ABSTRACT

The CO₂ uptake of Portland cement, fly ash and blast furnace slag concrete cylinders was determined after 10-year natural carbonation. The purpose was to provide data to better assess the exchanges of CO₂ during the life cycle of structures. The CO₂ uptake of cylinders (mass of bound CO₂ per unit of surface) was calculated from profiles of CO₂ content determined by thermogravimetric and chemical analyses. The CO₂ binding capacity of concrete with high slag content was found much lower than that of Portland cement concrete, due to the low

degree of carbonation of CaO from slag. The CO₂ uptakes of the studied specimens were however rather close. High carbonation depth of slag concretes compensates partly their lower binding capacity. The experimental results were compared to predictions of the European Standard EN 16757 model. The Standard model underestimates the CO₂ uptake of concretes with mineral addition mainly because of an underestimation of the carbonation depth.

2 **1. Introduction**

3

4 Life cycle analyzes showed that cement production, responsible for 65 – 85 % of CO₂
5 emissions from concrete manufacturing, accounts for 5 – 8 % of global CO₂ emissions (Miller
6 et al., 2016; Olivier et al., 2016; Andrew, 2019; Lim et al., 2019). Therefore, efforts to
7 mitigate CO₂ emissions from concrete manufacturing have focused on: (i) using alternative
8 fuels and raw materials during cement production, (ii) developing alternative low-carbon
9 binders, (iii) substituting with raw or mineral materials a part of clinker during cement
10 production or a part of cement during concrete manufacturing (Flower et al., 2007; Younsi et
11 al., 2013; Gartner et al., 2015; Feiz et al., 2015; Elchalakani et al., 2017; Younsi et al., 2019;
12 Costa et al., 2020; Ren et al., 2020; Esfahani et al., 2021; Younsi et al., 2021). However, to
13 establish a more complete life cycle inventory of concrete in terms of carbon footprint, in
14 addition to accounting for the CO₂ emissions due to its manufacture, it becomes essential to
15 consider also the CO₂ uptake due to its carbonation (Lagerblad et al., 2005; Galan et al., 2010;
16 Ashraf, 2016 ; Jang et al., 2016 ; Lee et al., 2016 ; Possan et al., 2016 ; Andrade et al., 2018;
17 Andersson et al., 2019; Sanjuán et al., 2019; Sanjuán et al., 2020; Witkowski et al., 2020;
18 Kwon et al., 2021). The CO₂ uptake is defined as the quantity of CO₂ bound by a concrete
19 structure and expressed in mass of bound CO₂ per unit area of this structure. For instance, the
20 study conducted by Pade and Guimaraes showed that, after 70 years, concrete structures
21 produced in 2003 will bind about 28 % of the CO₂ emissions from cement production (Pade et
22 al., 2007). (Yang et al., 2014) showed that concrete structure will bind 18 – 21 % of the CO₂
23 emissions from cement production, after 100 years. (Fitzpatrick et al., 2015) showed that
24 structures built in 1972 will bind, after 100 years, about 16 % of the CO₂ emissions from
25 cement production. The study of (Xi et al., 2016) showed that, due to their natural carbonation

1 occurring between 1930 and 2013, cementitious materials have bound 43 % of the CO₂
2 emissions from cement production for the same period. The authors concluded that
3 carbonation is an important carbon sink which is not yet included in life cycle inventories.

4 Carbonation is a natural aging process during which atmospheric CO₂ diffuses into the
5 pore network of concrete and chemically reacts with hydration products, forming mainly
6 CaCO₃ (Papadakis et al., 1991). This phenomenon can be considered from two opposing
7 points of view depending on how the role of chemical reactions involving CO₂ is considered:
8 (i) from the point of view of durability of reinforced concrete structures, chemical reactions
9 between CO₂ and hydration products can initiate the rebar corrosion by lowering the *pH* of the
10 pore solution. Carbonation is thus considered as a degradation phenomenon expected to
11 reduce the service life of structures, (ii) from the point of view of environmental impact, the
12 chemical reactions involving CO₂ allow bounding CO₂ within the concrete. Carbonation is
13 thus considered as a process contributing to the reduction of CO₂ emissions from concrete
14 manufacturing and use.

15 As pointed out by Andrade, very few studies were devoted to the quantification of bound
16 CO₂ (Andrade, 2020). The calculation of CO₂ uptake remains a very complex task since only
17 approximate calculation methods and empirical models are used (Andersson et al., 2013). A
18 standardized calculation method is presented in the Annex BB of the European Standard
19 EN 16757 (EN16757, 2017). The standard allows assessing the CO₂ uptake at different life
20 cycle stages by assuming a direct link between carbonation and amount of reactive CaO in
21 concrete. To assess the CO₂ uptake occurring during a given period, EN 16757 refers to the
22 concepts of: (i) carbonation rate, which is defined by considering both the compressive
23 strength class and the exposure conditions, (ii) degree of carbonation (ratio between
24 carbonated and available reactive CaO), (iii) maximum theoretical uptake of CO₂ in totally
25 carbonated concrete which is correlated with the reactive CaO content in the binder. Results

1 from some published works, such as those carried out by (Yang et al., 2014) and (Fitzpatrick
2 et al., 2015), are consistent with the calculations from EN 16757 in terms of CO₂ uptake.
3 However, the findings provided by these studies remain theoretical long-term assessments (up
4 to 100 years) that are difficult to validate with experimental data due to the lack of availability
5 of the latter, as mentioned previously (Andrade, 2020). It thus appears interesting to compare
6 experimental results obtained over a realistic and sufficiently long period exposure to natural
7 carbonation with prediction of models such as the EN 16757 standard model. Moreover, there
8 is also a lack of data on the CO₂ uptake of concrete made with blended binders that are
9 increasingly used to the detriment of Ordinary Portland Cement (OPC) to reduce the footprint
10 of concrete use.

11 In the view of these considerations, the present work aims at providing data on CO₂ uptake
12 due to atmospheric carbonation of various concretes. There is still a lack of this type of data in
13 the literature, especially for concretes with mineral additions. These data are necessary to
14 better assess the real environmental footprint of the use of concrete in civil engineering
15 structures with approach such as the one proposed by (Xi et al., 2016).

16 For this purpose, an experimental study was carried out on concretes designed with OPC,
17 blended cements containing fly ash or ground granulated blast furnace slag (GGBFS), and
18 partial substitutions of OPC with fly ash or GGBFS. The concretes were subjected to 10-year
19 natural carbonation, under sheltered and unsheltered conditions. During the exposure period,
20 the progress of carbonation was monitored by regular carbonation depth measurements. At the
21 end of the exposure period, the CO₂ uptake was determined by Thermogravimetric analysis
22 (TGA) coupled to chemical analysis by Inductively Coupled Plasma - Atomic Emission
23 Spectroscopy (ICP-AES). In the following, the results of this experimental investigation are
24 analyzed to assess the effect of both binder nature and exposure on CO₂ binding capacity,
25 degree of carbonation and CO₂ uptake of the studied specimens. Finally, the experimental

1 results are compared to calculations using the EN 16757 model and its range of validity is
2 discussed.

4 **2. Materials and methods**

5

6 *2.1. Materials*

7

8 The study was carried out on concrete mixtures designed with three cements as per the
9 European Standard EN 197-1 ([EN197-1, 2011](#)): an Ordinary Portland Cement CEM I 52.5 N
10 ~~from Lafarge France~~, a blended cement CEM II/B-V 32.5 R ~~from CCB Belgium~~, and a
11 ground granulated blast-furnace slag cement CEM III/C 32.5 N ~~from Calcia France~~. Other
12 constituents were used: a fly ash (FA) with low calcium content ~~from Surschiste France~~ as per
13 the European Standard EN 450-1 ([EN15167, 2006](#)), a ground granulated blast-furnace slag
14 (GGBFS) ~~from Ecocem Netherlands~~ as per the European Standard EN 15167-1 ([EN15167,](#)
15 [2006](#)), a siliceous sand (0/4 mm) and two crushed diorite gravels (6.3/10 and 10/14 mm) ~~from~~
16 ~~HeidelbergCement France~~ as per the European Standard EN 13139 ([EN13139, 2003](#)), and a
17 polycarboxylate superplasticizer Fluid-Optima 206[®] ~~from Chryse France~~ as per the European
18 Standard EN 934-2+A ([EN934-2, 2012](#)). [Table 1](#) shows the properties of the cementitious
19 materials used. The chemical compositions of the binders were obtained by X-ray
20 fluorescence (XRF) analysis. Note that the used sand is a sea sand which contains trace of
21 limestone due to shell particles. Its mass content of CaCO₃ is equal to 6.9%.

2 2.2. Mixtures

3

4 The proportions used in the mixes are given in [Table 2](#). Three concrete mixtures were used
5 as references: Ref I with CEM I, Ref II with CEM II and Ref III with CEM III. Three other
6 concrete mixtures were designed with partial substitution of CEM I with FA (FA 30) or
7 GGBFS (S 30 and S 75). Except for S 75, all the mixtures were designed as per the
8 prescriptive requirements from the French annex of the European Standard NF EN 206/CN
9 ([EN206/CN, 2014](#)) corresponding to the exposure class XC 3. These requirements are the
10 following: a minimum strength class C25/30, a minimum equivalent binder content
11 (Eq.binder) of 280 kg/m³, a maximum effective water-to-equivalent binder ratio
12 (W/Eq.binder) of 0.6, and a maximum cement substitution ratio (A/(A+C)) of 30 % for FA 30
13 and S 30. It should be noted that the requirements corresponding to XC 3 are equivalent to

1 those corresponding to XC 4. Moreover, the mixture S 75, which does not comply with the
 2 prescriptive requirements of EN 206, was designed with a cement substitution ratio of 75 %
 3 using the mix-design method suggested by (Khokhar et al., 2010). Its effective water-to-
 4 binder ratio ($W/(A+C)$) was optimized using the Bolomey's equation to obtain a 2-day
 5 compressive strength of 10 MPa. Finally, for all the mixtures, the amount of superplasticizer
 6 was adjusted to obtain a slump higher than 150 mm. Additional details on the mix-design
 7 method used can be found in (Younsi et al., 2011). In summary, the six studied concretes are
 8 equivalent in terms of site construction application, since they have the same workability and
 9 mechanical performances at early age and 28 days.

10 The concrete mixtures were cast, according to the European Standard EN 12390-12
 11 (EN12390-12, 2020), into Ø11X22 cm molds and stored in a room at 20 ± 1 °C for 24 h.
 12 Other physical, chemical and mechanical properties are given in Table 2. Especially, Table 2
 13 gives the total mass of CaO from the $CaCO_3$ of both sand and binder and from the anhydrous
 14 elements of binder (e.g., C_3S , C_2S). The parameter denoted α is the fraction of CaO from the
 15 binder to the total mass of CaO.

2 2.3. Carbonation conditions

3

4 Immediately after demolding at 1 day, the Ø11X22 cm specimens were subjected to natural
5 carbonation under sheltered conditions (exposure class XC 3 as per EN 206) and unsheltered
6 (XC 4) conditions for 10 years. This demolding at early age is not favorable for some
7 concretes, such as GGBFS concrete (Ref III), but this makes the study conditions more
8 representative of in working site conditions (i.e., poorly hydrated concrete cover), which
9 interest the project managers. Table 3 gives the ranges of temperature and relative humidity at
10 both exposure sites located in La Rochelle, France. In unsheltered conditions, the specimens
11 were placed on the floor of an outside laboratory platform. So, they were subject to rain,
12 wind, and solar radiation. Over the 10 years, the specimens were sometimes rotated, so that
13 the effect of solar radiation is on all sides. In the sheltered conditions, the specimens were
14 placed on shelves protected from external climatic conditions (rain and sun).

15

16 **Table 3**

17 Temperature and relative humidity at both exposure sites: averages and ranges (minimum and
18 maximum were obtained from 2-day moving averaging).

	Sheltered conditions	Unsheltered conditions
Temperature (°C)	18 (14 – 26)	13 (2 - 26)
Relative humidity (%)	70 (30 – 80)	77 (50 – 95)

1

2 2.4. Determination of carbonation depths by phenolphthalein spraying

3

4 Carbonation depths were determined at 1, 2, 3, 6 and 10 years on Ø11X5 cm specimens
5 saw-cut from the Ø11X22 cm specimens. The Ø11X5 cm specimens were split in half and a
6 pH indicator solution, namely a solution of 1% phenolphthalein, was sprayed on the split
7 sections to assess the carbonation depth as per the European Standard EN 12390-12
8 (EN12390-12, 2020). Before spraying phenolphthalein, the top and the bottom of the
9 Ø11X22 cm specimens were removed to only consider the carbonation depths due to radial
10 CO₂ diffusion. The carbonation depth is the mean value of depths d_i determined as shown in
11 Fig. 1. It should be kept in mind that phenolphthalein reveals area where pH is lower than 9
12 and not strictly speaking a fully carbonated area.

13

14

15

16 **Fig. 1.** Schematic presentation of the carbonation characterization by phenolphthalein
17 spraying: sawing of cylindrical specimen, then splitting of the obtained discs, and finally
18 determination of carbonation depths (d_i) after phenolphthalein spraying. Depths d_i are
19 measured outside the hatched zones (EN12390-12, 2020).

20

2.5. Carbonation characterization by TGA coupled to chemical analysis ICP-AES

Carbonation measurements were carried out after 10-year exposure by determining the bound CO₂ contents in concrete powders. The latter were obtained by drilling holes in Ø11X5 cm specimens, themselves saw-cut from the Ø11X22 cm specimens (Fig. 2). Before drilling holes, the top and the bottom of the Ø11X22 cm specimens were removed to only consider the radial carbonation. The centers of the holes were located at 4 different distances, from the core, chosen according to the carbonation depths revealed by phenolphthalein: 0; 15 – 20; 20 – 35 and 35 – 45 mm. For a given Ø11X5 cm specimen, a Ø8X50 mm hole was drilled through the core, and at each intermediate distance, 16 Ø5X50 mm holes were drilled. Moreover, the skin was removed to a depth of about 1 mm by planing. To avoid their carbonation, the powders were stored in a desiccator where the relative humidity was maintained at about 3 % by silica gel. The bound CO₂ contents were determined by thermogravimetric analysis (TGA) carried out on 210 ± 45 mg powders using a Setaram Setsys Evolution[®] device with a heating rate of 10 °C/min from 20 to 1000 °C in an argon atmosphere (Thiery et al., 2007; Bordy et al., 2017; Younsi et al., 2018). The mass of bound CO₂ corresponds to the loss of mass between 600°C and 900°C. In practice, this temperature range was refined by considering the derivative thermogravimetry (DTG) which reveals a peak at around 700°C due to the sample decarbonation. 2 to 3 replicates were used for TGA.

The bound CO₂ content determined by TGA is expressed in mg of CO₂ per mg of concrete powder. However, the powders are not enough homogenous and representative of the concrete. To express the bound CO₂ content as a function of a representative quantity of concrete, the binder content in each powder was assessed by chemical analysis (Turcry et al., 2014; Villain et al., 2007). The procedure consists of dissolving 100 ± 0.5 mg powder in 2 ± 0.01 mg nitric acid (HNO₃) for 24 hours. After that, a solution of HNO₃, with 1/50

1 dilution in pure water, is added. A week later, the suspension obtained is analyzed by
 2 Inductively Coupled Plasma-Atomic Optical Emission Spectroscopy (ICP-AES), using a
 3 Varian Vista device Pro[®], to determine its CaO content. From the latter, it is possible to
 4 deduce the binder content in each concrete powder, as explained in section 3.2. One replicate
 5 for each sampling position was used for chemical analysis.

6

7

8

9 **Fig. 2.** Schematic presentation of the carbonation characterization by TGA/ICP-AES.

10

11 *2.6. Calculation of CO₂ uptake from Standard EN 16575*

12

13 An empirical model for the prediction of CO₂ uptake by cement-based products is proposed in
 14 the European Standard EN 16757. In the following sections, the predictions of this model are
 15 compared to our experimental results. To facilitate the comparison, we adopt the following
 16 nomenclature.

17 The uptake of CO₂ is expressed by exposure surface [kg_{CO₂}/m²] as follows:

18

$$\text{Uptake}(t) = \text{CBC} \cdot X_c(t) \quad (1)$$

1

2 Where: CBC is the CO₂ binding capacity of the carbonated zone [kg_{CO₂} per m³ of concrete]
3 and X_c(t) is the carbonation depth [m] at an exposure time t [year].

4 In the model of European Standard, the carbonation depth is classically calculated as a
5 function of the square root of time:

6

$$X_c(t) = k\sqrt{t} \quad (2)$$

7

8 With: k the carbonation rate defined by considering the compressive strength class, the
9 exposure conditions (sheltered or unsheltered), and the type and the dosage of mineral
10 additions used.

11 The CO₂ binding capacity of the carbonated zone (CBC) is calculated with a conservative
12 approach assuming that only the calcium oxides from clinker can be carbonated (Eq. 3). This
13 approach is based on the point of view of the cement industry, since carbonation is seen in the
14 scope of CCUS (Carbon Capture, Utilization and Storage) as a way to use or consume the
15 CO₂ emitted during the production of clinker.

16

$$\text{CBC} = K \cdot U_K \cdot \text{DoC} \quad (3)$$

17

18 Where: CBC is the CO₂ binding capacity [kg_{CO₂} per m³ of carbonated concrete], K the clinker
19 content [kg_K/m³_{concrete}], U_K the maximum bound CO₂ by carbonation of CaO from the
20 clinker [kg_{CO₂}/kg_K], and DoC the degree of carbonation [-]. The latter is defined as the ratio
21 of the total bound CO₂ content for a given exposure and the theoretical maximum bound CO₂.

22 Values of DoC are proposed for 3 exposures, i.e., indoor (0.40), outdoor sheltered (0.75),

1 outdoor unsheltered (0.85). U_K is usually taken equal to 0.5 kg_{CO2}/kg_K (for a CaO content in
2 the clinker of around 65%).

3 To compare the model predictions with the experimental results, the model cannot be used as
4 is, because the diffusion of CO₂ in our cylindrical specimens is radial. The square-root of time
5 model given by Equation 2 is only valid for an axial diffusion. The calculated values of X_c
6 must be corrected with the method presented in Appendix 1, which considers the cylindrical
7 geometry for a sharp front carbonation. Knowing the corrected X_c , the CO₂ uptake is then
8 calculated as follows:

9

$$\text{Uptake} = \frac{1}{R} \int_{X_c}^R \text{CBC} \cdot r dr = \text{CBC} \left[\frac{R^2 - (R - X_c)^2}{R} \right] \quad (4)$$

10

11 where: R [m] is the radius of the cylindrical specimen.

12

13 **3. Results**

14

15 *3.1. Carbonation depths*

16

17 **Fig. 3** shows the time-evolution of the carbonation depths revealed after phenolphthalein
18 spraying. For both sheltered and unsheltered conditions, FA 30 is more resistant against
19 carbonation than Ref II, i.e. the reference with FA. S 30 and S 75 are more resistant than
20 Ref III, i.e. the reference with GGBFS. In terms of natural carbonation, concretes with cement
21 substitution thus exhibit a potential durability at least equivalent to that of the concretes with
22 blended cements. By applying the concept of equivalent performance stated by the European
23 Standard EN 206/CN, S 75, which does not comply with the prescriptive requirements of the
24 standard, can replace at least Ref III. This result is consistent with previous studies on this

1 concrete mixture (Younsi et al., 2013; Younsi et al., 2019). Moreover, although Ref III
2 complies with the prescriptive requirements of EN 206, it has the lowest resistance against
3 carbonation. This is usually explained by the fact that, due to its very low clinker content, it
4 has the lowest amount of carbonatable products and the highest water porosity (Table 2). Its
5 CO₂ diffusion coefficient should be also the highest one because carbonation increases the
6 CO₂ diffusivity of materials with high amount of GGBFS. For this kind of materials, recent
7 papers give evidence of increase in gas diffusivity due to microstructural changes (Boumaaza
8 et al., 2020a) or microcracking (Kangni-Foli et al., 2021) resulting from carbonation. Ref I
9 has the lowest carbonation rate, because it contains the highest clinker content, thus the
10 highest amount of carbonatable products (Table 2). In addition, its CO₂ diffusivity should be
11 the lowest since carbonation tends to decrease the gas diffusivity of materials with high
12 amount of clinker (Boumaaza et al., 2020a).

13 Concretes exposed to carbonation under unsheltered conditions exhibit lower carbonation
14 depths than those exposed to carbonation under sheltered conditions (relative deviations from
15 20 to 80 %). This result is expected because precipitation maintains the concrete pore network
16 often close to saturation, what limits gas diffusion (Houst et al., 2002; Yoon et al., 2007;
17 Ekolu, 2016 ; Huy Vu et al., 2019 ; Otieno et al., 2020). The diffusion of CO₂ is thus only
18 possible through the pore solution, which considerably slows down, the carbonation progress
19 since CO₂ diffusion coefficient in air is known to be 10⁴ times higher than that in water
20 (Thiery, 2005). Carbonation occurs mainly when the pore network is sufficiently dry up to the
21 carbonation depth reached before precipitation. Carbonation process is then mainly controlled
22 by the frequency and duration of the wetting/drying periods.

23

Fig. 3. Time-evolution of the carbonation depth in sheltered (left) and unsheltered conditions (right).

3.2. Binder content

Powder samples were obtained from drilling at different locations in the Ø11X5 cm specimens. Chemical analyzes allowed assessing the CaO content (%CaO) in these powder samples. The CaO is obtained from both the binder and the marine sand (the CaO comes from shells contains in the sand). Let us assume that the mass fraction α , as defined in section 2.2 and given in Table 2, is the same for the powder sample than for the concrete mixture. In other words, we consider that the powder samples contain the same proportions of sand and binder as in the concrete. The content of CaO obtained from the binder is then equal to α %CaO.

Knowing the CaO content in the binder used (%CaO_B), it was then possible to deduce the binder content in the powder as:

$$\%B = \frac{\alpha \%CaO}{\%CaO_B} \quad (5)$$

1 %CaO_B was calculated from the CaO content of each binder (Table 1) and from the mix
2 proportions (Table 2) as follows:

$$\%CaO_B = \%CaO_{CEM\ I, CEM\ II\ or\ CEM\ III} \text{ for Ref I, Ref II or Ref III} \quad (6)$$

$$\%CaO_B = 0.70 \%CaO_{CEM\ I} + 0.30 \%CaO_{FA\ or\ GGBFS} \text{ for FA 30 or S 30} \quad (7)$$

$$\%CaO_B = 0.25 \%CaO_{CEM\ I} + 0.75 \%CaO_{GGBFS} \text{ for S 75} \quad (8)$$

3

4 where: %CaO_{CEM I, CEM II or CEM III} [%] are the CaO contents in CEM I, CEM II and CEM III,
5 respectively. %CaO_{FA or GGBFS} [%] are the CaO contents in FA and GGBFS, respectively.

6 For a given concrete, the binder contents of the powders taken between 0 and 45 mm, i.e., in
7 the specimen core, were close, whatever the exposure conditions. Similarly, the binder
8 contents of the powder samples taken at 55 mm, i.e., in the skin, were close. Fig. 4 shows the
9 effect of the location (core versus skin) on the binder contents. The average %B are different
10 from those calculated from the concrete composition given in Table 2 (relative difference
11 from 18 to 59 %). This was expected since powder sampling by drilling or planing does not
12 allow maintaining the initial composition. The binder content in the powders obtained by
13 removing the skin by planing is higher than that in the powders taken by drilling the core. The
14 observed relative difference of about 40 % is explained by the “skin-effect”, which leads to a
15 surface layer richer in paste, thus in binder, than in the core (Kreijger, 1984). In the following,
16 the average binder contents shown in Fig. 4 were used to calculate the bound CO₂ content per
17 mass of binder. Different binder contents could have been used for each position. However,
18 we distinguished only two cases: samples in the core (between 0 and 45 mm from the center)
19 and samples in the skin (at 55 mm from the center). Let us recall that the sample is 110 mm
20 diameter. This procedure was preferred for less inaccuracy, since only one replicate was used
21 for chemical analysis.

22

Fig. 4. Average binder contents in the powder samples determined by chemical analysis, in the specimen core (between 0 and 45 mm from the center) and in the skin (at 55 mm from the center). The red dashed lines give the theoretical binder contents from the concrete compositions (Table 2).

3.3. Profiles of bound CO₂ content per mass of binder

The bound CO₂ content at a location r , denoted $(\%CO_2)_r$, expressed by mass of binder was determined from TGA on powders as follows (Eq. 9):

$$(\%CO_2)_r = 100 \cdot \left(\frac{\Delta m_{T_1 \rightarrow T_2}}{\%B \cdot m_P} \right)_r - 100 \cdot \beta \cdot \left(\frac{\Delta m_{T_1 \rightarrow T_2}}{\%B \cdot m_P} \right)_{r=0} \quad (9)$$

where: $\Delta m_{T_1 \rightarrow T_2}$ [g] is the mass loss of the concrete powder during TGA in the temperature range $[T_1 - T_2]$. Classically, T_1 and T_2 are close to 600°C and 900°C, respectively. %B [-] is the binder content in the powder assessed by ICP-AES (section 3.2). m_P [g] is the mass of the concrete powder tested by TGA. β is a correction factor accounting for the skin effect.

The center of the cylindrical specimen, i.e., $r = 0$, is unaffected by carbonation. The CO₂

1 content at this location results from the decarbonation of CaCO_3 supplied by both sand and
2 binder. By subtracting the value at $r = 0$, we obtain only the CO_2 bound by carbonation. For r
3 lower than 55 mm, the correction factor β is taken equal to 0. On the skin of the specimen, the
4 CaCO_3 content before carbonation is not the same than at $r = 0$. The difference is due to
5 higher contents of sand and binder (as shown in section 3.2). Thus, to determine the bound
6 CO_2 content at $r = 55$ mm, the content of CO_2 at $r = 0$ in Equation 9 is corrected by β . The
7 latter is calculated as the ratio of the binder content in the skin and the binder content in the
8 core ($\beta > 1$). Note that we assume that the proportions sand/binder are the same in the skin
9 than in the core.

10 [Fig. 5](#) shows: (i) the carbonation fronts revealed by phenolphthalein spraying and (ii) the
11 profiles of bound CO_2 content. The carbonation fronts are rather close to that suggested by the
12 bound CO_2 content profiles determined by TGA/ICP-AES analysis. However, the latter shows
13 that carbonation occurs more gradually, and in some cases more deeply than the pH front.
14 This result is consistent with literature, e.g. ([Omikrine-Metalssi et al., 2009](#)).

15 In the area defined by the pH front, the profiles determined for the sheltered condition are up
16 that for the unsheltered one. This suggests that unsheltered conditions, which strongly reduce
17 the carbonation rate, also decrease the bound CO_2 content. The result, which corresponds to
18 that of Houst and Wittmann ([Houst et al., 2002](#)), is not consistent with other studies which
19 report that, due to high humidity, unsheltered conditions slightly increase the bound CO_2
20 content ([Galan et al., 2010](#); [Andrade et al., 2018](#)). This result is discussed in section 4.1.

21 Ref III and S 75 exhibit maximum bound CO_2 contents that are about two times lower than
22 that of the other concretes, despite their higher carbonation depths. Moreover, these two
23 concretes bound more CO_2 in depth than in surface, although the binder content is higher in
24 the specimen skin. This could be explained by the fact that these concretes, especially Ref III,
25 are poorly hydrated in surface due to a too early demolding, as shown by numerical

1 computations in a previous study (Younsi et al., 2019). Anhydrous phases are less
 2 carbonatable than hydrates (Boumaaza et al., 2020b).

3

4

1 **Fig. 5.** Profiles of bound CO₂ content per mass of binder after 10-year natural carbonation.
2 Dash lines and colored areas indicate the locations of carbonation fronts determined by means
3 of phenolphthalein spraying and the variation ranges of these fronts, respectively (blue for
4 unsheltered conditions and orange for sheltered).

5

6 3.4. CO₂ uptake

7

8 The CO₂ uptake was assessed from the profiles of bound CO₂ content following the steps.
9 First, the content of bound CO₂ at a distance r from the core was expressed by volume of
10 concrete [kg_{CO₂}/m³]:

11

$$(CO_2)_r = B_r (\%CO_2)_r / 100 \quad (10)$$

12

13 where: (%CO₂)_r [%] is the bound CO₂ content at r expressed by mass of binder.
14 B_r [kg_{binder}/m³] is the binder content at r expressed by volume of concrete.

15 At the first 4 distances from the core, i.e., 0, (15 – 20), (20 – 35) and (35 – 45) mm, B_r was
16 assumed to be equal to the binder content of the concrete mixture (Table 2). At 55 mm, B_r was
17 calculated from this binder content multiplied by the ratio between the binder content
18 determined in the skin and that determined at the other distances. This ratio, deduced from the
19 profiles shown in Fig. 5, accounts for the fact that in the specimen skin, the binder content is
20 higher due to the “skin-effect”, which leads to a surface layer richer in binder (Kreijger,
21 1984). Moreover, as the skin was sampled to a depth of about 1 mm, both (%CO₂)_r and B_r
22 were assumed to be constant between 54 and 55 mm. Examples of profiles of (%CO₂)_r, B_r
23 and (CO₂)_r obtained for Ref I under sheltered conditions are given in Fig. 8.

24

Fig. 6. Profiles of bound CO₂ content $(\%CO_2)_r$ expressed by mass of binder and binder content B_r expressed by volume of concrete (left), and profile of bound CO₂ content $(CO_2)_r$ expressed by volume of concrete (right): example of Ref I under sheltered conditions.

Second, the CO₂ binding capacity (CBC) of the carbonated zone revealed by phenolphthalein, expressed in kg_{CO₂}/m³, was assessed by integration of the profile of $(CO_2)_r$:

$$CBC = \frac{2}{R^2} \int_{R-X_c}^R (CO_2)_r \, r \, dr \quad (11)$$

Table 4 gives the obtained value of CBC for each concrete. It should be noted that this value is an average CO₂ binding capacity of the carbonated zone, since the bound CO₂ is not necessarily uniform within this zone, as shown in Fig. 7. CBC as calculated is proposed because the depth X_c revealed by the pH indicator is usually the reference carbonation depth. It is also a comparison tool with the results of models such as that of standard EN 16757. Whatever the exposure condition, two sets of concretes can be distinguished: a set of

1 concretes with high CBC corresponding to concretes with binders of clinker content higher
 2 than 70%, i.e., Ref I, Ref II, FA 30 and S 30, and a set with lower CBC (up to two times
 3 lower), corresponding to concretes with clinker contents lower than 30%, i.e., Ref III and S
 4 75.

5

6 In the third step, we determine the CO₂ uptake of the specimen expressed by exposure area
 7 by integrating the profile of (CO₂)_r:

8

$$\text{Uptake} = \frac{1}{R} \int_0^R (\text{CO}_2)_r \, r \, dr \quad (12)$$

9

10 Table 4 gives for each concrete the value of uptake, which quantifies the CO₂ bound by the
 11 cylindrical specimen after 10 years of exposure. The CO₂ uptake is at least 3 times higher in
 12 sheltered conditions than in unsheltered ones. For a given exposure, the differences in uptake
 13 between the studied concretes are rather low, especially for the unsheltered conditions.

14

15 **Table 4**

16 CO₂ binding capacity (CBC) of the carbonated zone revealed by phenolphthalein [kgCO₂/m³]
 17 and CO₂ uptake [kgCO₂/m²] determined from the profiles of bound CO₂ content.

	Sheltered conditions						Unsheltered conditions					
	Ref I	Ref II	Ref III	FA 30	S 30	S 75	Ref I	Ref II	Ref III	FA 30	S 30	S 75
CBC	107	81	57	115	79	47	103	70	42	79	57	41
Uptake	1.47	1.74	1.46	1.79	1.47	1.08	0.46	0.49	0.56	0.50	0.32	0.30

18

19 **4. Discussion**

20

1 *4.1. Degree of carbonation*

2 The degree of carbonation (DoC) is defined as the ratio between the bound CO₂ content
3 (%CO₂) and the theoretical maximum bound CO₂ content (U_B):

4

$$\text{DoC} = \frac{\% \text{CO}_2}{U_B} \quad (13)$$

5

6 U_B can be assessed using Equation (14) assuming that all calcium oxides of the binder are
7 converted by carbonation into CaCO₃, except CaO reacting with SO₃ (Boumaaza et al.,
8 2020b; Steinour, 1959):

9

$$U_B = \% \text{CaO}_B \cdot \frac{M_{\text{CO}_2}}{M_{\text{CaO}}} - \% \text{SO}_3 \cdot \frac{M_{\text{CO}_2}}{M_{\text{SO}_3}} \quad (14)$$

10

11 Where: M_{CO₂}, M_{CaO} and M_{SO₃} [g/mol] are the molar masses of CO₂, CaO and SO₃,
12 respectively, %SO₃ the SO₃ content in the binder [%] provided by binder producers and
13 determined by XRF analysis (Table 1).

14 The highest degree of carbonation was calculated for each concrete and each exposure from
15 the profile of bound CO₂ content (Figure 7-left). Note that the highest DoC are in the
16 specimen skin, except for the mixtures with high content of GGBFS (Ref III and S 75). As
17 shown in section 3.3, the latter tend to be more carbonated in depth than in surface, especially
18 in unsheltered condition. Two parameters controlling DoC can be discussed: exposure and
19 nature of binder.

20

Fig. 7. The highest degrees of carbonation from the profiles of bound CO₂ content, calculated with the maximum bound CO₂ content considering carbonation of all CaO from binder (left) and with the maximum bound CO₂ content considering carbonation of CaO from the clinker only, as proposed by Standard EN1657 (right).

With respect to the effect of exposure conditions, DoC is found higher for sheltered specimens than for unsheltered ones. This result is a bit surprising since, in most of literature data, the degree of carbonation increases in the most wet conditions (Andrade, 2020; Andrade et al., 2018; Galan et al., 2010). This is usually explained by the fact that increasing the water saturation degree also increases the amount of available compounds for carbonation, since the carbonation reactions take place in the pore solution. As shown by (Boumaaza et al., 2020b; Steiner et al., 2020), ultimate DoC of hydrates depends strongly on the relative humidity. In our study, several reasons can be given to explain the lower degrees of carbonation in unsheltered conditions. First, it can be due to the sampling of powder at the specimen surface, especially in the case of Ref I, Ref II, FA 30 and S 30. The specimen skin not protected from rain was slightly degraded, probably due to leaching. It is therefore more difficult to have a precise determination of DoC at the specimen surface. It should be kept in mind that the carbonation depths determined for most of unsheltered specimens were low (around 5 mm)

1 and the profiles of bound CO₂ content rather sharp. Second, the oceanic climate of La
2 Rochelle (France) is windy. Rapid and frequent drying due to sunshine and wind, followed by
3 relatively short but heavy rainfall periods, could reduce the water content within the
4 carbonated zone, which could slightly hamper the carbonation reactions. The water content
5 however remains enough for slowing down the progress of the carbonation front. Under
6 sheltered conditions, with an acceptable relative humidity of the environment, the concrete
7 pore network remains partially saturated, perhaps even in equilibrium, which favors the
8 carbonation reactions (Houst et al., 2002; Leeman et al., 2015; Ekolu, 2016). Third, the
9 average temperatures of both exposure sites were not the same. The average temperature for
10 the sheltered specimens was about 5°C higher and the temperature range narrower (Table 3).
11 Although the influence of temperature on carbonation is difficult to understand because of
12 contradictory effects on the involved mechanisms, it is recognized that carbonation rate
13 increases when temperature increases, e.g., (Drouet et al., 2019). Finally, both exposure
14 conditions used in the present study could lead to substantially equal degrees of carbonation.
15 By way of comparison, note that Standard EN 16575 proposes close DoC values for the two
16 types of exposure, i.e., 75% for sheltered condition and 80% for unsheltered one.
17 The nature of binder is also a parameter which has a huge effect on the degree of carbonation.
18 It clearly appears that concretes with a high substitution of clinker by GGBFS, i.e., Ref III and
19 S 75, have much lower DoC, as defined by Equation 13, despite their higher carbonation
20 depths. There is no relationship between the carbonation depth, determined by means of a pH
21 indicator, and the degree of carbonation (Omikrine-Metalssi et al., 2009; Andrade, 2020).
22 Ref III and S 75 exhibit the lowest average bound CO₂ contents although their CaO contents
23 are close to those of FA 30 and Ref I, respectively (Table 2). To better understand this
24 tendency, the degrees of carbonation were also calculated assuming that only calcium oxide
25 from clinker can be carbonated. This approach is proposed by EN 16757, i.e., U_B is taken

1 equal to U_K . Fig. 8 shows the difference between U_K from EN 16757 and U_B calculated with
 2 the entire CaO content of the binder (Eq. 14). The highest differences are for mixtures with
 3 GGBFS. In the case of mixtures with fly ash, i.e., Ref II and FA 30, U_K and $\%CO_2max$ are
 4 almost equal because of the very low CaO content of fly ash.
 5

6
 7
 8 **Fig. 8.** Maximum theoretical bound CO_2 content as per the definition of this study (U_B) *versus*
 9 values obtained using EN 16757 (U_K).

10
 11 In Figure 7 (right), the degrees of carbonation so obtained for the mixtures with GGBFS are
 12 much higher, and even higher than 100% (i.e., losing the physical sense of this parameter), as
 13 shown by Andrade (Andrade, 2020). This result highlights that a part of the calcium oxides
 14 supplied by GGBFS contributes to the uptake of CO_2 . To assess the degree of carbonation of
 15 the calcium oxide from slag, the global DoC, as defined previously in Equation 13, was
 16 rewritten as follows:

$$17 \quad DoC = 100 \frac{\%CO_2}{U_B} = 100 \frac{U_K \cdot DoC_K \cdot \%K + U_S \cdot DoC_S \cdot \%S}{U_B} \quad (15)$$

18

1 Where: U_i is the maximal content of CO_2 bound by CaO of the constituent i , DoC_i is the
2 degree of carbonation of the constituent i , and $\%i$ is the content of i in the binder. K and S
3 denote clinker and slag, respectively. U_i is calculated with the CaO content in the constituent
4 i , (Equation 14).

5 In Equation 15, all parameters, except DoC_S , are known if we assume that DoC_K is equal to
6 the degree of carbonation found for Ref I, i.e., the mixture made with a Portland cement.
7 Calculated values of DoC_S are given in Table 5. These values are only rough estimations due
8 to the high standard deviations obtained for DoC . These orders of magnitude show that the
9 degree of carbonation of CaO from slag is much lower than that of CaO from clinker, but not
10 negligible, except in unsheltered conditions. Our estimations confirm recent results of (Saillo
11 et al, 2021) obtained from an in-depth study of the mineral changes in cement pastes due to
12 carbonation. The authors show that calcium from slag is less carbonatable than that of clinker.
13 Moreover, a large amount of slag can remain unreacted even after a long-term water curing. In
14 our case, the specimens were removed from the mold after 1 day and exposed to drying, what
15 strongly disadvantages hydration (Younsi et al., 2019). From our data, it remains however
16 difficult to propose a single empirical value to predict the degree of carbonation of slag.
17 Moreover, the combination of CO_2 with the cementitious elements is undoubtedly more
18 complex than a simple separation of the binding capacity of CaO as a function of the
19 constituent origin as proposed by Equation 15. The mineral assemblages of Portland cement
20 and that of binders with GGBFS are quite different. GGBFS promotes calcium silicate
21 hydrate (C-S-H) with lower Ca/Si ratio than that of Portland cement. Through experimental
22 observations, (Steiner et al., 2020) confirms that the carbonation rate and the CO_2 binding
23 capacity of C-S-H decreases with the Ca/Si ratio.

24

25 **Table 5**

- 1 Calculated degrees of carbonation: degree as defined in Eq. 15 (DoC), degree of CaO from
- 2 Ref I binder (DoC_K) and degree of CaO from slag (DoC_S).

	Sheltered conditions			Unsheltered conditions		
	S 30	Ref III	S 75	S 30	Ref III	S 75
DoC (%)	72	56	50	47	42	25
DoC _K (%)	83	83	83	72	72	72
DoC _S (%)	31	48	32	~0	40	~0

3

4 4.2. CO₂ uptake

5

6 To analyze the CO₂ uptake of the studied specimens, the results obtained for mixture Ref I

7 made with the high clinker content are used as reference values for comparison. The relative

8 differences in CBC, X_c and CO₂ uptake are given in Figure 9. There is no clear correlation

9 between the CO₂ binding capacity of the material and the CO₂ uptake of the specimen. For

10 instance, Ref III has high relative differences in CBC (-50%) but CO₂ uptakes rather close to

11 the uptake of Ref I (relative differences lower than 20%). In fact, as shown also in Figure 9,

12 the relative differences in carbonation depth of Ref III are very high. For this concrete, the

13 high carbonation depths partly compensate the lower binding capacity. A similar analysis can

14 be made for Ref II, FA 30, S 30 and S 75.

15

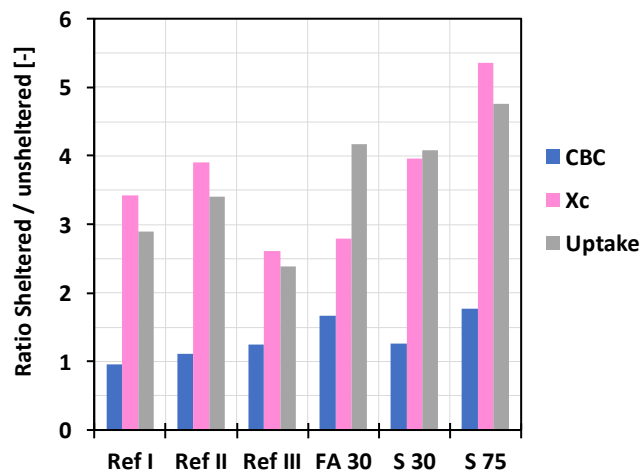

16

1 **Fig. 9.** Relative differences in CO₂ binding capacity (CBC), carbonation depth (X_c) and CO₂
 2 uptake between Ref I and other studied concretes, for sheltered (left) and unsheltered (right)
 3 exposure conditions after 10 years of natural carbonation.

4
 5 To highlight the effect of exposure, the results from experiments are presented differently in
 6 Figure 10. The latter gives the ratios of values for sheltered conditions and values for
 7 unsheltered ones. These ratios are between 1 and 1.8 for CO₂ binding capacity while they are
 8 much higher for carbonation depth and CO₂ uptake. This means that CBC is much less
 9 impacted by the exposure for all studied materials, than X_c and CO₂ uptake. Once again, the
 10 role of X_c is decisive for the CO₂ uptake at the specimen scale.

11

12

13 **Fig. 10.** Effect of exposure conditions on CO₂ binding capacity (CBC), carbonation depth
 14 (X_c) and CO₂ uptake: ratios of values for sheltered conditions and values for unsheltered ones.

15

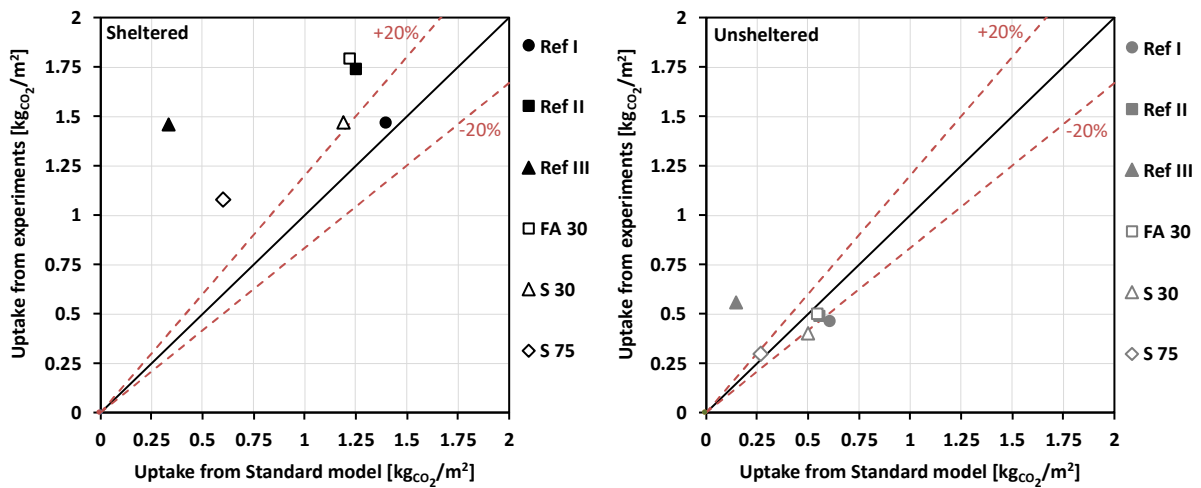

16 *4.3. Comparison with prediction of EN 16757 model*

17

18 Figure 11 compares the CO₂ uptakes obtained experimentally and values calculated using the
 19 Standard EN 16757 model. The latter underestimates the uptake in sheltered conditions with

1 errors of at least 20% for most of concretes. The prediction is good only for Portland cement-
 2 based concrete, i.e., Ref I. The predictions are better for unsheltered concretes with errors
 3 lower than 20%, apart for Ref III whose predicted uptake is 3 times lower than that from
 4 experiments. To understand the differences between experimental and computed values,
 5 analysis can be made as previously, i.e., in terms of CBC and X_c .

6

7

8

9 **Fig. 11.** CO₂ uptakes calculated from experimental data *versus* values calculated as per
 10 EN 16757: sheltered (left) and unsheltered conditions (right).

11

12 Figure 12 shows that the standard model tends to overestimate the binding capacities of
 13 concrete for unsheltered conditions, except for Ref III. The wrong estimation of CBC results
 14 from errors in degree of carbonation (DoC) and theoretical bound CO₂ content (U_B). In the
 15 case of concrete with high clinker content (Ref I, Ref II, FA 30 and S 30), the latter is
 16 correctly computed by the model, because U_B is equal to U_K (Fig. 8). Thus, the main error
 17 comes from DoC which is significantly lower from experiments than from the model (see
 18 section 4.1). In the case of Ref III, both DoC and U_B used by the model are not correct.
 19 Standard DoC (75 or 80%) is higher than experimental DoC (around 50%) and U_B is taken

1 equal to U_K considering that only calcium oxides from clinker can be carbonated, while, as
 2 shown previously, a part of CaO from slag also binds CO_2 . However, the overestimation of
 3 DoC compensates partly the underestimation of U_B . Globally, the differences in CBC between
 4 experiments and model for Ref III are lower than the differences in CO_2 uptake.
 5

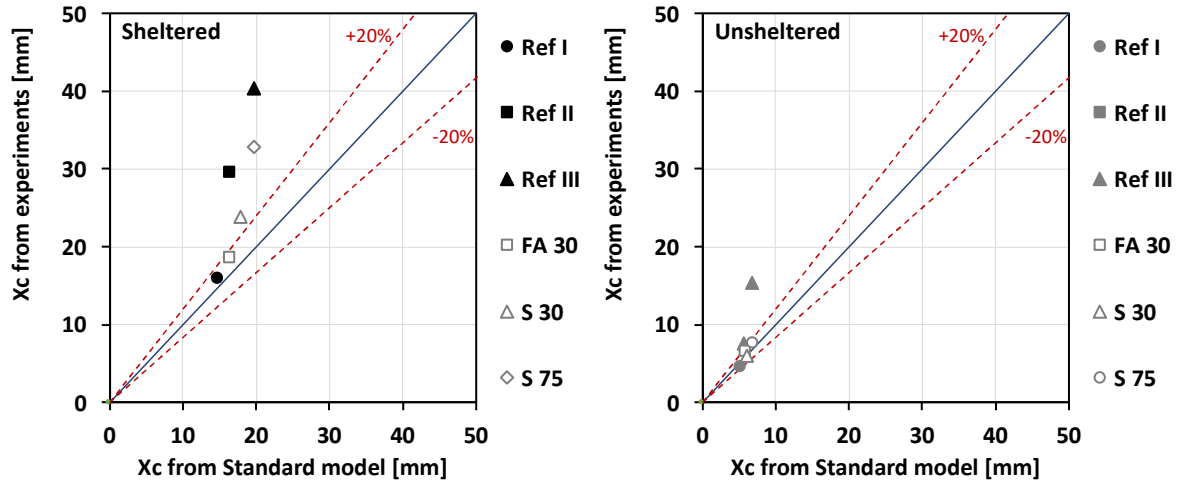

6
 7
 8 **Fig. 12.** CBC from experiments *versus* values calculated as per EN 16757: sheltered
 9 conditions (left) and unsheltered conditions (right).

10
 11 As revealed by Figure 13, lot of the difference between experimental and computed values
 12 come from the underestimation of the carbonation depth by the model. Especially, for
 13 sheltered conditions, the model error is high for most of concretes. Prediction is good only for
 14 the Portland cement concrete. The model accuracy is better for the unsheltered conditions,
 15 apart for Ref III.

16 Finally, these analyses show that efforts to improve predictions of CO_2 uptake should focus
 17 primarily on the carbonation rate, which is not predicted with sufficient accuracy for
 18 concretes with low clinker content. As suggested by Andrade (Andrade, 2020), adjustments
 19 per country for the carbonation rate should be proposed because of the diversity of cements

1 used and exposure conditions. Another solution could be the extrapolation of the carbonation
 2 rate from results of accelerated carbonation tests, as proposed in models for service life
 3 design, e.g. (fib, 2006).

4

5

6

7 **Fig. 13.** Carbonation depths from experiments *versus* values as per EN 16757: sheltered
 8 conditions (left) and unsheltered conditions (right).

9

10 5. Conclusions

11

12 An experimental study of CO₂ uptake after 10 years natural carbonation was carried out on
 13 concretes designed with Portland cement (OPC), blended cements containing fly ash (FA) or
 14 ground granulated blast furnace slag (GGBFS) and partial substitutions of OPC with FA
 15 (30 %) or GGBFS (30 and 75 %). These concretes were designed to have equivalent strengths
 16 at early age and 28 days. 1 day after casting, concrete cylinders were subjected to a 10-year
 17 natural carbonation, under sheltered and unsheltered conditions. The CO₂ uptake, i.e., the
 18 bound CO₂ content per m² of exposed surface, was determined from profiles of bound CO₂
 19 obtained by TGA and chemical analyses. The main conclusions are the following.

- 1 • 10-year natural carbonation monitoring shows that the concretes with cement substitution
2 with fly ash or GGBFS have carbonation depths close to those of concretes with blended
3 cements containing the same additions. Thus, their potential durability is at least
4 equivalent to that of the latter. This confirms prediction from previous studies based on
5 accelerated carbonation tests.
- 6 • The concretes kept in sheltered conditions have higher CO₂ uptake than in unsheltered
7 conditions. In sheltered conditions, the CO₂ uptake was between 1.1 and 1.8 kg/m² (of
8 exposure area) while in unsheltered ones it was between 0.3 and 0.6 kg/m², depending on
9 the concrete mixture. This is mainly due to the deeper ingress of CO₂ when concrete is
10 sheltered from rain and remains under more stable moisture conditions.
- 11 • The CO₂ binding capacity, i.e., the bound CO₂ content in the carbonated depth, was found
12 lower in the rainy conditions than in the sheltered one, what was somewhat unexpected
13 with respect to literature. This tendency could be due to differences in parameters such as
14 temperature or drying rate between both exposure conditions. The following conclusions
15 are the same whatever the exposure conditions.
- 16 • CO₂ binding for concretes with high content of GGBFS consumes calcium oxides from
17 both clinker and GGBFS. However, the degree of carbonation of CaO from GGBFS is
18 much lower than the degree of carbonation of CaO from clinker. The low Ca/Si ratio of C-
19 S-H produced by hydration of GGBFS and poor hydration degree of GGBFS could
20 explain this finding. As a result, the CO₂ binding capacity is up to two times lower for the
21 concretes with high content of GGBFS than for the other studied concretes.
- 22 • No correlation was found between the CO₂ binding capacity of the material and the CO₂
23 uptake of the specimen. Concretes with the lowest CO₂ binding capacity have also the
24 highest carbonation depth. Since the CO₂ uptake can be assessed as the product of the CO₂
25 binding capacity and the carbonation depth determined from pH change (accounting for

1 the structure geometry), a low CO₂ binding capacity can be partly compensated by a high
2 carbonation depth.

- 3 • The model from the Annex BB of the European Standard EN 16757 underestimates the
4 CO₂ uptakes, especially for concretes under sheltered conditions and concretes with high
5 content of GGBFS. The predictions were found correct mainly for the OPC concrete. The
6 wrong estimation of the CO₂ uptake comes from wrong estimation of the CO₂ binding
7 capacity but, above all, from misestimation of the carbonation depth.

8 Based on these results, some adjustments of the European Standard EN 16757 could be
9 proposed to better assess the CO₂ uptake, especially for concretes with high GGBFS content.

10 In terms of carbonation rate, the adjustment factors defined by the standard to account for the
11 effect of mineral additions should be increased. In the design phase of a project, the
12 carbonation rate could be deduced from accelerated carbonation test, rather than assessed
13 from tabulated values. In terms of CO₂ binding capacity of concrete with high GGBFS
14 content, two approaches could be suggested. First, the CO₂ binding capacity can be calculated
15 considering only CaO from clinker and high degree of carbonation, as proposed in the present
16 model. This approach leads to an underestimation of the binding capacity, which could be
17 viewed as a “safety approach”. Second, the CO₂ binding capacity could be calculated more
18 realistically considering all the CaO from the binder, but with degree of carbonation at least
19 two times lower than that proposed currently. Further in-deep research is needed to better
20 define the degree of natural carbonation of hydrates produced by GGBFS.

21 Also, for a better representativeness, this study should be extended to concretes from old
22 real structures but including different types of binders.

22

23 **Appendix – Calculation of the time-evolution of the carbonation depth in cylindrical** 24 **geometry**

25

1 First, let us recall how we obtain the time-evolution of the carbonation depth in axial
2 geometry (i.e., the “classic” square-root of time model).

3 Several assumptions were made:

4 - The main parameters, i.e., the gaseous CO₂ diffusion coefficient (D), the content of
5 carbonatable compounds in concrete (n_c) and the ambient concentration of CO₂ (C₀),
6 were assumed to be constant.

7 - The chemical reactions were assumed to be much faster than the gas diffusion. As a
8 result, the carbonation front progresses only when all the carbonatable compounds at
9 the front are consumed. The front separates two zones, a “completely” carbonated
10 zone where CO₂ diffuses and, more in depth, a non-carbonated zone where the
11 concentration of CO₂ is null.

12 In the carbonated zone, the Fick’s second law can be applied:

13

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial x^2} \quad (\text{A.1})$$

14

15 Where: C is the concentration of gaseous CO₂ at time t and depth x.

16 Due to the second assumption, the time variation of the concentration of CO₂ is very small
17 ($\partial C/\partial t \approx 0$). Thus, the profile of C is a linear function of the depth x:

18

$$C = C_0 \left(1 - \frac{x}{x_c}\right) \quad (\text{A.2})$$

19

20 Where: x_c is the carbonation depth.

21 At the carbonation front, the amount of CO₂ diffusing through a surface S during a time dt is
22 consumed by the carbonatable compounds in an elementary volume dV = Sdx_c:

1

$$-SD \frac{\partial C}{\partial x} dt = n_c dV \quad \Leftrightarrow \quad D \frac{C_0}{n_c} dt = x_c dx_c \quad (\text{A.3})$$

2

3 By integrating Equation (A.3), the time evolution of the carbonation depth can be written as:

4

$$X_c = \sqrt{\frac{2DC_0}{n_c}} \sqrt{t} \quad (\text{A.4})$$

5

6 In the case of a cylindrical geometry with a radial diffusion, the previous model cannot be

7 applied because the Fick's second law takes a different form:

8

$$\frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial r^2} + \frac{D}{r} \frac{\partial C}{\partial r} \quad (\text{A.5})$$

9

10 Where r is the radial location, so as $r = R - x$, with R is the radius of the cylinder.11 With the same assumption than previously (very small time-variations), the profile of CO_2 12 concentration as a function of x can be written as a function of the depth x :

13

$$C = C_0 \left(\frac{\ln(R - x) - \ln(R - x_c)}{\ln(R) - \ln(R - x_c)} \right) \quad (\text{A.6})$$

14

15 Then, from the equality of the diffusing and the consumed amounts of CO_2 :

16

$$-SD \frac{\partial C}{\partial x} dt = n_c dV \quad \Leftrightarrow \quad D \frac{C_0}{n_c} dt = (R - x_c) (\ln(R) - \ln(R - x_c)) dx_c \quad (\text{A.7})$$

17

1 By integrating Equation (A.7), we establish the following relationship between carbonation
2 depth and time:

$$D \frac{C_0}{n_c} t = -\frac{X_c^2}{4} - \ln(R) \frac{X_c^2}{2} + \ln(R - X_c) \frac{(R - X_c)^2}{2} + R \ln(R) X_c + R \frac{X_c}{2} + \frac{R^2 \ln(R)}{4} \quad (\text{A.8})$$

4
5 Equation (A.8) can be solved numerically to determine X_c at a given time t . The left-hand side
6 parameter DC_0/n_c can be deduced from empirical models giving X_c as a function of the
7 square-root of time (axial geometry), such as the model from standard EN16575:

$$X_c = A\sqrt{t} \quad (\text{A.9})$$

9
10 From Equation (A.4), DC_0/n_c is thus equal to $A^2/2$.

11
12 Figure A.1 compares results obtained for both geometries, i.e., axial and cylindrical:
13 carbonation depths (related to the cylinder radius R) as a function of time from Equation A.4
14 and A.8, respectively. These results were obtained for a cylinder of 55 mm in radius, a CO_2
15 concentration of 500 ppm ($2.10^{-2} \text{ mol/m}^3$), a diffusion coefficient of $5.10^{-7} \text{ m}^2/\text{s}$ and a
16 concentration of carbonatable compounds of 1000 mol/m^3 . The difference between values
17 from both geometries remains small when the carbonation depth X_c is lower than 40% of the
18 specimen radius, i.e., 22 mm for the present example. Beyond this ratio, the use of Equation
19 A.6 is necessary to calculate the time-evolution of X_c for a radial carbonation, instead of the
20 classical square-root of time model (with the same assumption than the latter, e.g., a constant
21 DC_0/n_c).

22

1
2 **Fig. A.1.** Comparison of calculated values for axial and cylindrical geometries: ratio between
3 carbonation depth and radius versus square root of time (left) and absolute error versus the
4 ratio for the cylindrical geometry (right). Calculations were done using data given in the text.
