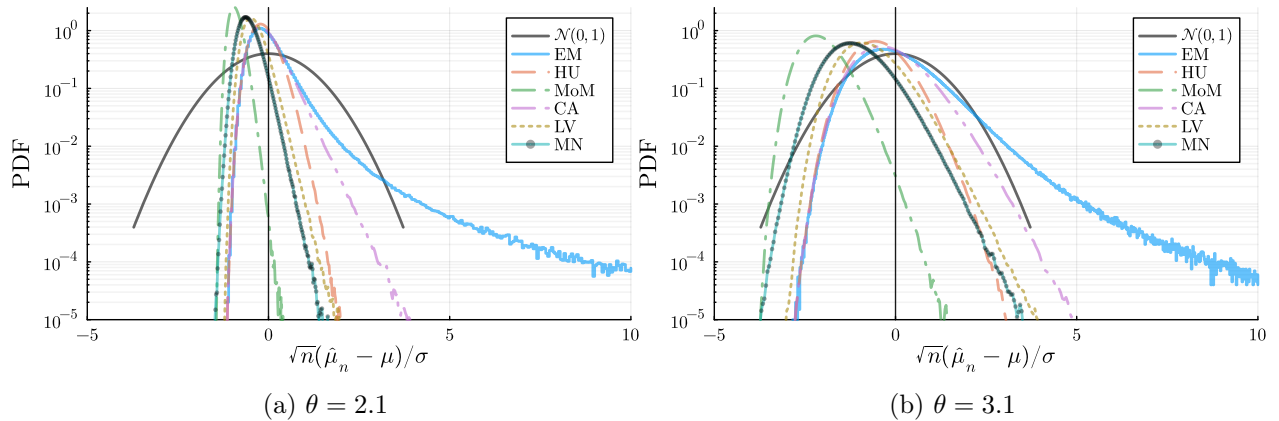

Figure 6.1: Distribution of $\sqrt{n}(\hat{\mu}_n - \mu_X)/\sigma_X$ for different estimators. The X are i.i.d. random variables of Pareto distribution with parameter θ . The number of samples is $n = 56$ and uncertainty level $\delta = 3e^{-8} \simeq 0.1\%$. The distributions are based on $M = 10^7$ replicas.

6.2 Tests for Robust Quasi Monte Carlo

6.2.1 QMC Numerical Methods and Software

Choosing between all the different available LD sequences is difficult and one is never consistently better than others in terms of variance reduction, for example [34] finds that Lattice can in some cases outperform digital nets and in some others not, see discussion [54, Chapter 16 End Notes]. While most theoretical results use Nested Uniform Scrambling (NUS, see Subsection 4.3.1) for scrambling [46], other methods like digital shift or Linear Matrix Scrambling [39] (or both combined) are commonly used and implemented in software like `scipy.stats.qmc` [68], `qmcpy` [8] because they are much faster and their variance reduction performances look as good as NUS. See [50] for a comparison of some scrambling methods. In our numerical example, we use the NUS [46] implemented in Julia [3]. The authors of this paper contributed to the collaborative Julia package `QuasiMonteCarlo.jl` [67] by adding the several randomization methods used in this work. Some of this code was inspired by the R code described on Owen’s personal webpage [55]. The authors also developed a Julia package `RobustMeans.jl` [40] containing all the robust mean estimators used in this paper. The code (script, plot instruction, notebooks and package version) to reproduce the figures presented in this paper are available at the GitHub repository <https://github.com/dmetivie/Robust-Randomized-Quasi-Monte-Carlo-paper-code>. Note that for practitioners, the actual implementation time of QMC and RQMC methods is a major concern and one can prefer fast implementation to strong theoretical guarantees.

6.2.2 Integrand F

Several papers have provided careful numerical tests, see for example [34, 61, 49, 16, 29]. Different types of “difficult” integrands F can be considered:

- The nominal dimension d of \boldsymbol{x} is typically large. This is a common case encountered in financial

or engineering problems.

- F is not much smooth, for instance it is only $\mathcal{C}^1([0, 1]^d)$, or it oscillates a lot.
- F is square integrable but not more (heavy-tailed distributions). This is typical in risk management applications.

Such functions are found in the literature and also in applications such as finance where F represent some gain, and $\mu(F)$ is the average gain or the risk evaluation.

We consider integrands of the form [54, Chapter 15]

$$F(\mathbf{x}) = F_{\beta, G}(\mathbf{x}) = \prod_{k=1}^d (1 + \beta_k G_k(x_k)) \quad (6.1)$$

where for all $k \in \{1, \dots, d\}$, $G_k : [0, 1] \mapsto \mathbb{R}$ satisfies

$$\int_0^1 G_k(x) dx = 0, \quad \int_0^1 G_k^2(x) dx = 1 \quad (6.2)$$

for $\beta \in \mathbb{R}^d$. It is easy to show that

$$\mu(F) = 1 \quad \text{and} \quad (\sigma(F))^2 = \prod_{k=1}^d (1 + \beta_k^2) - 1.$$

We now consider $G_k(\mathbf{x}) = G_\varepsilon^{(1)}(x)$ for all $k \in \{1, \dots, d\}$ with

$$G_\varepsilon^{(1)}(x) = \frac{\sqrt{2\varepsilon}(2\varepsilon + 1)}{|1 - 2\varepsilon|} \left(\frac{1}{x^{\frac{1}{2}-\varepsilon}} - \frac{2}{2\varepsilon + 1} \right). \quad (6.3)$$

Here $\varepsilon \neq 1/2$ (the limit case $\varepsilon \rightarrow 1/2$ would lead to a log function, we discard this case for the sake of simplicity). The function $G_\varepsilon^{(1)}$ satisfies the conditions Eq. (6.2) for $\varepsilon \in (0, 1/2) \cup (1/2, +\infty)$. Moreover, for such ε , $F_{\beta, G} \in L^2([0, 1])$. The β control how each dimension participates in the integrand. We choose

$$\beta_k = \frac{\beta}{\log(1 + k)},$$

so that the larger dimensions participate less than the first (but the logarithmic decay remains very gentle compared to the exponential ones often considered in the literature). For $\varepsilon \in (0, 1/2)$, F has singularities and thus is unbounded.

6.2.3 Numerical Results

For all the tests, $M = 10^4$ realizations are used to obtain the distributions. We compute the sample variance as $\bar{\sigma}_N^2 = \frac{1}{n} \sum_{i=1}^n (\bar{\mu}_N^{(i)}(F) - \mu(F))^2$. We use this estimator to calibrate the α parameter for Catoni Eq. (3.7) and Huber Eq. (3.5) estimators.

In Figures 6.2, 6.3 and 6.4, we show examples of Monte Carlo (MC) vs. Randomized Quasi Monte Carlo integration in dimension $d = 17$ with both non-singular and singular integrands. In Figure 6.2,

we show only the empirical $(1 - \delta)$ -quantile for the absolute error $|\hat{\mu}_{N,n}(F) - \mu(F)|/\mu(F)$ while in Figure 6.3, we show the distribution of the standardized error compared with a Normal distribution. This is an example where F is bounded and smooth, yet the EM with RQMCS performs worse than robust mean estimators: indeed, for $\delta \approx 5.5\%$ (resp. $\delta \approx 0.1\%$) compare the top whiskers (orange color for RQMC) in Figure 6.2a (resp. 6.2b) of EM with other robust mean estimators, and compare the distributon of EM and other robust mean estimators on Figure 6.3a (resp. 6.3b).

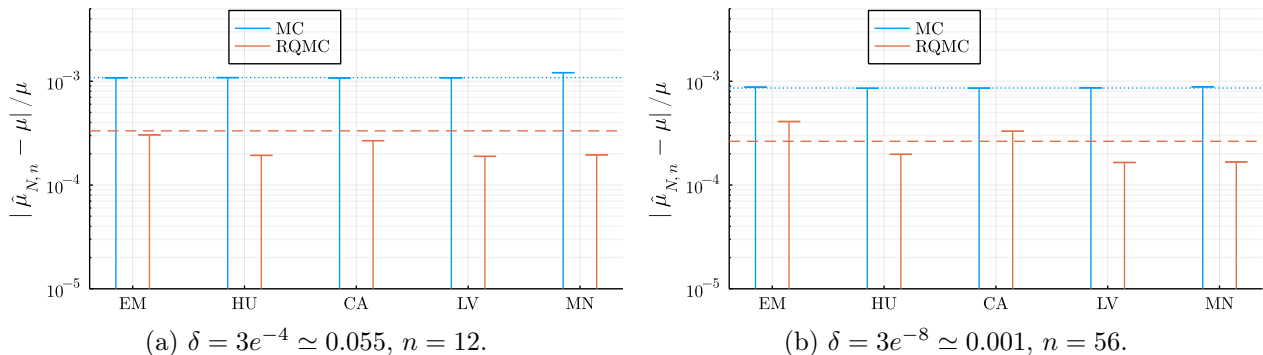

Figure 6.2: Estimated quantile $\hat{Q}_{1-\delta}$ of the distribution of $|\hat{\mu}_{N,n}(F) - \mu(F)|/|\mu(F)|$ where $F = F_{\beta, G_\varepsilon^{(1)}}$ is defined in Eqs. (6.1), Eq. (6.3) with $\varepsilon = 2 \times 10^4$ and β such that $\sigma(F) = 1/2$ (i.e. $\beta \simeq 0.192$). We use $d = 17$, $N = 2^{16}$. Here F is smooth and bounded of range $[-0.01, 200]$. The mean estimator acronyms are defined in the text. The RQMC is based on the first N points of a nested uniform scrambled of the Sobol' sequence. The horizontal lines show the $\bar{\sigma}_N \Phi^{-1}(1 - \delta/2)/\sqrt{n}$ values.

In Figure 6.4, we show an example with a singular integrand. We represent for the absolute error $|\hat{\mu}_{N,n}(F) - \mu(F)|/\mu(F)$ the estimate quantile $\hat{Q}_{1-\delta}$ (top of the whisker) and estimated quantiles $\hat{Q}_{1/4}, \hat{Q}_{3/4}$ forming the box. The dots are the remaining outliers.

We now demonstrate numerically that for a given budget $B = N \times n$, the best choice is to take n as small as possible. For example, in Figure 6.6 with the Lee-Valiant estimator Eq. (3.9), we fix $B = n \times N = 458752$ and vary n and N . The box plots clearly show that with $N = 8192$ and $n = 56$ the estimator has the smallest error.

In Figure 6.5, we change the integrand F by changing the G_ε to

$$G_\varepsilon^{(2)}(x) = (x^{\varepsilon-1/2} |x - 1/2|^{\varepsilon-1/2} - \eta_1^{(\varepsilon)})/\eta_2^{(\varepsilon)} \quad (6.4)$$

where $\eta_1^{(\varepsilon)}, \eta_2^{(\varepsilon)}$ ensure that Eqs. (6.2) are satisfied. These can be computed explicitly or numerically but are not detailed here. This function has multiple singularities at those 2^d points whose coordinates take values on either 0 or 1/2. The results are very similar to the case with corner singularity, indicating that robust mean estimators $\hat{\mu}_{N,n}$ still perform well.

Observations:

- Case where F is bounded and smooth ($\varepsilon = 2 \times 10^4$) – Figures 6.2 and 6.3. The range of F is approximately $[-0.01, 200]$ and most of the distribution is located around -0.01 . As announced with the MC approach, each $\bar{\mu}_N^{(i)}(F)$ is expected to approximately follow a Normal distribution because N is large. Thus, the estimate $\hat{\mu}_{N,n}(F)$ is also approximately Normal,

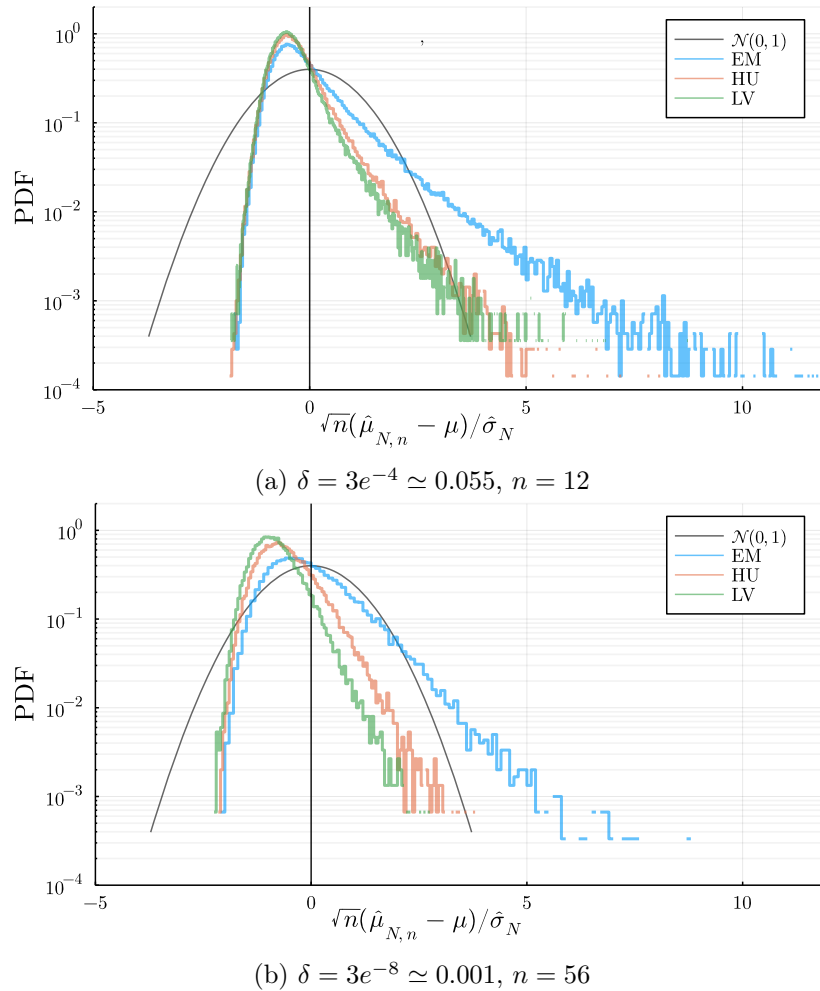

Figure 6.3: Same data as Figure 6.2 but only for the RQMCS. We depict the full standardized distribution against the normal distribution. Distributions of the estimators are far from being Gaussian and EM performs worse than robust mean estimators.

which is observed since all estimators are almost on the theoretical Normal quantile level $\sigma_N^{(\text{MC})}(F)\Phi^{-1}(1 - \delta/2)/\sqrt{n}$. For RQMCS, the Central Limit theorem generally does not apply or if it applies, the asymptotic behavior might be long to reach even for very large N . Here despite the function being smooth and the scrambling method being as in the Loh Central Limit theorem [35, Theorem 1] (the condition on the dimension d is not respected, so the theorem does not apply directly) the $\bar{\mu}_N^{(i)}(F)$ are far from being Normal random variables, as it can be checked from Figures 6.3a and 6.3b.

- When F is singular at the origin as $x^{-1/2+\varepsilon}$, mimicking a heavy tail distribution, the advantages of combining Robust estimators with RQMCS are even more striking, see Figures 6.4 and 6.5. Empirical mean (EM) estimators yield $1 - \delta$ quantile of error that is usually much larger than other robust estimators (the $1 - \delta$ quantile of error hardly matches the ideal Gaussian quantile,

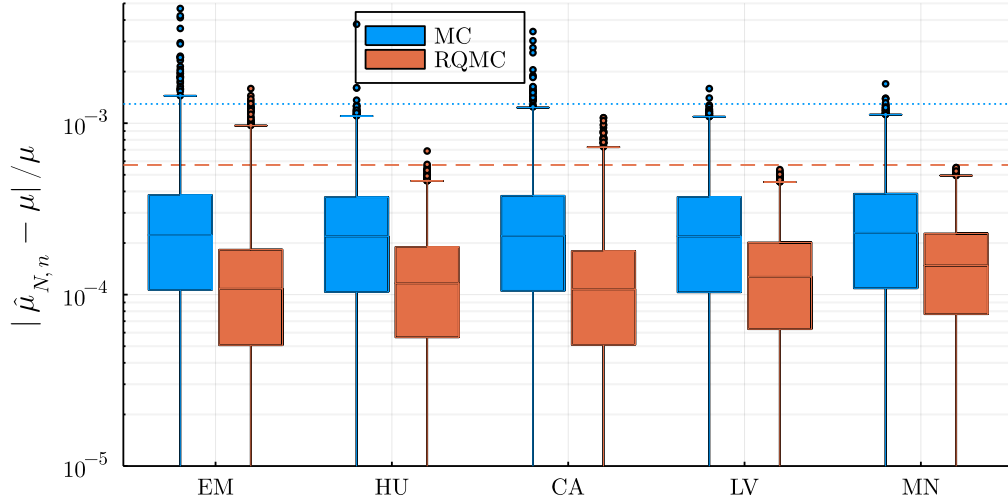

Figure 6.4: Box plot distribution of $|\hat{\mu}_{N,n}(F) - \mu(F)|/|\mu(F)|$ where $F = F_{\beta, G_\varepsilon^{(1)}}$ is defined in Eqs. (6.1), Eq. (6.3) with $\varepsilon = 0.05$ and β such that $\sigma(F) \simeq 0.5$ (i.e. $\beta \simeq 0.192$). We use $d = 17$, $n = 56$, $N = 2^{16}$, $\delta = 3e^{-8} \simeq 0.001$. The mean estimator acronyms are defined in the text. The RQMC is based on the first N points of a nested uniform scrambled of the Sobol's sequence. The upper whisker is set to extend up to $\hat{Q}_{1-\delta}$. The horizontal lines show the $\bar{\sigma}_N \Phi^{-1}(1-\delta/2)/\sqrt{n}$ values.

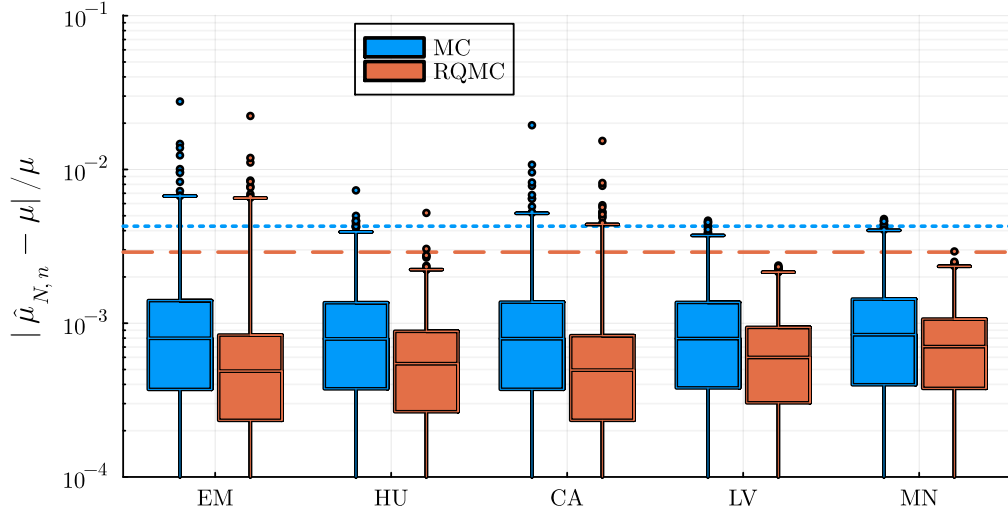

Figure 6.5: Box plot distribution of $|\hat{\mu}_{N,n}(F) - \mu(F)|/|\mu(F)|$ where $F = F_{\beta, G_\varepsilon^{(2)}}$ is defined in Eqs. (6.1),(6.4) with $\varepsilon = 0.04$ and β such that $\sigma(F) \simeq 0.5$ (i.e. $\beta \simeq 0.223$). We use $d = 7$, $n = 56$, $N = 2^{11}$, $\delta = 3e^{-8} \simeq 0.001$. The mean estimator acronyms are defined in the text. The RQMC is based on the first N point of a nested uniform scrambled of the Sobol's sequence. The upper whisker is set to extend up to $\hat{Q}_{1-\delta}$. The horizontal lines show the $\bar{\sigma}_N \Phi^{-1}(1-\delta/2)/\sqrt{n}$ values.

and is often well above, as a difference with robust estimators).

Note that in Figures 6.4 and 6.5, the lower whiskers (small errors) are missing on purpose, in order to zoom out on the largest errors. In Figure 6.5, we observe that the central limit

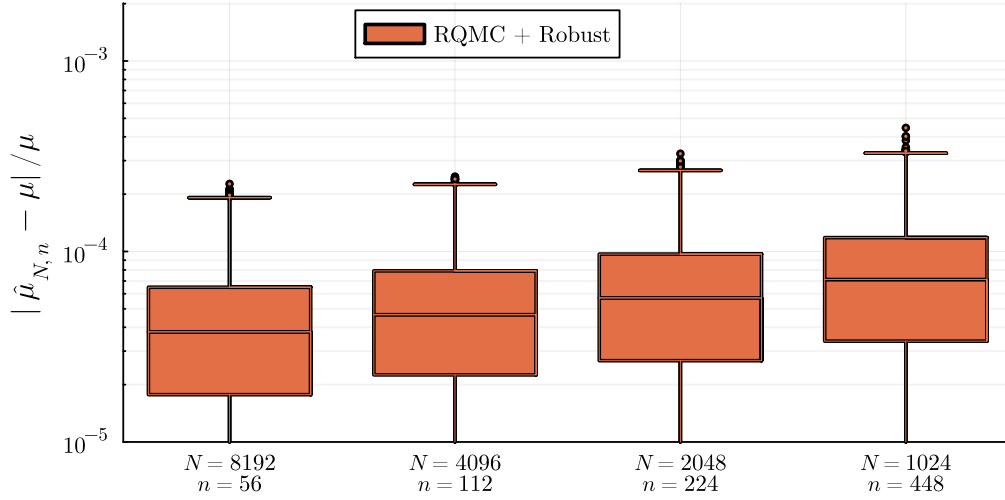

Figure 6.6: For a fixed budget, $B = n \times N = 458752$ this is the Box plot distribution of $|\hat{\mu}_{N,n}(F) - \mu(F)|/|\mu(F)|$ where $F = F_{\beta, G_\varepsilon^{(1)}}$ is defined in Eqs. (6.1), Eq. (6.3) with $\varepsilon = 0.35$ and β such that $\sigma(F) \simeq 0.5$ (i.e. $\beta \simeq 0.210$). We use $d = 10$, $\delta = 3e^{-8} \simeq 0.001$. The robust mean estimator used here is the Lee-Valiant estimator Eq. (3.9). The RQMC is based on the first N point of a nested uniform scrambled of the Sobol's sequence. The upper whisker is set to extend up to $\hat{Q}_{1-\delta}$.

theorem regime is not completely reached for MC simulations, despite $N = 2^{15}$ (the quantile of the error is far from the ideal Gaussian quantile $\frac{\sigma_N(F)\sqrt{N}}{\sqrt{B}}\Phi^{-1}(1 - \delta/2)$).

- Let us compare different Robust RQMC estimators on Figures 6.4 and 6.5 (box plots in orange color). We observe that the Catoni estimator (CA) hardly achieves the ideal Gaussian bound $\mathcal{B} := \frac{\sigma_N(F)\sqrt{N}}{\sqrt{B}}\Phi^{-1}(1 - 2/\delta)$ (dashed line) for the $1 - \delta$ quantile of absolute error, while other estimators do. In addition, the tail distributions of Median-of-Means (MoM) and Huber (HU) estimators exceed well \mathcal{B} , while for the Lee-Valiant (LV) and Minsker-Ndaoud (MN) estimators, their entire distributions are seemingly above \mathcal{B} . Last, the error of Lee-Valiant estimator is slightly more concentrated around 0 than the one for the Minsker-Ndaoud estimator. All in all, these experiments are in favor of the Lee-Valiant estimator; more exhaustive tests would be necessary to validate a systemic recommendation of Lee-Valiant estimator.
- As expected – Figure 6.6 – the smaller n and larger N combination produce the best result by fully taking advantage of the Quasi Monte Carlo variance reduction. For the sake of completeness, Table 6.1 compiles the minimal values of n granted by the theoretical error bounds of robust mean estimators.
- Even integrand not singular as in Definition 4.4 can benefit from Robust RQMC method, see Figure 6.2.

Table 6.1: Theoretical minimal values of n justifying the use of robust mean estimators, as a function of δ

	Median-of-means: $n \geq \lceil 8 \log(1/\delta) \rceil$	Huber and Catoni estimators: $n > 2 \log(2/\delta)$	Lee-Valiant estimator: $n \geq \log(\frac{1}{\delta})$
$\delta = 5.0\%$	$n \geq 24$	$n \geq 8$	$n \geq 3$
$\delta = 1.0\%$	$n \geq 37$	$n \geq 11$	$n \geq 5$
$\delta = 0.1\%$	$n \geq 56$	$n \geq 16$	$n \geq 7$

7 Conclusion

In this paper, we are interested with robust and efficient estimation methods for very generic integrals. We want to provide accurate error bounds for the estimate. So far, the main tool is to use asymptotic normality, which might either be long to be satisfied or not valid when using RQMCS with generic integrands.

We review various sub-Gaussian estimators from the most well known e.g., median-of-means, Huber Z-estimator, to the newest e.g., Lee-Valiant and Minsker-Ndaoud. These estimators are compared in terms of theoretical advantage and disadvantage, as well as in a numerical illustration. We then introduce the concept of (Randomized) Quasi Monte Carlo methods with a special focus on scrambled nets which are known to always produce asymptotically better convergence than MC for any fixed input function F as long as $F \in L^2$. We prove a new asymptotic scaling for the variance when F is smooth but singular at the origin.

Our paper proposes a new methodology combining the two previous concepts to fully exploit the variance reduction $(\sigma_N(F))^2 = o(1/N)$ provided by Randomized QMC thanks to sub-Gaussian estimators. First it is used to build non-asymptotic quasi-optimal – up to logarithmic terms – confidence intervals which are opposed to classical concentration inequalities which are always sub-optimal with respect to their variance dependence. Then, we illustrate numerically both for bounded smooth integrands and for singular ones, the practical benefits of our Robust Randomized Monte Carlo methodology. It turns out that all RQMC estimators perform similarly for bounded integrands, while for singular ones, Robust RQMC estimators behave better; among them, the Lee-Valiant estimator with RQMCS is the best. In addition, for a given budget $B = N \times n$, it is better to take n small and N large.

This paper only deals with one-dimensional valued integrands $F : [0, 1]^d \rightarrow \mathbb{R}$. One natural question is how does the proposed methodology generalize in \mathbb{R}^q for $q > 1$? The sole concept of sub-Gaussian estimator is different. Some recent efforts, e.g., [37] have been made to find robust mean multidimensional estimators. These are defined as estimators satisfying $\hat{\mu}_{n,\delta}(X_1, \dots, X_n)$ for a sample of random vector X_1, \dots, X_n (up to multiplicative constants)

$$\mathbb{P} \left(\|\hat{\mu}_{n,\delta} - \mu_X\| \geq \sqrt{\frac{\text{Tr}(\Sigma)}{n}} + \sqrt{\frac{2\lambda_{\max} \log(1/\delta)}{n}} \right) \leq \delta$$

where $\|\cdot\|$ is the Euclidean norm, Σ is the covariance matrix, and λ_{\max} its maximum eigenvalue. How do variance reduction methods such as Quasi Monte Carlo influence sub-Gaussian bounds? Do we still expect a strong gain over the Empirical Mean estimator and multidimensional concentration inequality? These issues are left for further investigation.

A Variance of unbounded integrands

Our purpose is to establish Theorems 4.3 and 4.4. We use the standard notations from Section 4.

Framework. We consider functions satisfying Definition 4.4 (with $A_k \in (0, 1)$) where there is only one singularity at the origin. Essentially, we treat here the case of smooth functions with a singularity at the origin.

Low-Variation extensions of F . Following ideas by Sobol' [60] and Owen [51, Section 2.3], we extend F into $\tilde{F} \in \text{BVHK}$ as follows. Given $\eta \in (0, 1)$ whose value is set later, define the hyperbolic region avoiding 0 (the location of the singularity of F) by

$$K_\eta := \left\{ \mathbf{x} \in [0, 1]^d \mid \prod_{1 \leq k \leq d} x_k \geq \eta \right\},$$

The next construction ensures that $F = \tilde{F}$ on K_η and that

$$|\tilde{F}(\mathbf{x}) - F(\mathbf{x})| \leq \tilde{B} \prod_{k=1}^d x_k^{-A_k}, \quad \forall \mathbf{x} \notin K_\eta, \quad (\text{A.1})$$

for some constant \tilde{B} . Note that K_η contains the anchor point $\mathbf{1}$, in the sense that $\mathbf{x} \in K_\eta$ implies $[\mathbf{x}, \mathbf{1}] \subseteq K_\eta$. Under this condition, we can write

$$F(\mathbf{x}) = F(\mathbf{1}) + \sum_{u \neq \emptyset} \int_{[\mathbf{1}_u, \mathbf{x}_u]} \frac{\partial^{|u|} F}{\partial \mathbf{x}_u}(\mathbf{z}_u : \mathbf{1}_{-u}) d\mathbf{z}_u,$$

where we recall that for $\mathbf{z} = (z_1, \dots, z_d) \in [0, 1]^d$, \mathbf{z}_u stands for the components z_j such that $j \in u$ and $\mathbf{z}_u : \mathbf{1}_{-u}$ denotes the point $\mathbf{y} \in [0, 1]^d$ with $y_j = z_j$ for $j \in u$ and $y_j = 1$ for $j \notin u$. The low variation extension is

$$\tilde{F}(\mathbf{x}) = F(\mathbf{1}) + \sum_{u \neq \emptyset} \int_{[\mathbf{1}_u, \mathbf{x}_u]} \mathbb{1}_{\mathbf{z}_u : \mathbf{1}_{-u} \in K_\eta} \frac{\partial^{|u|} F}{\partial \mathbf{x}_u}(\mathbf{z}_u : \mathbf{1}_{-u}) d\mathbf{z}_u.$$

Indeed, by the fundamental theorem of calculus $\tilde{F} = F$ on $\mathbf{x} \in K_\eta$. In addition, from [51, Proof of Theorem 5.5] and taking advantage of Definition 4.4, we get $\tilde{F} \in \text{BVHK}$, with $V_{\text{HK}}(\tilde{F}) = \mathcal{O}(\eta^{-\max_k A_k})$ assuming the largest A_k is unique and $\mathcal{O}(\eta^{-\max_k A_k - \varepsilon})$ for any $\varepsilon > 0$ otherwise. Last, this extension \tilde{F} satisfies the error bound Eq. (A.1), see [51, Lemma 5.1].

If we consider the RQMC sequence $(\mathbf{R}_1, \dots, \mathbf{R}_N)$ not necessarily inside K_η , the estimator Eq. (4.2) satisfies

$$\begin{aligned}
& |\bar{\mu}_N(F) - \mu(F)| \\
& \leq \left| \frac{1}{N} \sum_{j=1}^N \tilde{F}(\mathbf{R}_j) - \int_{[0,1]^d} \tilde{F}(\mathbf{x}) d\mathbf{x} \right| + \int_{[0,1]^d} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})| d\mathbf{x} + \frac{1}{N} \sum_{j=1}^N |F(\mathbf{R}_j) - \tilde{F}(\mathbf{R}_j)| \\
& \stackrel{(4.1)}{\leq} D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N) V_{\text{HK}}(\tilde{F}) + \int_{K_\eta^c} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})| d\mathbf{x} + \frac{1}{N} \sum_{j=1}^N |F(\mathbf{R}_j) - \tilde{F}(\mathbf{R}_j)|. \quad (\text{A.2})
\end{aligned}$$

Bound on L^1 -Error. Let us prove Theorem 4.3. Take the expectation in Eq. (A.2):

$$\mathbb{E} (|\bar{\mu}_N(F) - \mu(F)|) \leq \mathbb{E} (D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N)) V_{\text{HK}}(\tilde{F}) + 2 \int_{K_\eta^c} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})| d\mathbf{x}.$$

From [51, Lemma 5.4], we get

$$\int_{\prod_k x^k < \eta} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})| d\mathbf{x} \leq \mathcal{O}(\eta^{1-\varepsilon - \max_k A_k}). \quad (\text{A.3})$$

Hence, we obtain

$$\mathbb{E} (|\bar{\mu}_N(F) - \mu(F)|) = \mathcal{O}(N^{-1+\varepsilon/2}) \mathcal{O}(\eta^{-\max_k A_k - \varepsilon/2}) + \mathcal{O}(\eta^{1-\varepsilon - \max_k A_k}),$$

whence the result when we take $\eta = N^{-1}$. Theorem 4.3 is proved. \square

Bound on the variance. To get the analog result for the variance, take the square of Eq. (A.2) and the expectation: it gives

$$\begin{aligned}
\text{Var}(\bar{\mu}_N(F)) & \leq 3 \mathbb{E} \left(D_N^*(\mathbf{R}_1, \dots, \mathbf{R}_N)^2 \right) V_{\text{HK}}(\tilde{F})^2 + 3 \left(\int_{K_\eta^c} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})| d\mathbf{x} \right)^2 \\
& \quad + 3 \mathbb{E} \left(\left(\frac{1}{N} \sum_{i=1}^N |F(\mathbf{R}_i) - \tilde{F}(\mathbf{R}_i)| \right)^2 \right).
\end{aligned}$$

Setting $\eta = N^{-1}$, the two first terms on the above right-hand side are $\mathcal{O}(N^{-2+\varepsilon+2\max_k A_k})$ using the same estimates as before (i.e., Eq. (A.3) and the bound on $V_{\text{HK}}(\tilde{F})$). It remains to upper-bound the last term. Expanding the square of the average, using the decomposition Eq. (4.5) and that the joint distribution $\Psi(d\mathbf{x}, d\mathbf{y})$ has a uniformly bounded density (by a constant C_Ψ), it readily follows

$$\begin{aligned}
& \mathbb{E} \left(\left(\frac{1}{N} \sum_{i=1}^N |F(\mathbf{R}_i) - \tilde{F}(\mathbf{R}_i)| \right)^2 \right) \\
& = \frac{1}{N} \int_{[0,1]^d} |F(\mathbf{x}) - \tilde{F}(\mathbf{x})|^2 d\mathbf{x} + \frac{N-1}{N} \int_{[0,1]^d \times [0,1]^d} |F(\mathbf{x}) - \tilde{F}(\mathbf{x})| |F(\mathbf{y}) - \tilde{F}(\mathbf{y})| \Psi(d\mathbf{x}, d\mathbf{y})
\end{aligned}$$

$$\leq \frac{1}{N} \int_{K_\eta^c} |F(\mathbf{x}) - \tilde{F}(\mathbf{x})|^2 d\mathbf{x} + C_\Psi \left(\int_{K_\eta^c} |F(\mathbf{x}) - \tilde{F}(\mathbf{x})| d\mathbf{x} \right)^2. \quad (\text{A.4})$$

Similarly to Eq. (A.3) and using Eq. (A.1), we derive

$$\int_{\prod_k x^k < \eta} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})|^2 d\mathbf{x} \leq \mathcal{O}(\eta^{1-\varepsilon-2\max_k A_k}), \quad (\text{A.5})$$

for any $\varepsilon > 0$. Taking $\eta = N^{-1}$, plugging Eq. (A.5) and Eq. (A.3) into Eq. (A.4) gives

$$\begin{aligned} \mathbb{E} \left(\left(\frac{1}{N} \sum_{i=1}^N |F(\mathbf{R}_i) - \tilde{F}(\mathbf{R}_i)| \right)^2 \right) &= \mathcal{O} \left(\frac{1}{N} N^{-1+\varepsilon+2\max_k A_k} + (N^{-1+\varepsilon+\max_k A_k})^2 \right) \\ &= \mathcal{O}(N^{-2+2\varepsilon+2\max_k A_k}). \end{aligned}$$

This gives (the arbitrary ε values are adjusted to correspond)

$$\text{Var}(\bar{\mu}_N(F)) = \mathcal{O}(N^{-2+\varepsilon+2\max_k A_k}).$$

This asymptotic regime is better than Monte Carlo $\mathcal{O}(N^{-1})$ when $\max_k A_k < 1/2$. \square

Remark A.1. *In the case where the assumption of bounded density for the joint density distribution Ψ is not available, we can still use the rough bound*

$$\mathbb{E} \left(\left(\frac{1}{N} \sum_{i=1}^N |F(\mathbf{R}_i) - \tilde{F}(\mathbf{R}_i)| \right)^2 \right) \leq \mathbb{E}(|F(\mathbf{R}_1) - \tilde{F}(\mathbf{R}_1)|^2) = \int_{\prod_k x^k < \eta} |\tilde{F}(\mathbf{x}) - F(\mathbf{x})|^2 d\mathbf{x}.$$

With the use $\eta = N^{-1}$ and Eq. (A.5), we obtain

$$\text{Var}(\bar{\mu}_N(F)) = \mathcal{O}(N^{-1+\varepsilon+2\max_k A_k}),$$

which for $\max_k A_k < 1/4$ is better than Monte Carlo.

B Bounded density for the joint distribution $\Psi(d\mathbf{x}, d\mathbf{y})$

This joint distribution function Ψ is studied in detail for a base b digital scrambled (t, m, d) -nets in [69]. Their definition of base b digital scramble includes NUS and other types of scrambles. This boundedness hypothesis of Ψ is satisfied all over $[0, 1]^{2d}$ for digital nets $(0, m, d)$ in base b , where we can obtain using [69, Lemma 3.4 and Theorem 3.6],

$$\frac{\Psi(d\mathbf{x}, d\mathbf{y})}{d\mathbf{x}d\mathbf{y}} \leq \frac{2^{d+1}b^{m+d}}{(b^m - 1)(b - 1)^d} \leq 2^{d+1} \sup_{N \geq 2} \left(\frac{N}{N - 1} \right)^{d+1} = 4^{d+1}$$

uniformly in \mathbf{x}, \mathbf{y} . \square
