Abstract

Distributed Denial of Service (DDoS) cyberattacks represent a major security risk for network operators and internet service providers. They thus need to invest in security solutions to protect their network against DDoS attacks. The present work focuses on deploying a network function virtualization based architecture to secure a network against an on-going DDoS attack. We assume that the target, sources and volume of the attack have been identified. However, due to 5G network slicing, the exact routing of the illegitimate flow in the network is not known by the internet service provider. We seek to determine the optimal number and locations of virtual network functions in order to remove all the illegitimate traffic while minimizing the total cost of the activated virtual network functions. We propose a robust optimization framework to solve this problem. The uncertain input parameters correspond to the amount of illegitimate flow on each path connecting an attack source to the target and can take values within a predefined uncertainty set. In order to solve this robust optimization problem, we develop an adversarial approach in which the adversarial sub-problem is solved by a Branch & Price algorithm. The results of our computational experiments, carried out on medium-size randomly generated instances, show that the

Email addresses: celine.gicquel@lri.fr (Céline Gicquel), vanier@lix.polytechnique.fr (Sonia Vanier) proposed solution approach is able to provide optimal solutions within short computation times.

1 1. Introduction

Distributed Denial of Service (DDoS) attacks are among the top threats 2 to network operators and internet service providers (ISPs). A distributed 3 denial of service is a type of cyberattack in which multiple compromised 4 computer systems attack a target, such as a server or a website, and cause 5 a denial of service for its legitimate users. DDoS flooding attacks are often 6 launched through the use of botnets. A botnet is a network of user computers or Internet of Things (IoT) devices that are remotely controlled by a hacker 8 through malwares. Under the direction of the hacker, an army of botnets 9 can launch a DDoS attack against a target by simultaneously sending to it a 10 large amount of traffic or service requests. The flood of incoming messages, 11 connection requests or malformed packets exhausts the resources of the target 12 and forces it to slow down or even shut down, thereby preventing it to provide 13 service to its legitimate users. 14

In recent years, the number, intensity and diversity of DDoS attacks have 15 increased dramatically. Thus, in 2016, the BBC website was targeted by a 16 DDoS attack of more than 600 Gbps and was unavailable for a few hours 17 (Khandelwal, 2016). More recently, Amazon announced that its AWS Shield 18 service mitigated a 2.3 Tbps DDoS attack in February 2020 (AWS, 2020). 19 There is also a continuous appearance of new attack vectors, i.e. new tech-20 niques enabling hackers to launch a DDoS attack, and new combinations of 21 attack vectors: see e.g. the recent report provided in (Netscout Systems, 22 2020) and (FBI, 2020). This trend is likely to continue and even accentu-23 ate in the near future. Namely, with the development of the Internet of 24 Things, systems based on smart devices (such as sensors) connected to the 25 Internet are widely deployed. This increases the vulnerability of networks 26 and the number of potential DDoS targets: see among others Rahimi et al. 27 (2018), Akpakwu et al. (2018), Fysarakis et al. (2016) and Silva et al. (2020). 28 Furthermore, as mentioned e.g. by Grawe (2020), the COVID-19 pandemic 29

has forced organizations to accelerate their digital transformation plans, thus
 further increasing the attack surface for hackers and criminals.

DDoS attacks can be very damaging for the organization they target. For 32 instance, a survey carried out in 2017 by the cybersecurity company Kapersky 33 Lab estimated the average cost of a DDoS attack for large (1000+) businesses 34 to be around \$2.3 millions (Berard, 2018). This cost mainly comprises the 35 cost incurred in fighting the attack and restoring service, the investment in 36 an offline or back-up system while online services are unavailable, the loss of 37 revenue or business opportunities and the loss of trust from customers and 38 partners. 39

Many DDoS mitigation solutions have been proposed to protect organi-40 zations' networks, servers and services. The traditional approach consists in 41 deploying specialized hardware security appliances that are fixed in terms of 42 strength, functionality and capacity. This means in particular that the loca-43 tion and capacity (in terms of the volume of malicious traffic it can process) 44 of the defense appliances are determined in advance, before the DDoS attacks 45 actually take place. As explained e.g. by Fayaz et al. (2015), companies are 46 thus forced to over provision by deploying appliances capable of handling a 47 high but predefined volume of attack at several points in the network. A 48 second approach consists in using an external cloud-based DDoS protection 49 service. In this case, when under attack, all the incoming traffic to the tar-50 geted service is diverted towards a cloud scrubbing center managed by a third 51 party. In the scrubbing center, the traffic is inspected and only the legitimate 52 traffic is routed back towards its destination. These cloud-based services are 53 more flexible and scalable than dedicated hardware appliances. They how-54 ever raise concerns relative to customers' privacy violation and often lead to 55 increased latency (Alharbi and Aljuhani, 2017). 56

Network Function Virtualization (NFV) is a recent network architecture 57 concept in which network functions (e.g. network address translation, fire-58 walling, domain name service, etc.) are implemented as software and de-59 ployed as virtual machines running on general purpose commodity hardware 60 (Jakaria et al., 2016). Virtualization increases manageability, reliability and 61 performance of the network and allows a flexible and dynamic implemen-62 tation of the network services, which significantly reduces the cost of the 63 infrastructure and simplifies the deployment of new services. These numer-64 ous benefits have convinced operators to largely embrace virtualization of 65 network functions: see e.g. Donovan (2014) and Savi (2018). 66

⁶⁷ NFV offers new possibilities to counter DDoS attacks. In particular, its

flexibility and reactivity allows to postpone the DDoS defense deployment after the attack is detected. This allows to place adapted defense mechanisms where they are needed and to launch them depending on the scale of the attack (Fayaz et al., 2015). Moreover, NFV-based mitigation approaches do not require the use of an external service provider, which reduces the privacy and latency issues encountered by cloud-based DDoS mitigation.

As mentioned e.g in Alharbi and Aljuhani (2017), Silva et al. (2020) 74 and Jakaria et al. (2016), NFV is a promising technology to mitigate DDoS 75 attacks. However, in order to fully leverage its potential, some difficulties 76 should be overcome. First, virtual network functions (VNFs) are instan-77 tiated on virtual machines. These virtual machines consume the limited 78 computing resources (CPU, memory,...) of the servers on which they run. 79 When designing an NFV-based infrastructure to counter an on-going DDoS 80 attack in a network, these limitations in the available computing resources 81 should be taken into account. The number of VNFs which can be instan-82 tiated at each node of the network depends on the resources of the servers 83 located at this node. Second, each VNF has a limited filtering capacity and 84 can thus remove only part of the attack flow. The filtering capacity of a VNF 85 corresponds to the maximum amount of malicious flow an instance of this 86 VNF can stop. If the malicious flow going through a VNF is larger than its 87 filtering capacity, the excess malicious flow is forwarded in the network and 88 may thus reach its target. This translates into the fact that, in order to stop 80 all the malicious traffic of an attack, several VNFs may have to be placed at 90 different nodes on the paths used to route the flow between its source and its 91 target. A carefully optimized VNF placement strategy taking into account 92 both the limited computing resources in the network and the limited filtering 93 capacity of a VNF is thus needed. 94

In the present work, we focus on the deployment of an architecture based on the NFV technology to secure a network against DDoS attacks. We assume that the on-going attack has been detected and that its ingress points, its volume and its target have been identified. Based on this information, we seek to determine the optimal number and location of VNFs in order to remove all the illegitimate traffic while trying to minimize the total cost of the activated VNFs.

We take here the perspective of an internet service provider (ISP) aiming at providing a DDoS mitigation service to its customers in a 5G network. Among the key features of 5G networks is network slicing: see e.g. Vyakaranam and Krishna (2018). Network slicing is an architecture in which

Figure 1: 5G network slicing

the physical network infrastructure managed by an ISP is partitioned into 106 multiple virtual independent networks termed slices. Each slice is an iso-107 lated end-to-end network which is lent by the ISP to a single customer and 108 is adapted to meet the specific requirements of this customer in terms of 109 quality of service (bandwidth, reliability, latency, etc.). See Figure 1 for a 110 graphical illustration of 5G network slicing. Network slicing thus provides 111 an opportunity to the ISP to flexibly configure its physical network so as 112 to simultaneously fulfill quality-of-service requirements that may strongly 113 vary from one customer to the next. However, on each slice of the network, 114 the routing of the flow will not be managed anymore by the ISP but by its 115 customer which will rely on its own proprietary routing algorithms. This 116 significantly enhances the difficulty for the ISP of providing a DDoS mitiga-117 tion service as it will not control the exact routing of the malicious flow that 118 needs to be stopped. 119

Our main contributions are thus threefold. First, we present a robust op-120 timization (RO) model to optimally design an NFV-based DDoS mitigation 121 infrastructure in the context of 5G network slicing. This model explicitly 122 takes into account the fact that the ISP is not aware of the exact routing 123 of the attack flow. This is done by considering the malicious flow routing 124 as an input parameter of the optimization problem which is subject to un-125 certainty. To the best of our knowledge, this is the first time such a robust 126 optimization model is investigated to design a DDoS mitigation infrastruc-127 ture in 5G networks. Second, we propose an efficient algorithm to solve 128 the robust optimization problem. This algorithm relies on an adversarial 129 approach which decomposes the problem into a master problem and an ad-130 versarial sub-problem. The master problem seeks to optimally place the 131

filtering VNFs while taking into account a limited number of possible mali-132 cious flow routings. The adversarial sub-problem aims at finding the worst 133 flow routing for a given VNF infrastructure and is used to generate new rout-134 ings, i.e. new constraints, to be taken into account in the master problem. 135 Moreover, as the adversarial sub-problem involves an exponential number 136 of decision variables, we develop a Branch & Price algorithm to solve it in 137 a computationally efficient way. Third, we provide the results of computa-138 tional experiments carried out on medium-size randomly generated instances. 139 These results show that the proposed solution algorithm is able to efficiently 140 provide optimal or near-optimal solutions within short computation times. 141

The paper is organized as follows. We first review the related literature in Section 2. We then provide in Section 3 a formal description of the problem, discuss its modeling as a robust optimization problem and present a complexity analysis. We describe in Section 4 the adversarial solution approach proposed to solve this RO problem. Numerical results carried out on medium-size randomly generated instances are provided in Section 5. Finally, Section 6 gives a conclusion and some research perspectives.

¹⁴⁹ 2. Related works

We provide in this section a brief overview of the works closely related to 150 ours. We first discuss papers proposing NFV-based infrastructures for DDoS 151 mitigation. We then consider papers dealing with the optimal placement 152 of virtual network functions in a network for generic cases and focus on 153 two recent works studying the optimal placement of VNFs in a network for 154 the specific case of DDoS mitigation. Finally, we review the literature on 155 the network flow interdiction problem as this problem shares some common 156 features with our problem. 157

¹⁵⁸ 2.1. NFV-based infrastructures for DDoS mitigation

NFV-based infrastructures to counter DDoS attacks are investigated in 159 several recent papers. Fung and McCormick (2015) propose a solution based 160 on request prioritization to protect an online application server from a DDoS 161 attack. The incoming requests to the servers are categorized into two pri-162 ority levels: requests from trusted sources are assigned a high priority and 163 are guaranteed to be served whereas requests from untrusted sources are as-164 signed a low priority and will be served based on the resource availability 165 on the server. The proposed architecture makes use of a VNF for priority 166

assignment and flow dispatching. Another widely used mitigation strategy 167 against DDoS attacks is flow filtering: see e.g. Silva et al. (2020). Basically, 168 flow filtering consists in analyzing the information contained in the headers 169 of the data packets to block the malicious flow. The filtering process thus 170 exploits information such as the source and destination IP addresses, the 171 origin and destination ports or the network layer protocol to identify mali-172 cious packets and drop them. Jakaria et al. (2016), Rashidi et al. (2018) and 173 Jakaria et al. (2019) investigate a DDoS mitigation framework in which this 174 filtering process is carried out by VNFs which are dynamically allocated as 175 needed depending on the volume of the attack. More precisely, their frame-176 work aims at protecting an online product server against a specific type of 177 DDoS attacks, termed SYN floods, which exploit some weak points of the 178 TCP internet protocol. This framework involves a dispatcher/load balancer 179 which receives the incoming packets from the internet and distributes them 180 to filtering VNFs instantiated on commodity servers. These VNFs verify 181 the source IP address of each packet, drop the packet in case it is illegiti-182 mate or forward it to the product server in case its source is white-listed. 183 Finally, Fayaz et al. (2015) and Alharbi and Aljuhani (2017) propose DDoS 184 mitigation infrastructures in which VNFs may have a variety of functions 185 depending on the type of the attack. 186

187 2.2. Optimal placement of virtual network functions

In their survey on network function placement, Li and Qian (2016) distin-188 guish between two types of placement problems. The first one corresponds 189 to the case where independent network functions, i.e. functions which do 190 not interact with one another, should be placed in the network. The second 191 one, called service chaining, applies when each flow must traverse a prede-192 fined sequence of network functions (such as firewall \rightarrow intrusion detection 193 system \rightarrow proxy) between its ingress point and its destination point in the 194 network. Note that the problem under study in this work belongs to the 195 first type of problem as we consider a single type of network functions. We 196 refer the reader to Demirci and Sagiroglu (2019) for a general overview of the 197 literature on the optimal placement of virtual network functions and focus 198 in what follows on the specific context of DDoS mitigation. 199

To the best of our knowledge, there are only two works dealing with the problem of optimally placing VNFs in a network to counter an on-going DDoS attack. Fayaz et al. (2015) develop the Bohatei system based on NFV and SDN (software-defined networking). Their system includes a resource

manager which determines the type, number and location of VNFs to be 204 instantiated based on the available information on the ingress points, tar-205 get, type and volume of the on-going attack so as to minimize the costs 206 related to the malicious flow traffic. They consider a case in which the mit-207 igation of each type of DDoS attack (e.g. SYN food, DNS amplification 208 or UDP flood) is a multi-step process requiring the use of different types 209 of network functions. They formulate the underlying optimization problem 210 as a mixed-integer linear program and solve it using a two-step heuristic. 211 Jakaria et al. (2019) consider an architecture involving two types of VNFs, 212 namely dispatchers and filtering agents, to counter SYN flood attacks. They 213 deploy these VNFs through virtual machines running on commodity servers. 214 The objective is to process all the incoming traffic while using a minimum 215 number of commodity servers. Their mathematical model is formulated as 216 a constraint satisfaction (SAT) problem (Apt, 2003). It takes into account 217 the limited computing resources of each commodity server, the limited band-218 width of the links between the dispatchers and the filtering agents and the 219 relation between the packet filtering rate of a VNF and the computing re-220 sources allocated to the virtual machine on which it is instantiated. Note 221 that, contrary to the problem under study here, both Fayaz et al. (2015) and 222 Jakaria et al. (2019) assume in their problem modeling that the flow of the 223 attack, once detected, can be flexibly routed towards the launched virtual 224 machines. 225

226 2.3. Network flow interdiction problem

In the network flow interdiction problem, an attacker and a defender take 227 measurements on a capacitated network. The defender seeks to maximize 228 the flow through the network, while the attacker suppresses some arcs to 229 minimize the maximum flow. Each arc has a removal cost. Thus, the goal 230 for the attacker is to select a subset of arcs to remove without exceeding 231 a fixed budget. The network interdiction problem is known to be an NP-232 complete problem: see Phillips (1993) and Wood (1993). However, it can 233 be solved in polynomial time for certain categories of graphs such as planar 234 graphs (Phillips, 1993; Wollmer, 1964). 235

Different classes of the network flow interdiction problem are studied in the literature: see e.g. Church et al. (2004). Baffier et al. (2018) investigate an adaptive network interdiction flow problem. The defender aims to maximize the flow value and the attacker seeks to minimize the remaining flow value by removing a set of k links. The goal is to find a robust flow

against any k edge attack. A bilevel optimization framework is developed 241 to address this problem. Naoum-Sawaya and Ghaddar (2017) also formu-242 late the problem as a bi-level mixed-integer program. An iterative cutting 243 plane algorithm is proposed and implemented in a branch-and-cut approach. 244 Lim and Smith (2007) study problems with discrete and continuous inter-245 dictions. They describe a linearized model to optimize the discrete network 246 interdiction problem and compare it to a penalty model. For the continuous 247 case, they describe an optimal partitioning algorithm as well as a heuristic 248 procedure to estimate the optimal value of the objective function. Alther 240 et al. (2010) propose two classes of polynomially separable valid inequalities 250 for the Maximum Flow Network Interdiction Problem. An approximation 251 factor-preserving reduction from a simpler interdiction problem is also devel-252 oped. Lei et al. (2018) consider maximum flow interdiction problem under 253 interdiction-effect uncertainties. The problem is characterized as a Stack-254 elberg game. They consider risk-neutral and risk-averse behaviors of the 255 two players. Five bi-level/tri-level programming models for different risk-256 preference combinations are investigated. An application of the network 257 interdiction problem to security issues is studied by Guo et al. (2016). The 258 problem is to optimally interdict illegal network flow in the context of the 259 containment of the flow of drugs through the US-Mexico border patrol. A 260 Stackelberg game model for network interdiction flow with a single source-261 destination flow is presented. The proposed solution approach is based on 262 column generation and constraint generation algorithm. Fu and Modiano 263 (2019) propose a new paradigm for network interdiction that models sce-264 narios. The interdiction is performed through injecting bounded-value flows 265 to maximally reduce the throughput of the residual network. They study 266 two problems under the paradigm: deterministic flow interdiction and ro-267 bust flow interdiction. An algorithm with logarithmic approximation ratio is 268 developed. 260

Note that the present works investigates a defender-attacker problem 270 which significantly differs from the network flow interdiction problem. Namely, 271 in our case, the defender, i.e. the internet service provider, allocates secu-272 rity resources without changing the network topology. Virtual functions are 273 deployed on network nodes in order to suppress attacking flows but this 274 security mechanism does not remove any component (node or link) in the 275 network. Our goal is to minimize the costs of VNFs deployment while grad-276 ually eliminating the malicious flows, rather than destroying links to prevent 277 the attacker from reaching its target. This implies significant differences in 278

the mathematical formulations of the problem. The methodologies proposed in the existing works can therefore not be directly applied to our problem.

²⁸¹ 3. Problem description and mathematical modeling

In this section, we first describe in a more formal way the optimization problem under study and present the proposed robust optimization model. We then provide a small illustrative example. Finally, we discuss the use of aggregated filtering constraints in the problem formulation and study its complexity status.

287 3.1. Problem definition

The network topology is modeled by a digraph $\mathcal{G} = (\mathcal{N}, \mathcal{L})$ in which \mathcal{N} , 288 the set of nodes, represents specific equipment in the network and \mathcal{L} , the set 289 of arcs, corresponds to the links that can be used to route the traffic. The 290 routing of the traffic in the network is limited by the bandwidth b_l of each link 291 l. In practice, part of this bandwidth is used to route the legitimate traffic in 292 the network. In the present work, for the sake of simplicity, we assume that 293 the bandwidth consumed by the legitimate traffic is negligible as compared 294 to the one consumed by the illegitimate traffic. We thus consider that the 295 illegitimate traffic may use all the bandwidth of a link if needed. 296

The illegitimate traffic corresponding to the on-going DDoS attack is rep-297 resented as a set \mathcal{A} of attacks: attack $a \in \mathcal{A}$ corresponds to an illegitimate 298 traffic of F^a Mbps between a source $s^a \in \mathcal{N}$ and the target $t \in \mathcal{N}$ of the 299 DDoS attack. Source nodes, $\{s_a, a \in \mathcal{A}\}$, are network access nodes (also 300 termed gateways) managed by the ISP. They are able to compute the num-301 ber of incoming packets and to detect suspicious traffic entering the network. 302 In contrast, the target node t is a strategic node belonging to an external net-303 work managed by a customer which subscribed to a security service provided 304 by the ISP. The ISP must thus secure this node against the on-going DDoS 305 attack but it is not allowed to install any software (i.e. to deploy VNFs) on 306 this node. The malicious traffic corresponding to the attack thus has to be 307 stopped before it reaches t. 308

As explained in the introduction, in the present work, we consider the case in which an ISP lends slices of its physical network infrastructure to its customers and each of these customers uses its own flow routing algorithms to route the flow on the slice assigned to it. The result is that by the time the ISP has to decide on the NFV-based DDoS mitigation infrastructure, it does

not know the exact routing of the malicious flow to be stopped. Let \mathcal{P}^a be 314 the set of all potential paths between s^a and t for attack a. $\mathcal{N}^{a,p}$ (resp. $\mathcal{L}^{a,p}$) 315 denotes the set of nodes (resp. the set of links) belonging to path $p \in \mathcal{P}^a$ and 316 $\mathcal{P}^{a}(n)$ denotes the subset of paths of \mathcal{P}^{a} going through node n. The amount 317 of malicious flow of attack $a \in \mathcal{A}$ on path $p \in \mathcal{P}^a$, denoted by $f^{a,p}$, is thus 318 subject to uncertainty. However, even if the exact value of parameter $f^{a,p}$ 319 is unknown, there are some restrictions on its potential value. Namely, we 320 know that the total amount of malicious flow routed on the paths belonging 321 to \mathcal{P}^a may not be greater than F^a , the amount of illegitimate traffic of 322 attack a. Moreover, the malicious flow routing must comply with the limited 323 bandwidth of each link. These two pieces of information should be exploited 324 as best as possible to avoid using more network resources than necessary for 325 the DDoS attack mitigation. 326

In the considered DDoS mitigation framework, VNFs are used to filter and 327 stop the illegitimate traffic before it reaches its target. A VNF instantiated 328 on a node $n \in \mathcal{N}$ of the network can be seen as a software running on the 329 server located at node n and filtering the flow going through n. As explained 330 in Section 2, this filtering process mainly consists in selectively stopping 331 unwanted traffic by exploiting the information contained in the header of 332 each data packet. This information can be the source, destination, port or 333 routing protocol of the data packet to be processed. The filtering capacity of 334 a VNF corresponds to the number of packets it can receive and process per 335 second: if the malicious flow the VNF has to handle is larger than its filtering 336 capacity, the excess flow is forwarded in the network and may thus reach its 337 target. This filtering capacity is linked to the amount of computing resources 338 consumed by the VNF on the server where it is instantiated. Indeed, data 339 packets arriving at the VNF are first extracted and stored in memory. They 340 then undergo several processing cycles on the available CPUs in order to 341 analyze their content. Thus, the number of CPUs allocated to the VNF 342 strongly limits its packet processing rate. Moreover, widely used filtering 343 rules consist in analyzing the destination of a set of packets and storing them 344 in memory. If there are too many packets targeting the same destination at 345 the same time, these packets are considered as suspicious and are discarded. 34F Consequently, the filtering process requires some memory to implement the 347 malicious traffic filtering rules. The set of available VNF types is described by 348 $\mathcal{V} = \{1, ..., V\}$. A VNF of type v is characterized by its filtering capacity ϕ^v , 349 its cost K^{v} and its computing resources consumption. The set of computing 350 resources (CPU, memory, etc.) is denoted by $\mathcal{R} = \{1, ..., R\}$. Let k^{rv} be the 351

amount of computing resource r required by the instantiation of one VNF of type v and Cap_n^r the amount of computing resource r available at node n.

Table 1 summarizes the notation used to describe the input parameters of the various mathematical models throughout the paper.

The optimization problem consists in identifying the location and number of VNFs to be placed in the network so as to stop all the malicious flow before it reaches its target, and this whatever its routing through the network, while minimizing the cost of the instantiated VNFs and complying with the limitations on the computing resources.

361 3.2. Mathematical formulation

We propose to handle this optimization problem using a robust opti-362 mization (RO) approach. A robust optimization problem is an optimization 363 problem in which some parameters are subject to uncertainty. In a RO prob-364 lem, the uncertainty on the input parameters is not described in terms of 365 probability distributions but rather by means of an uncertainty set contain-366 ing all the possible values that these parameters may take. Solving a RO 367 problem consists in finding a solution which is feasible for any realization of 368 the uncertain parameters in the uncertainty set and which provides the best 369 possible value of the objective function. The reader is referred to Gorissen 370 et al. (2015) for a practical introduction on robust optimization. 371

In the present case, the routing of the malicious flow in the network is 372 not known by the ISP. The amount of malicious flow of attack $a \in \mathcal{A}$ on 373 path $p \in \mathcal{P}^a$, $\tilde{f}^{a,p}$, can thus be seen as an uncertain input parameter for the 374 problem of optimally placing VNFs to counter the DDoS attack. However, 375 as mentioned in Subsection 3.1, even if the exact value of parameter $f^{a,p}$ 376 is unknown, its value should comply with two restrictions. First, for each 377 attack a, the total flow routed in the network may not be larger than the 378 total attack traffic, i.e. we have $\sum_{p \in \mathcal{P}^a} \tilde{f}^{a,p} \leq F^a$ for each attack $a \in \mathcal{A}$. 379 Second, the flow routed on each $lin\vec{k} l$ of the network may not exceed the 380 bandwidth b_l of this link. We thus have $\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a \text{ s.t. } l \in \mathcal{L}^{a,p}} \tilde{f}^{a,p} \leq b_l$ for 381 each link l. 382

This means that the uncertain malicious flow routing, $\tilde{f} = {\tilde{f}^{a,p} \text{ s.t. } a \in \mathcal{A}, p \in \mathcal{P}^a}$, belongs to the uncertainty set \mathcal{U} defined by:

${\mathcal A}$	Set of all on-going attacks to be stopped
${\mathcal C}$	Collection of restricted sets of paths
${\cal G}$	Graph representing the telecommunication network
${\cal L}$	Set of links used to route the traffic in the network
$\mathcal{L}^{a,p}$	Set of all links belonging to path $p \in \mathcal{P}^a$
${\mathcal N}$	Set of nodes, i.e. of pieces of equipment in the network
$\mathcal{N}^{a,p}$	Set of all nodes belonging to path $p \in \mathcal{P}^a$
$\mathcal{N}(\widetilde{f})$	Subset of nodes through which part of the malicious flow transits when
	it is routed according to routing \tilde{f}
\mathcal{P}^{a}	Set of all paths between s^a and t
$\mathcal{P}^a(n)$	Subset of paths in \mathcal{P}^a such that $n \in \mathcal{N}^{a,p}$
\mathcal{P}_{R}^{a}	Restricted set of paths for attack a
$\mathcal{R}^{}$	Set of computing resources
\mathcal{U}	Uncertainty set
\mathcal{U}_R	Restricted uncertainty set
\mathcal{V}	Set of available VNF types
А	Number of attacks
b_l	Bandwidth of link l
Cap_n^r	Amount of computing resource r available at node n
F^{a}	Total illegitimate traffic of attack a
$\widetilde{f}^{a,p}$	Unknown amount of malicious flow of attack $a \in \mathcal{A}$ routed on path $p \in \mathcal{P}^a$
\widetilde{f}	Unknown routing of the DDoS attack ; $\tilde{f} = \{\tilde{f}^{a,p} \text{ s.t. } a \in \mathcal{A}, p \in \mathcal{P}^a\}$
\overline{f}	Given routing belonging to the uncertainty set \mathcal{U}
K^{v}	Cost of instantiating a VNF of type v
k^{rv}	Amount of resource r required to instantiate a VNF of type v
R	Number of computing resources
s^a	Source, i.e. ingress point, of attack a
t	Target common to all on-going attacks
V	Number of available VNF types
\overline{x}	Given placement of the filtering VNFs in the network
ϕ^v	Filtering capacity of a VNF of type v

Table 1: Notation for the input parameters used in the various mathematical models

Problem RVNFD

 $\begin{array}{ll} x_n^v & \text{Number of VNFs of type } v \text{ placed at node } n \\ \text{Problem TP} \\ d_n^{a,p} & \text{Amount of filtering capacity placed at node } n \text{ allocated to stopping} \\ & \text{the malicious flow relative to attack } a \text{ and routed on path } p \\ \text{Problem } DMP(\mathcal{U}_R) \\ x_n^v & \text{Number of VNFs of type } v \text{ placed at node } n \\ \text{Problems } AP(\overline{x}), RAP(\overline{x}, \mathcal{C}) \text{ and } \underline{RAP}(\overline{x}, \mathcal{C}) \\ f^{a,p} & \text{Amount of flow related to attack } a \text{ routed on path } p \\ z_n & z_n = 1 \text{ if some malicious flow transits through } n, \text{ to 0 otherwise} \\ \end{array}$

Table 2: Notation for the decision variables used in the various mathematical models

$$\mathcal{U} = \{ \tilde{f} \ge 0 | \sum_{p \in \mathcal{P}^a} \tilde{f}^{a,p} \le F^a, \qquad \forall a \in \mathcal{A}$$
$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a \text{ s.t. } l \in \mathcal{L}^{a,p}} \tilde{f}^{a,p} \le b_l, \qquad \forall l \in \mathcal{L} \}$$

Note that the first restriction on \tilde{f} is expressed as an inequality rather 385 than as an equality. Namely, in some cases, it may not be possible to route all 386 the malicious flow of the attack in the network due to the limited bandwidth 387 of the network links. In these cases, expressing the restriction as an equality 388 would lead to an empty uncertainty set. For the RO problem, this would 389 mean that there is no malicious flow routed in the network, i.e. no malicious 390 flow to be stopped by the VNF-based infrastructure, whereas in practice part 391 (but not all) of the attack flow will be routed in the network. 392

We introduce the integer decision variables x_n^v which represent the number of VNFs of type v placed at node n: see Table 2 for a summary of the decision variables used in the various mathematical models investigated in the paper. Using the previously introduced notation, the robust virtual network function deployment problem, which will be denoted by RVNFD in what follows, is formulated as follows:

$$Z^* = \min \sum_{v \in \mathcal{V}} \sum_{n \in \mathcal{N}} K^v x_n^v \tag{1}$$

$$\sum_{v \in \mathcal{V}} k^{rv} x_n^v \le Cap_n^r \qquad \qquad \forall n \in \mathcal{N}, \forall r \in \mathcal{R}$$
(2)

$$\sum_{n \in \mathcal{N}(\tilde{f})} \sum_{v \in \mathcal{V}} \phi^v x_n^v \ge \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a} \tilde{f}^{a,p} \qquad \forall \tilde{f} \in \mathcal{U}$$
(3)

$$x_t^v = 0 \qquad \qquad \forall v \in \mathcal{V} \tag{4}$$

$$x_n^v$$
 integer $\forall n \in \mathcal{N}, \forall v \in \mathcal{V}$ (5)

The objective (1) is to minimize the total costs of the deployed VNFs. 399 Constraints (2) ensure that the VNFs installed at each node n do not con-400 sume more than the available computing capacity for each computing re-401 source. Constraints (3) translate the fact that we seek to avoid any damage 402 to the target by stopping all the malicious flow before it reaches it. In Con-403 straints (3), $\mathcal{N}(\tilde{f}) = \{n \in \mathcal{N} \setminus \{t\} | \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a(n)} \tilde{f}^{a,p} > 0\}$ represents the 404 subset of nodes n through which part of the malicious flow transits when 405 considering the flow routing f. Constraints (3) impose that, for each pos-406 sible routing f, the total filtering capacity installed on the nodes traversed 407 by a strictly positive amount of malicious flow in the routing f, i.e on the 408 nodes belonging to $\mathcal{N}(f)$, is larger than the total malicious flow actually 409 routed through the network in f. Constraints (4) forbid any filtering at the 410 targeted node. Note that Constraints (3) are robust constraints that should 411 hold for any flow routing belonging to the uncertainty set \mathcal{U} . 412

413 3.3. Small illustrative example

Before discussing some theoretical aspects relative to the formulation and complexity of Problem RVNFD, we provide a small illustrative example to facilitate the understanding of the proposed models and methods.

Let us consider a small network \mathcal{G} including $|\mathcal{N}| = 5$ nodes and $|\mathcal{L}| =$ 5 links, each one with a bandwidth of $b_l = 15$ Mbsp. The malicious flow corresponding to the on-going DDoS attack enters the network at a gateway located at node 1 and targets a critical customer node located at node 5: we thus have A = 1, $s_1 = 1$ and t = 5. We consider R = 1 computing resource corresponding to the number of CPUs available at each node: we have $Cap_n^1 = 4$ CPUs available at node $n \in \{1,2\}$ and $Cap_n^1 = 2$ CPUs

Figure 2: Small illustrative example: two possible routings for the malicious flow

Figure 3: Small illustrative example: robust VNF placement

available at node $n \in \{3, 4\}$. There is a single type of filtering VNF, i.e. V = 1. Each instantiated VNF has a filtering capacity of $\phi_1 = 5$ Mbps and requires $k^{1,1} = 2$ CPUs.

Figure 2 displays two possible routings of the malicious flow. This one may use $|\mathcal{P}^1| = 2$ paths from node 1 to reach its target: path p = 1 corresponds to $1 \to 2 \to 5$ and path p = 2 to $1 \to 3 \to 4 \to 5$. The routing displayed on the left correspond to $\tilde{f}_{left} = (\tilde{f}_{left}^{1,1}, \tilde{f}_{left}^{1,2}) = (15,5)$, the routing displayed on the right to $\tilde{f}_{right} = (\tilde{f}_{right}^{1,1}, \tilde{f}_{right}^{1,2}) = (5,15)$. \tilde{f}_{left} and \tilde{f}_{right} are two elements (in fact two extreme points) of the uncertainty set \mathcal{U} .

By solving Problem RVNFD for this small instance, we obtain the VNF 433 placement shown in Figure 3. It consists in placing two VNFs at nodes 1 434 and 2 (i.e. $x_1^1 = x_2^1 = 2$) and one VNF at nodes 3 and 4 (i.e. $x_3^1 = x_4^1 = 1$.) 435 Finally, Figure 4 presents how the malicious flow may be filtered by the 436 instantiated VNFs in case it is routed according to f_{left} (see the network on 437 the left) or according to f_{right} (see the network on the right). Note how, in 438 both cases, all the malicious flow is filtered and stopped before it reaches the 439 target located at node 5. 440

Figure 4: Small illustrative example: malicious flow filtering for two possible routings

⁴⁴¹ 3.4. Discussion on the aggregated attack filtering constraints

Constraints (3) can be seen as aggregated attack filtering constraints en-442 suring that the total filtering capacity installed on the set of nodes traversed 443 by f is larger than the total malicious flow routed through the network. As 444 such, they do not guarantee that the filtering capacity installed on each po-445 tential path $p \in \mathcal{P}^a$ of each attack a is enough to stop all the flow related to 446 attack a routed on this path, i.e. that the filtering capacity installed on each 447 path $p \in \mathcal{P}^a$ is larger than $f^{a,p}$. However, we show in what follows that, for 448 any feasible solution \overline{x} of Problem RVNFD and any flow \overline{f} belonging to \mathcal{U} . 449 we can find at least one allocation of the filtering capacity installed at each 450 node n to the flows going through n such that all the malicious traffic can be 451 filtered. This can be done by solving the following transportation problem 452 denoted by TP. 453

Let $d_n^{a,p}$ be the decision variable representing the amount of filtering capacity installed at node n dedicated to stopping the malicious flow routed on path $p \in \mathcal{P}^a, a \in \mathcal{A}$.

$$Z_{TP}^* = \min \sum_{n \in \mathcal{N}} \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a(n)} d_n^{a,p} \tag{6}$$

$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a(n)} d_n^{a,p} \le \sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v \qquad \forall n \in \mathcal{N} \setminus \{t\}$$
(7)

$$\sum_{n \in \mathcal{N}^{a,p} \setminus \{t\}} d_n^{a,p} \ge \overline{f}^{a,p} \qquad \forall a \in \mathcal{A}, \forall p \in \mathcal{P}^a$$
(8)

$$d_n^{a,p} \ge 0 \qquad \qquad \forall n \in \mathcal{N}, \forall a \in \mathcal{A}, \forall p \in \mathcal{P}^a(n) \qquad (9)$$

The objective (6) seeks to minimize the total amount of filtering capacity used to stop the malicious flow. Constraints (7) ensure that, at each node ⁴⁵⁹ n, the total amount of filtering capacity allocated to stop the flow routed on ⁴⁶⁰ each path $p \in \mathcal{P}^a$ of each attack a going through node n is not larger that the ⁴⁶¹ amount of filtering capacity available at node n. Constraints (8) guarantee ⁴⁶² that, for each attack a and each path $p \in \mathcal{P}^a$ used to route the attack in \overline{f} , ⁴⁶³ the total amount of filtering capacity dedicated to p on the nodes belonging ⁴⁶⁴ to it is large enough to stop all the malicious flow routed on p before it reaches ⁴⁶⁵ t.

Proposition 1. If \overline{x} is a feasible solution of Problem *RVNFD* and \overline{f} a flow belonging to the uncertainty \mathcal{U} , there exists at least one feasible solution for Problem *TP*, i.e. one allocation of the installed filtering capacity to the paths used by the attacks such that the total filtering capacity allocated to each path p of each attack a is larger than $\overline{f}^{a,p}$.

⁴⁷¹ *Proof.* The proof is done by contradiction.

Let assume that Problem TP is unfeasible. It means that there exists a subset of attacks $\mathcal{A}' \subset \mathcal{A}$ and a subset of paths $\mathcal{P}'^a \subset \mathcal{P}^a$ for each attack $a \in \mathcal{A}'$ such that $\sum_{n \in \mathcal{N}'} \sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v < \sum_{a \in \mathcal{A}'} \sum_{p \in \mathcal{P}'^a} \overline{f}^{a,p}$ where $\mathcal{N}' =$ $\cup_{a \in \mathcal{A}', p \in \mathcal{P}'^a} \mathcal{N}^{a,p}$. In other words, it exists a subset of paths $\mathcal{P}'^a, a \in \mathcal{A}'$, such that the total filtering capacity installed on the nodes belonging to \mathcal{N}' is insufficient to stop the flow going through these nodes.

Let us consider the routing f' defined by: $f'^{a,p} = \overline{f}^{a,p}$ if $a \in \mathcal{A}'$ and $p \in \mathcal{P}'^a$ and $f'^{a,p} = 0$ otherwise. We have $\mathcal{N}(f') = \mathcal{N}'$. As f' belongs to the uncertainty set \mathcal{U} and \overline{x} is a feasible solution of Problem RVNFD, the constraint $\sum_{n \in \mathcal{N}(f')} \sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v \ge \sum_{a \in \mathcal{A}'} \sum_{p \in \mathcal{P}'^a} f'^{a,p}$ should hold. This is in contradiction with the strict inequality written above.

In other words, solving Problem TP provides a VNF placement ensuring that all the malicious flow of the attack will be stopped provided we use an allocation of the filtering capacity to the paths actually used by the attack which complies with Constraints (7)-(9). Lemma 1 guarantees that such an allocation exists. However, solving Problem RVNFD does not guarantee that any allocation of the installed filtering capacity to the paths actually used by the attack will enable the ISP to block all the malicious flow.

491 3.5. Complexity analysis

⁴⁹² **Proposition 2.** Problem *RVNFD* is NP-hard, even if the uncertainty set \mathcal{U} ⁴⁹³ contains a finite and discrete set of potential routings. 494 Proof. The proof is done by reduction from the minimum set covering prob 495 lem.

Consider an instance I' of the minimum set covering problem. I' includes N potential location sites (indexed by n = 1, ..., N) for the facilities and Ddemand points (indexed by $\delta_1, ..., \delta_D$). For each demand point $\delta_d, d = 1, ..., D$, we define the subset of potential location sites, $\mathcal{N}(\delta_d) \subset \{1, ..., N\}$, which may cover it. The objective of the minimum set covering problem is to cover all demand points while minimizing the total number of opened facilities.

This instance of the minimum set covering problem can be transformed 502 into an instance I of Problem RVNFD as follows. The graph $\mathcal{G} = (\mathcal{N}, \mathcal{L})$ has 503 N+1 nodes and N links. The nodes indexed by n=1...N correspond to 504 nodes where VNFs may be instantiated by the ISP and the node indexed by 505 N+1 corresponds to the target of the attack: we thus have $\mathcal{N} = \{1, ..., N+1\}$. 506 There is a link $l \in \mathcal{L}$ between each node indexed by n = 1...N and the node 507 indexed by N + 1. Each link has a bandwidth equal to $b_l = 1$. The DDoS 508 attack enters the network at A = N ingress points corresponding to the 509 nodes indexed by n = 1...N (i.e. $s^a = a$ for a = 1...N) and targets node 510 N+1 (i.e. t=N+1). We set $F^a = \frac{1}{4}$ for each attack a. 511

Each attack *a* may thus use a single path to reach the target: for each *a* in $\mathcal{A}, |\mathcal{P}^a| = 1$ and the path indexed by (a, 1) corresponds to $a \to t$. A routing in the network is thus a vector $f_d = (f_d^{1,1}, ..., f_d^{a,1}, ..., f_d^{A,1})$ describing the flow of malicious traffic on the single path of each attack. For each demand point $\delta_d, d = 1...D$, of the minimum set covering problem, we add a routing f_d in the discrete uncertainty set \mathcal{U}_D with $f_d^{a,p} = \frac{1}{A}$ if node *a* belongs to $\mathcal{N}(\delta_d)$ and $f_d^{a,p} = 0$ otherwise.

We consider a single computing resource (R = 1) with $Cap_n^1 = 1$ for each node n in $\{1, ..., N\}$. There is a single type of VNF indexed by v = 1 with a cost equal to $K^1 = 1$, a filtering capacity ϕ^1 equal to 1 and a consumption of the computing resource $k^{1,1}$ equal to 1. The total amount of malicious flow in any routing $f_d \in \mathcal{U}_D$, $\sum_{a \in \mathcal{A}} F^a$, is less than or equal to 1. Consequently, placing a VNF on any node belonging to $\mathcal{N}(f_d)$ suffices to ensure that the aggregated filtering constraints (3) will be satisfied for routing f_d .

Moreover, as the sets $\mathcal{N}(\delta_d)$ and $\mathcal{N}(f_d)$ coincide for each d, a demand point δ_d will be covered in instance I' as long as a VNF is instantiated on a node belonging to $\mathcal{N}(f_d)$ in instance I. As a consequence, determining, for instance I, the minimum cost VNF placement enabling to stop all the malicious flow, whatever its routing $f_d \in \mathcal{U}_D$, provides the minimum set of potential location sites covering all demand points in instance I'. Solving instance I' of Problem RVNFD thus provides a solution to instance I of the minimum set covering problem.

As the minimum set covering problem is known to be NP-hard (see e.g. Korte and Vygen (2012)), the results follows.

536

Figure 5 illustrates this reduction on a small instance I' of the minimum set cover problem with N = 3 potential location sites (represented as dashed nodes indexed from 1 to 3) and D = 4 demand points represented by the nodes denoted by δ_1 to δ_4 . We have $\mathcal{N}(\delta_1) = \{1, 2\}, \ \mathcal{N}(\delta_2) = \{1, 2, 3\}, \mathcal{N}(\delta_3) = \{2\}$ and $\mathcal{N}(\delta_4) = \{3\}$. The corresponding graph is displayed at the top of Figure 5.

This instance of the minimum set covering problem can be transformed 543 into an instance I of Problem RVNFD as follows. The corresponding graph 544 $\mathcal{G} = (\mathcal{N}, \mathcal{L})$ has N + 1 = 4 nodes and N = 3 links: see the bottom part 545 of Figure 5. The DDoS attack enters the network at A = 3 ingress points 546 corresponding to the nodes indexed by n = 1...3 (i.e. $s^1 = 1, s^2 = 2$ and 547 $s^3 = 3$) and targets node t = 4. We set $F^a = \frac{1}{A} = 0.33$ for each attack 548 a. A routing $f_d = (f_d^{1,1}, f_d^{2,1}, f_d^{3,1})$ describes the amount of malicious flow 549 routed on the single path $a \rightarrow 4$ that may be used by each attack a to 550 reach the target. For each demand point $\delta_d, d = 1...D$, of the minimum 551 set covering problem, we add a routing f_d in the discrete uncertainty set 552 \mathcal{U}_D such that $f_d^{a,p} = \frac{1}{A}$ if node *a* belongs to $\mathcal{N}(\delta_d)$ and $f_d^{a,p} = 0$ otherwise. 553 This gives $f_1 = (0.33, 0.33, 0), f_2 = (0.33, 0.33, 0.33), f_3 = (0, 0.33, 0)$ and 554 $f_4 = (0, 0, 0.33)$. We thus have $\mathcal{N}(\delta_d) = \mathcal{N}(f_d)$ for each d = 1...D. We set 555 $R = 1, Cap_n^1 = 1$ for $n = 1..3, V = 1, K^1 = 1, \phi_1 = 1$ and $k^{1,1} = 1$ as 556 described in the proof of Proposition 2. 557

The optimal solution of instance I' consists in placing a VNF at nodes 2 and 3 as this suffices to ensure that the aggregated filtering constraints (3) will be respected for all routings in the discrete uncertainty set \mathcal{U}_D . This gives an optimal solution of instance I which consists in opening a facility at the potential sites 2 and 3.

563 4. Solution approach

As explained e.g. by Gorissen et al. (2015), Problem RVNFD may seem intractable as such as the number of constraints (3) is infinite. Two main ways have been proposed in the literature to handle this difficulty.

Figure 5: Reduction of an instance of the minimum set covering problem (top) into an instance of Problem RVNFD (bottom)

The first one consists in applying reformulation techniques which result in the formulation of a deterministic problem with a finite number of constraints: see e.g. Bertsimas and Sim (2004). In our case, the use of these reformulation techniques is not possible. Namely, the worst case reformation of Constraints (3) would lead to the following expression:

$$\min_{\tilde{f}\in\mathcal{U}}\sum_{n\in\mathcal{N}}\mathbb{I}\Big(\sum_{a\in\mathcal{A}}\sum_{p\in\mathcal{P}^a(n)}\tilde{f}^{a,p}>0\Big)\sum_{v\in\mathcal{V}}\phi^v x_n^v - \sum_{a\in\mathcal{A}}\sum_{p\in\mathcal{P}^a}\tilde{f}^{a,p}>0$$
(10)

where $\mathbb{I}\left(\sum_{a\in\mathcal{A}}\sum_{p\in\mathcal{P}^a(n)}\tilde{f}^{a,p}>0\right)$ is an indicator function that is equal to one if $\sum_{a\in\mathcal{A}}\sum_{p\in\mathcal{P}^a(n)}\tilde{f}^{a,p}>0$ and zero otherwise. The resulting inner minimization problem cannot be formulated as a linear program (but rather as a mixed-integer linear program) due to the presence of this indicator function. It is thus not possible to use the duality theory to reformulate it and obtain a computationally tractable robust counterpart as is commonly done in this type of reformulation approach.

The second possible way of solving a RO problem such as Problem RVNFD 579 consists in applying an adversarial approach. Such approaches are based on 580 the decomposition of the initial problem into a master problem and a sub-581 problem. The master problem, called the decision maker problem in this 582 context, can be seen as a restricted version of the original RO problem in 583 which only a finite number of extreme points $\mathcal{U}_R \subset \mathcal{U}$ of the uncertainty 584 set (instead of the whole uncertainty set \mathcal{U}) are used to express the robust 585 constraints. This problem is a deterministic optimization problem with a 586 finite number of constraints and is thus computationally tractable. The sub-587 problem is called the adversarial problem. Given the solution provided by 588 the decision maker problem, the adversarial problem seeks to find an extreme 589 point of \mathcal{U} for which this solution is infeasible. If no such extreme point can 590 be found, the current solution of the decision maker problem is optimal for 591 the initial RO problem. If such an extreme point is found, we add it to the 592 restricted set \mathcal{U}_R and reiterate the process. The finite convergence of this 593 algorithm is ensured by the fact that the uncertainty set \mathcal{U} has a finite num-594 ber of extreme points. Adversarial approaches have been successfully used 595 to solve RO problems arising in a variety of applications: see among others 596 Bienstock and Ozbay (2008), Attila et al. (2017), van Hulst et al. (2017) and 597 Agra et al. (2018). 598

599 4.1. Adversarial approach

The proposed adversarial approach thus iteratively solves the decision 600 maker problem and the adversarial sub-problem. At each iteration, the deci-601 sion maker problem is solved using the current restricted uncertainty set \mathcal{U}_R 602 and provides a placement of the VNFs \overline{x} which is optimal for this restricted 603 uncertainty set. \overline{x} being given, the adversarial problem is solved to find the 604 worst-case routing of the malicious flow for the VNF placement described by 605 \overline{x} , i.e. to find an extreme point of \mathcal{U} wich maximises the infeasibility of \overline{x} if it 606 exists. In case such an extreme point is found, we update the restricted un-607 certainty set \mathcal{U}_R by adding the newly found routing f and go on to the next 608 iteration. Otherwise, \overline{x} is feasible for all extreme points of \mathcal{U} , the current 609 VNF placement \overline{x} is optimal and the algorithm stops. 610

611 4.1.1. Decision maker sub-problem

The decision maker problem, denoted by $DMP(\mathcal{U}_R)$, can be formulated as follows:

$$Z^*_{DMP}(\mathcal{U}_R) = \min \sum_{v \in \mathcal{V}} \sum_{n \in \mathcal{N}} K^v x^v_n$$
(11)

$$\sum_{v \in \mathcal{V}} k^{rv} x_n^v \le Cap_n^r \qquad \qquad \forall n \in \mathcal{N}, \forall r \in \mathcal{R}$$
(12)

$$\sum_{n \in \mathcal{N}(\tilde{f})} \sum_{v \in \mathcal{V}} \phi^v x_n^v \ge \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a} \tilde{f}^{a,p} \qquad \forall \tilde{f} \in \mathcal{U}_R$$
(13)

$$x_t^v = 0 \qquad \qquad \forall v \in \mathcal{V} \tag{14}$$

$$x_n^v$$
 integer $\forall n \in \mathcal{N}, \forall v \in \mathcal{V}$ (15)

Problem $DMP(\mathcal{U}_R)$ thus displays the same structure as the initial RO 614 problem but the number of Constraints (13) is now finite. Moreover, as will 615 be shown by the numerical experiments provided in Section 5, in practice, 616 the cardinality of \mathcal{U}_R , and as a consequence the number of Constraints (13) 617 involved in the formulation, remain rather limited when implementing the 618 adversarial approach. Problem $DMP(\mathcal{U}_R)$ can thus be directly solved by 619 a mixed-integer linear programming solver with a reasonable computational 620 effort. 621

622 4.1.2. Adversarial sub-problem

Let us now focus on the adversarial sub-problem. In order to formulate it, we introduce the following decision variables:

625 - $f^{a,p}$: amount of malicious flow of attack *a* routed on path $p \in \mathcal{P}^a$,

- $z_n \in \{0, 1\}$: $z_n = 1$ if there is a positive amount of malicious flow transiting through node n, 0 otherwise.

Given the current VNF placement \overline{x} , the maximum amount of malicious flow which can reach its target can be found by solving the following mixedinteger linear program, denoted by $AP(\overline{x})$.

$$Z_{AP}^{*}(\overline{x}) = \max \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^{a}} f^{a,p} - \sum_{n \in \mathcal{N} \setminus \{t\}} (\sum_{v \in \mathcal{V}} \phi^{v} \overline{x}_{n}^{v}) z_{n}$$
(16)

$$\sum_{p \in \mathcal{P}^a} f^{a,p} \le F^a \qquad \qquad \forall a \in \mathcal{A} \qquad (17)$$

$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a} \sum_{\text{s.t. } l \in \mathcal{L}^{a,p}} f^{a,p} \le b_l \qquad \qquad \forall l \in \mathcal{L} \qquad (18)$$

$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a(n)} f_p^a \le (\sum_{a \in \mathcal{A}} F^a) z_n \qquad \qquad \forall n \in \mathcal{N} \setminus \{t\} \qquad (19)$$

$$f^{a,p} \ge 0 \qquad \qquad \forall p \in \mathcal{P}^a \qquad (20)$$

$$z_n \in \{0, 1\} \qquad \qquad \forall n \in \mathcal{N} \qquad (21)$$

The linear variables f thus describe the worst-case routing of the mali-631 cious flow for the VNF placement \overline{x} . Constraints (17) ensure that, for each 632 attack, the total amount of flow of attack a routed through the network is 633 smaller that the total amount of flow of the attack F^a . Note that due to the 634 limited bandwidth of the network links, it might not be possible to route all 635 the flow of attack a through the network: Constraints (17) are thus formu-636 lated as inequalities rather than as equalities. Constraints (18) guarantee 637 that the flow routed on each link does not exceed its bandwidth. In other 638 words, Constraints (17), (18) and (20) make sure that the solution of 639 problem $AP(\overline{x})$ provides a flow f belonging to the uncertainty set \mathcal{U} . 640

The objective function (16) seeks to maximize the amount of malicious flow which will reach its target, i.e. which will not be filtered by a VNF between its source and its target. Note that the filtering capacity $\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v$ placed at node *n* can stop part of the malicious flow only if there is a positive flow routed through node *n*, i.e. only if $\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a(n)} f_p^a > 0$. ⁶⁴⁶ $\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a} f_p^a - \sum_{n \in \mathcal{N} \setminus \{t\}} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v) z_n$ thus computes the total amount ⁶⁴⁷ of unfiltered flow as the difference between the total flow routed through the ⁶⁴⁸ network, $\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}^a} f_p^a$, and the total amount of 'active' filtering capacity, ⁶⁴⁹ $\sum_{n \in \mathcal{N} \setminus \{t\}} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v) z_n$. This 'active' filtering capacity is given by the sum ⁶⁵⁰ of the filtering capacities installed at the nodes *n* through which a positive ⁶⁵¹ amount of malicious flow transits. Constraints (19) ensure that, for each ⁶⁵² node *n*, variable z_n is equal to 1 as soon as there is some positive amount of ⁶⁵³ malicious flow which is routed through node *n*.

Note that, similar to what is done in Constraint (3) of the initial RO 654 problem, in the objective function (16) of the adversarial sub-problem, the 655 total amount of unfiltered flow is computed in an aggregate manner, i.e. by 656 looking at the total routed flow and at the total active filtering capacity on 657 all nodes of the network. In a feasible solution of problem $AP(\overline{x})$, this might 658 lead to an underestimation of the malicious flow which will reach its target. 659 Namely, we may have a subset of nodes \mathcal{N}' such that the total flow routed 660 through the nodes $n \in \mathcal{N}'$, $\sum_{a \in \mathcal{A}} \sum_{p \in \bigcup_{n \in \mathcal{N}'} \mathcal{P}^a(n)} f_p^a$, is smaller than the total filtering capacity placed on these nodes, $\sum_{n \in \mathcal{N}'} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v)$. In this case, 661 662 the actual filtering taking place at some of the nodes $n \in \mathcal{N}'$ is not equal to 663 $\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v$ but to a smaller value. More precisely, the total filtering taking 664 place on the subset of nodes \mathcal{N}' is equal to $\sum_{a \in \mathcal{A}} \sum_{p \in \bigcup_{n \in \mathcal{N}'} \mathcal{P}^a(n)} f_p^a$ rather 665 than to $\sum_{n \in \mathcal{N}'} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v)$. This means that the objective function (16) 666 overestimates the actual filtering taking place on the part of the network 667 corresponding to \mathcal{N}' and thus underestimates the amount of unfiltered ma-668 licious flow. However, we show in what follows that such a situation cannot 669 occur in an optimal solution of $AP(\overline{x})$. 670

Proposition 3. Any optimal solution of $AP(\overline{x})$ provides the worst-case routing for the given VNF placement \overline{x} .

⁶⁷³ *Proof.* Let us consider a solution of $AP(\overline{x})$ in which there is at least one ⁶⁷⁴ subset of nodes \mathcal{N}' such that the total flow routed through the nodes $n \in \mathcal{N}'$, ⁶⁷⁵ $\sum_{a \in \mathcal{A}} \sum_{p \in \bigcup_{n \in \mathcal{N}'} \mathcal{P}^a(n)} f_p^a$, is smaller than $\sum_{n \in \mathcal{N}'} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v)$. We show that ⁶⁷⁶ this solution cannot be optimal for $AP(\overline{x})$.

It is namely possible to build another feasible solution of $AP(\overline{x})$ by setting to 0 the flow on all the paths belonging to $\bigcup_{n \in \mathcal{N}'} \mathcal{P}^a(n)$ and by setting z_n to 0 for all nodes $n \in \mathcal{N}'$. The objective value of the obtained solution will be increased by $\sum_{n \in \mathcal{N}'} (\sum_{v \in \mathcal{V}} \phi^v \overline{x}_n^v) - \sum_{a \in \mathcal{A}} \sum_{p \in \bigcup_{n \in \mathcal{N}'} \mathcal{P}^a(v)} f_p^a > 0$, i.e. will be strictly larger than the one of the initial solution. This latter can therefore 682 not be optimal.

683 4.2. Resolution of the adversarial sub-problem

The adversarial sub-problem $AP(\overline{x})$ is a mixed-integer linear program which could theoretically be solved directly by a mathematical programming solver. However, the number of paths that could possibly be used to route the malicious flow of a given attack *a* between its source s^a and the target *t*, and as a consequence the number of flow variables $f^{a,p}$, grows exponentially fast with the network size.

This difficulty may be overcome by using a column generation technique. In a column generation algorithm, we start solving problem $AP(\bar{x})$ with a restricted number of flow variables (i.e. of columns), which provides an initial feasible solution. This initial solution is then improved by iteratively adding new flow variables (i.e. by generating new columns) to the formulation of the problem until no more improving flow variables can be found.

Let $RAP(\overline{x}, \mathcal{C})$ be a restricted version of problem $AP(\overline{x})$ in which only a subset of the flow variables $f^{a,p}$ are explicitly considered. Here, \mathcal{C} denotes a collection of subsets of paths. More precisely, we have $\mathcal{C} = \{\mathcal{P}_R^a, a \in \mathcal{A}\}$ where $\mathcal{P}_R^a \subset \mathcal{P}^a$ is the restricted subset of potential paths available for attack a taken into account in the problem formulation.

 $RAP(\overline{x}, \mathcal{C})$ can be formulated as follows:

$$Z_{RAP}^{*}(\overline{x}, \mathcal{C}) = \max \sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}_{R}^{a}} f_{p}^{a} - \sum_{n \in \mathcal{N} \setminus \{t\}} (\sum_{v \in \mathcal{V}} \phi^{v} \overline{x}_{n}^{v}) z_{n}$$
(22)

$$\sum_{p \in \mathcal{P}^a_p} f^a_p \le F^a \qquad \qquad \forall a \in \mathcal{A} \quad (23)$$

$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}_{R}^{a} \text{ s.t. } l \in \mathcal{L}^{a,p}} f_{p}^{a} \leq b_{l} \qquad \qquad \forall l \in \mathcal{L} \quad (24)$$

$$\sum_{a \in \mathcal{A}} \sum_{p \in \mathcal{P}_{R}^{a}(n)} f_{p}^{a} \leq (\sum_{a \in \mathcal{A}} F^{a}) z_{n} \qquad \forall n \in \mathcal{N} \setminus \{t\} \quad (25)$$

$$f_p^a \ge 0 \qquad \qquad \forall p \in \mathcal{P}_R^a \quad (26)$$

$$z_n \in \{0, 1\} \qquad \qquad \forall n \in \mathcal{N} \quad (27)$$

Note that $RAP(\overline{x}, C)$ displays the same structure as $AP(\overline{x})$ but the objective and constraints are expressed using a limited number of flow variables

 $f^{a,p}$, namely those corresponding to paths belonging to the restricted subset \mathcal{P}_{R}^{a} , for each attack $a \in \mathcal{A}$.

The column generation process, i.e. the process of adding new flow variables $f^{a,p}$, relies on the linear relaxation, denoted by <u>RAP(\overline{x}, C)</u>, of $RAP(\overline{x}, C)$.

More precisely, at each iteration of the column generation algorithm, in 709 order to identify improving flow variables to be added to the formulation, we 710 first solve $RAP(\overline{x}, \mathcal{C})$ with the current collection of path subsets \mathcal{C} . We then 711 solve the pricing problem for each attack $a \in \mathcal{A}$. It consists in finding a flow 712 variable $f^{a,p}$ with a positive reduced cost, i.e. a flow variable whose inclusion 713 in the linear programming formulation might lead to an improvement of the 714 objective function, or determining that no such variable exists. If at least 715 one improving flow variable is found, we carry on with a new iteration of the 716 algorithm. If no such variable is found, it means that the current solution 717 of $RAP(\overline{x}, \mathcal{C})$ is an optimal solution of the $AP(\overline{x})$, the linear relaxation of 718 $AP(\overline{x})$, and we stop. 719

Let α_a be the dual value of Constraint (23) relative to attack a, β_l the dual value of Constraint (24) relative to link l and γ_n the dual value of Constraint (25) relative to node n in the optimal solution of $\underline{RAP}(\overline{x}, \mathcal{C})$. The reduced cost of variable $f^{a,p}$ is given by $rc^{a,p} = 1 - (\alpha_a + \sum_{l \in \mathcal{L}^{a,p}} \beta_l + \sum_{n \in \mathcal{N}^{a,p}} \gamma_n)$.

Given an attack $a \in \mathcal{A}$, solving the pricing problem, i.e. identifying 725 the variable $f^{a,p}$ with the largest reduced cost, thus amounts to finding the 726 path $p \in \mathcal{P}^a$ with the smallest value of $\sum_{l \in \mathcal{L}^{a,p}} \beta_l + \sum_{n \in \mathcal{N}^{a,p}} \gamma_n$. This can be done by looking for the shortest path between s^a and t in the weighted 727 728 digraph $(\mathcal{N}, \mathcal{L}, w)$ in which each link l has a weight of $w_l = \beta_l + \gamma_{dest(l)}$ where 729 dest(l) is the destination node of link l. This shortest path problem can be 730 solved in polynomial time by Dijskra's algorithm. If a variable $f^{a,p}$ with a 731 positive reduced cost is found, the corresponding path is added to \mathcal{P}_{R}^{a} and 732 the collection \mathcal{C} is updated accordingly. 733

Algorithm 1 provides a formal description of the column generation algorithm used to solve $\underline{AP}(\overline{x})$.

⁷³⁶ Note that Algorithm 1 solves to optimality the linear relaxation of $AP(\overline{x})$. ⁷³⁷ In order to solve the original adversarial sub-problem $AP(\overline{x})$, which is a ⁷³⁸ mixed-integer linear program, we consider two alternative ways of using it.

The first one corresponds to an exact Branch & Price algorithm. Basically, a Branch & Price algorithm is a Branch & Bound method in which, at each node of the search tree, new variables may be added to the linear pro**input** : A VNF placement \overline{x} and a collection of path subsets C**output:** An updated collection of path subsets \mathcal{C} begin repeat stop $\leftarrow 0$ solve $RAP(\overline{x}, \mathcal{C})$ with a linear programming solver get the dual values (α, β, γ) of Constraints (23)-(25) for l=1 to L do $w_l \leftarrow \beta_l + \gamma_{dest(l)}$ end for a=1 to A do find the shortest path p_s between s^a and t in $(\mathcal{N}, \mathcal{L}, w)$ $rc_{p_s}^a \leftarrow 1 - (\alpha_a + \sum_{l \in \mathcal{L}_{p_s}^a} \beta_l + \sum_{n \in \mathcal{N}_{p_s}^a} \gamma_n)$ if $rc_{p_s}^a > 0$ then $\begin{array}{l} \mathcal{C}^{\sigma}_{p_s} > 0 \quad \text{order} \\ \text{stop} \leftarrow 1 \\ \mathcal{P}^a_R \leftarrow \mathcal{P}^a_R \cup \{p_s\} \\ \textbf{J} \end{array}$ end end until stop = θ ; end

Algorithm 1: Column generation algorithm solving <u>AP</u>(\overline{x}) to optimality

gramming relaxation. More precisely, the Branch & Price algorithm starts 742 solving the restricted version of the adversarial sub-problem $RAP(\overline{x}, \mathcal{C})$ with 743 an initial collection of path subsets \mathcal{C} , using a branch-and-bound method. 744 At each node of the Branch & Bound search tree, we use Algorithm 1 to 745 solve $AP(\overline{x})$ and add new columns in the formulation (i.e. new paths in \mathcal{C}). 746 When no new column can be generated by Algorithm 1, i.e. when the linear 747 relaxation of the restricted master problem has been solved to optimality at 748 the current Branch & Bound node, we either get an integer feasible solution 749 of the initial problem $AP(\overline{x})$ or we branch on a fractional variable z_n to 750 create new nodes in the search tree and continue with the Branch & Bound 751 algorithm. The algorithm stops when there are no more open nodes in the 752 search tree. 753

The second one is a heuristic algorithm. In this case, we first solve $\underline{AP}(\overline{x})$ using Algorithm 1. When Algorithm 1 stops, we get the updated collection of path subsets \mathcal{C} , reintroduce the integrality constraints on variables $z_n, n \in \mathcal{N}$, and solve the restricted problem $RAP(\overline{x}, \mathcal{C})$ as a mixed-integer linear program. Note that this algorithm may provide a sub-optimal solution of $AP(\overline{x})$ as the collection of path subsets \mathcal{C} obtained by solving $\underline{AP}(\overline{x})$ may not be the same as the one needed to obtain an optimal solution of $AP(\overline{x})$.

761 4.3. Summary of the proposed solution approach

The overall proposed solution approach is described by Algorithm 2 for the case where the adversarial sub-problem is solved exactly and Algorithm 3 for the case where the adversarial sub-problem is solved heuristically.

In Algorithms 2 and 3, the restricted uncertainty set \mathcal{U}_R is initialized as 765 an empty set whereas the restricted path subset \mathcal{P}_{R}^{a} to be used for each attack 766 $a \in \mathcal{A}$ initially contains a single path, namely the shortest path in terms of 767 hops between the source of attack a and the target. Moreover, note that the 768 subsets $\mathcal{P}_R^a, a \in \mathcal{A}$, are not reinitialized at each iteration of the adversarial 769 algorithm. This means that the improving paths found while solving $AP(\overline{x}^{i})$, 770 where \overline{x}^i denotes the solution of $DMP(\mathcal{U}_R)$ found at iteration *i* of the ad-771 versarial algorithm, are part of the initial collection of path subsets provided 772 to Algorithm 1 when it will be used to solve $AP(\overline{x}^{j})$, where \overline{x}^{j} denotes the 773 solution of $DMP(\mathcal{U}_R)$ found at any iteration j > i of the adversarial algo-774 rithm. Our preliminary numerical experiments namely showed that this was 775 more computationally efficient than reinitializing the subsets $\mathcal{P}_R^a, a \in \mathcal{A}$, at 776 each iteration of the adversarial algorithm. 777

778 5. Numerical results

779 5.1. Instances

We randomly generated a set of medium-size instances of the problem following the indications provided by public data released by different cloud and telecom providers.

Network. We used 4 internet network topologies. The first three ones 783 correspond to three internet networks described in the Internet Topology Zoo 784 library, IntelliFiber (N = 73, L = 96), Colt Telecom (N = 153, L = 179)785 and Cogentco (N = 197, L = 245): see Knight et al. (2011) and Knight et al. 786 (2013) for more detail. We also used a topology corresponding to the former 787 network of the French company Free (V = 120, E = 167): see Ferre (2010). 788 Recall that the problem under study arises within the general context of 789 5G network slicing. As a consequence, we do not consider in our problem 790

begin $\mathcal{U}_R \leftarrow \emptyset$ build the weighted digraph $\mathcal{G} = (\mathcal{N}, \mathcal{L}, w)$ with $w_l = 1, \forall l \in \mathcal{L}$ for a=1 to A do find the shortest path p_s between s^a and t in \mathcal{G} $\mathcal{P}_R^a \leftarrow \{p_s\}$ end $\mathcal{C} \leftarrow \{\mathcal{P}_R^a, a \in \mathcal{A}\}$ repeat solve $DMP(\mathcal{U}_R)$ and record the current VNF placement \overline{x} solve $RAP(\overline{x}, \mathcal{C})$ with a Branch & Price algorithm using Algorithm 1 to generate new columns at each node of the search tree and record the updated collection of path subsets С if $Z^*_{RAP}(\overline{x}, \mathcal{C}) > 0$ then record the optimal flow routing \overline{f} $\mathcal{U}_R \leftarrow \mathcal{U}_R \cup \{\overline{f}\}$ end until $Z^*_{RAP}(\overline{x}, \mathcal{C}) \leq 0;$ end

Algorithm 2: Solution algorithm with an exact solution of the adversarial sub-problem

the whole physical network installed by the ISP but only the portion of this 791 network, i.e. the virtual network or slice, lent by the ISP to the customer 792 currently undergoing a DDoS attack. Thus, the bandwidth b_l of a link be-793 tween two nodes does not correspond to the total bandwidth of the physical 794 link installed by the ISP between these nodes but only to the portion of 795 this bandwidth allocated to the virtual network dedicated to the customer 796 under attack. This is why we randomly generated values of b_l correspond-797 ing to rather small transmission capacities. More precisely, the bandwidth 798 b_l of each link was randomly generated using a discrete distribution with a 799 support equal to $\{4.8, 12, 20, 40, 100\}$ Mbps. 800

Computing resources. R = 2 types of computing resources were taken into account at each node: the number of CPUs and the memory. We considered three types of nodes: low computing capacity with Cap = (8, 32), medium computing capacity with Cap = (40, 160) and high computing cabegin $\mathcal{U}_R \leftarrow \emptyset$ build the weighted digraph $\mathcal{G} = (\mathcal{N}, \mathcal{L}, w)$ with $w_l = 1, \forall l \in \mathcal{L}$ for a=1 to A do find the shortest path p_s between s^a and t in \mathcal{G} $\mathcal{P}_R^a \leftarrow \{p_s\}$ end $\mathcal{C} \leftarrow \{\mathcal{P}_R^a, a \in \mathcal{A}\}$ repeat solve $DMP(\mathcal{U}_R)$ and record the current VNF placement \overline{x} solve $RAP(\overline{x}, \mathcal{C})$ using Algorithm 1 and record the updated collection of path subsets \mathcal{C} solve $RAP(\overline{x}, \mathcal{C})$ as a mixed-integer linear program if $Z^*_{RAP}(\overline{x}, \mathcal{C}) > 0$ then record the optimal flow routing \overline{f} $\mathcal{U}_R \leftarrow \mathcal{U}_R \cup \{\overline{f}\}$ end until $Z^*_{RAP}(\overline{x}, \mathcal{C}) \leq 0;$ end

Algorithm 3: Solution algorithm with a heuristic solution of the adversarial sub-problem

pacity with Cap = (400, 1600). In each considered network topology, we 805 assign each node to a type according to its degree. Thus, nodes with a 806 degree less than 2 were assigned a low computing capacity, nodes with a de-807 gree between 3 and 5 were assigned a medium computing capacity and nodes 808 with a degree larger than 6 were assigned a high computing capacity. Table 3 809 provides a summary of the percentage of nodes assigned to each type (low, 810 medium and high computing capacity) for each considered network topology. 811 **VNFs.** V = 1 type of VNFs was considered requiring $\gamma^{1,1} = 4$ CPUs 812 and $\gamma^{1,2} = 16$ units of memory, providing a filtering capacity of $\phi^n = 16$ 813 Mbps, with a unit cost of $K^1 = 130$. 814

Attacks. The number of sources was set to $A \in \{5, 10, 15, 20, 30, 40\}$. In each instance, the sources and target of the attack were randomly selected. The intensity F^a of each attack (in Mbps) was randomly generated following the normal distribution $\mathcal{N}(50, 25)$.

For each considered network topology and value of A, we randomly gen-

Topology	N	L	%Low	%Medium	%High
IntelliFiber	73	96	62%	37%	1%
Colt Telecom	153	179	72%	24%	4%
Cogentco	197	245	59%	39%	2%
Free	120	167	66%	28%	6%

Table 3: Percentage of nodes assigned to a low, medium or high computing capacity for each network topology

erated 5 instances, leading to a total of 140 instances.

821 5.2. Results

Each generated instance was solved using Algorithms 2 and 3. In both 822 cases, the decision maker problem was solved as a mixed-integer linear pro-823 gram using the CPLEX 12.8.9 solver with the default settings. The adver-824 sarial sub-problem was solved using either the Branch & Price algorithm 825 embedded in the SCIP 7.0.0 solver (Algorithm 2) or the simplex and Branch 826 & Cut algorithms embedded in the CPLEX 12.8.9 solver (Algorithm 3). All 827 tests were carried out on an PC running under Windows 10 equipped with 828 an Intel Core i5-8350U processor (4 cores, frequency of 1.9GHz) and a 16 820 GB RAM with a 2400MHz speed. Note that the CPLEX 12.8.9 solver, in 830 its default settings, is set to use a number of threads equal to the number of 831 available cores whereas the SCIP 7.0.0 solver is by default single-threaded. 832

For each algorithm, each network topology and each considered value of *A*, we report in Table 4 the average value over the 5 corresponding instances of:

- Cost: the cost of the optimal VNF placement,
- #IT: the average number of iterations of the algorithm,
- #P: the total number of source-target paths added to C by column generation over the course of the algorithm,
- *Time*: the total computation time in seconds of the algorithm.

Algorithm 3 is an approximate solution algorithm which may provide a solution which is not feasible for the initial robust optimization problem, i.e. for Problem RVNFD. Indeed, as the adversarial sub-problem is solved

heuristically, the amount of malicious flow that will reach the target may 844 be underestimated in some cases so that the filtering constraints (13) added 845 to the decision maker problem may not be tight enough. In order to es-846 timate the impact of this heuristic resolution, we carry out the following 847 post-optimization analysis. We consider the optimal VNF placement \overline{x}_{app} 848 obtained with Algorithm 3. We solve problem $AP(\overline{x}_{app})$ exactly using the 849 Branch & Price algorithm. We then record AD the actual damage, i.e. the 850 amount of malicious flow which will actually reach its target, if we use the 851 VNF placement \overline{x}_{app} . We then compute the percentage of total unfiltered 852 flow % UF as $\% UF = \frac{100AD}{\sum_{a \in \mathcal{A}} F^a}$. We report in Table 4, for each set of 5 853 instances, #Inf the number of instances for which the solution obtained 854 with Algorithm 3 was infeasible and Max % UF the maximum percentage of 855 unfiltered flow. 856

Results from Table 4 first show that Algorithm 2 is able to provide optimal 857 solutions to the RO problem with a reasonable computational effort. Namely, 858 the average computation time, over the 140 considered instances, is 22s. 859 This performance is mainly explained by the fact that both the number 860 of iterations #IT of the algorithm (and as a consequence the number of 861 Constraints (13) of $DMP(\mathcal{U}_R)$) and the number of source-target paths #P862 generated by column generation (and as a consequence the number of flow 863 variables in $AP(\overline{x})$ stay limited. 864

However, the computation time of Algorithm 2 exceeds 60s for 10 out 865 of the 140 considered instances. This might be a problem as the decisions 866 on the VNFs deployment should be taken as quickly as possible after the 867 attack detection and identification. The approximate Algorithm 3 might 868 prove useful in such cases. It is namely able to provide optimal solutions 869 of the RO problem for 137 out of the 140 considered instances, and this 870 with an average computation time below 3s and a maximum computation 871 time of 25s. Moreover, for the 3 instances for which the solution provided 872 by Algorithm 3 did not comply with the original robust constraints (3), the 873 amount of malicious flow which could reach the target stays below 3%, which 874 seems acceptable. 875

876 6. Conclusion

This paper described a new robust optimization approach for the defense against Distributed Denial of Service (DDoS) attacks in the context of 5G

 Table 4: Numerical results

network slicing. More precisely, we considered the problem of optimally de-879 ploying virtual network functions in order to stop an ongoing DDOS attack. 880 We assumed that the target, sources and volume of the attack are identified 881 but that the exact routing of the illegitimate traffic on the network is not 882 known. To take into account these uncertainties, we proposed a robust opti-883 mization (RO) model and developed an adversarial approach to solve it. This 884 iterative approach is based on the decomposition of the initial problem into 885 a master problem and a sub-problem. The master problem is a restricted 886 version of the original RO problem in which only a finite number of possible 887 malicious flow routings are used to express the robust constraints. Consid-888 ering the current placement of VNF provided by the solution of the master 889 problem, the adversarial sub-problem seeks to find a malicious flow routing 890 that maximizes the amount of attack reaching its target. We tested the ef-891 ficiency of our algorithms on medium-sized randomly generated instances. 892 The results of computation experiments show that our approach is able of 893 providing optimal solutions in short computation times. 894

Current work suggests several possible directions for future research. In 895 terms of problem solving, it might be possible to further improve the decom-896 position approach by carrying out a polyhedral study of the problem and 897 developing new valid inequalities to help solving it more quickly. As for the 898 problem modeling, a first research direction could consist in studying a disag-899 gregated formulation of the robust filter constraints. This could ensure that 900 the instantiated VNFs will be able to stop all the malicious flows regardless 901 of the allocation of filtering capacities. It would also be interesting to study 902 how the legitimate traffic, which will consume network resources and whose 903 routing is also unknown, could be taken into account in the model. 904

905 Acknowledgement

The authors would like to thank Kahina Lazri and Paul Chaignon (Orange Labs Products & Services) for their highly appreciated help in understanding and modeling the optimization problem. We are also grateful to Claudia D'Ambrosio (Laboratoire d'Informatique de l'École Polytechnique, CNRS, France) and Andrea Lodi (Ecole Polytechnique Montréal, Canada) for their fruitful advice on the problem modeling and solving.
