Abstract

The synergistic effect of nuclear (S_n) and electronic (S_e) energy loss observed in some ABO_3 has attracted considerable attention due to the real possibility to modify various near-surface properties, such as the electronic and optical properties, by patterning ion tracks in the defective near-surface regions. In this study, we show that low-energy ion-induced disordering in conjunction with ionizing ion irradiation (18 MeV Si, 21 MeV Ni and 91.6 MeV Xe) is a promising approach for tailoring ion tracks in the near-surface of defective KTaO_3 . Experimental characterization and computer simulations reveal that the size of these latent ion tracks increases with S_e and level of pre-existing damage. These results further reveal that the threshold S_e value (S_e^{th}) for track creation increases with decreasing pre-damage level. The values of S_e^{th} increase from 5.02 keV/nm for a pre-existing fractional disorder of 0.53 to 10.81 keV/nm for pristine KTaO_3 . Above these thresholds, amorphous latent tracks are produced due local melting and rapid quenching. Below a disorder fraction of 0.08 and $S_e \leq 6.68$ keV/nm, the synergistic effect is not active, and damage accumulation is suppressed due to a competing ionization-induced damage annealing process. These results indicate that, depending on S_e and the amount of pre-existing damage, highly ionizing ions can either enhance or suppress damage accumulation in KTaO_3 , thus providing a pathway to tailoring defects states. Comprehending the conflicting roles of highly ionizing ions in defective ABO_3 oxides is vital for understanding and predictive modeling of ion-solid interactions in complex oxides, as well as for achieving control over ion track size in the near-surface of defective KTaO_3 .

1. Introduction

Near-surface modification by ion beams is still an open research topic in material science because it allows tailoring material properties by accurately controlling microstructural modifications at the atomic level [1–8]. Experimental studies [4,9,10] have revealed that ion irradiation is a promising technique to manipulate various near-surface properties of complex oxides, such as ABO_3 perovskites. The most studied near-surface property changes in perovskite materials include modified electronic [11–16] and optical [3,10,17–19] properties. Research has shown that irradiation of $KTaO_3$ with inert noble gases, having energies within the keV to MeV range, enables new functionalities of $KTaO_3$. For example, low-energy Ar irradiation has been successfully applied in the transformation of $KTaO_3$ from an insulator to a conducting material by creating oxygen vacancies [12]. On the other hand, impurities and defect scattering, which are intrinsically associated with both ion implantation [20–22] and ion irradiation [11,12] processes, can limit the mobility of electrons, particularly at low temperatures. Consequently, ion-beam processing can have contrasting effects on near-surface properties of materials. Thus, understanding and predicting the relationships between ion-irradiation conditions and damage evolution in $KTaO_3$ are critical for a diverse range of applications.

Since $KTaO_3$ and related oxide perovskites have been put forward as candidate materials to immobilize radioactive waste, several previous investigations [23–25] have mimicked the self-radiation effects of alpha decay, which produces alpha particles and recoil nuclei, by using low-energy ions that primarily undergo collisional energy loss with target nuclei (S_n). These studies have reported that collisional-damage accumulation leads to complete amorphization in $KTaO_3$, if the irradiation is performed below the critical amorphization temperature, T_c . Research has shown that T_c in $KTaO_3$ ranges from 640 to 880 K and decreases with decreasing ion mass [23,24].

Researchers have shown that the formation of buried amorphous layers for waveguide barriers in KTaO_3 via noble gas ion irradiation (e.g., He [26]) requires relatively high fluences that can lead to gas bubbles forming [4]. In this respect, heavier ions (e.g., Ar [4]) are more effective for generation of buried amorphous layers, because the ion fluences needed for amorphization are lower than for lighter ions. However, obtaining equivalent buried layer thicknesses, (typically a few micrometers), as in the case of helium ion irradiations, requires much higher ion energies [4]. Since electronic energy loss (S_e) constitutes the main deceleration process for high energy particles, the understanding of electronic excitations and ionization processes driven by S_e is important for the production of electro-optical devices based on nanoscale phase transformations and defects induced in the crystal structure by highly-ionizing ions.

Although irradiation with highly-ionizing ions provides a potential approach to the fabrication of waveguides in perovskites (e.g., KTaO_3), the response of KTaO_3 to such high-energy ions has not been studied in as much detail as low-energy ion-induced disordering and amorphization in KTaO_3 [23–25,27]. In fact, only one study [18] has focused on irradiation of KTaO_3 with swift heavy ions (SHIs), and they reported that irradiation of KTaO_3 with SHIs (358 MeV Ni, with $S_e \sim 13.8$ keV/nm) results in discontinuous latent ion track formation in pristine KTaO_3 . An ion track in materials is a cylindrical column of either defective crystalline or amorphous material along the ion path, which forms upon rapid quenching of a molten or high-temperature state produced by the dissipation of high electronic energy density via electron-phonon coupling to the atomic subsystem [4]. It has been demonstrated that the dimensions and structure of the ion tracks are dependent on S_e and material composition [4]. Moreover, there is generally a composition-dependent threshold in S_e (S_e^{th}) above which tracks are formed. Research has shown that the S_e^{th} value may be less than 1 keV/nm for polymers; whereas for metals, it can be greater than several tens of keV/nm [28]. It has also been

1
2
3 demonstrated that there is generally a substantial dependence of S_e^{th} values for track formation
4
5 on compositional changes within the same crystal structure. For example, the experimentally-
6
7 measured S_e^{th} for formation of discontinuous tracks in pristine SrTiO_3 is about 10 keV/nm
8
9 [29]; whereas for pristine KTaO_3 , it is determined to be 13.8 keV/nm [18].

10
11
12 A previous experimental study on the sensitivity of pre-damaged SrTiO_3 to highly-
13
14 ionizing ions has indicated that pre-existing defects have a synergistic effect on the dissipation
15
16 of electronic energy that enables the creation of amorphous tracks over the region of pre-
17
18 existing damage [30]. They reported that the S_e^{th} value for amorphous track creation in pre-
19
20 damaged SrTiO_3 is about 6.7 keV/nm. It is evident that the synergistic interaction between the
21
22 highly-ionizing ions and pre-existing defects dramatically reduces the S_e^{th} value (i.e., from 10
23
24 keV/nm to 6.7 keV/nm) for creation of such tracks. This same experimental study has also
25
26 revealed that the diameter of the tracks increases with the amount of pre-existing damage and
27
28 S_e of the incident ions. Molecular dynamics (MD) simulations have confirmed this synergistic
29
30 stimulation of amorphous track creation in both pre-damaged SrTiO_3 [31] and KTaO_3 [32] for
31
32 conditions corresponding to 21 MeV Ni ion irradiation ($S_e \sim 9.9$ and 10.16 keV/nm in SrTiO_3
33
34 and KTaO_3 , respectively). This synergistic effect in KTaO_3 was later experimentally validated
35
36 using 21 MeV Ni ions in a study on the irradiation response of pre-damaged KTaO_3 [33]. This
37
38 same experimental study also revealed that no measurable damage was produced in pristine
39
40 KTaO_3 (see inset of Fig. S1a), which suggests that the S_e^{th} value for track creation in pristine
41
42 KTaO_3 is greater than 10.16 keV/nm. Furthermore, this study reported that the effective track
43
44 diameter increases linearly with increasing S_e for low disorder levels, while track size tends to
45
46 saturate at high values of S_e and high disorder levels [33]. The existence of this dependence
47
48 was further corroborated by MD simulations [34]. More recently, Han et al. [18] have
49
50 indicated thresholds of about 12.0 and 13.8 keV/nm, respectively, for the creation of spherical
51
52 defects and discontinuous tracks in pristine KTaO_3 with 358 MeV Ni ions, which are in the
53
54
55
56
57
58
59
60

1
2
3 high velocity regime (i.e., ion energy above the peak in S_e). However, none of the existing
4
5 experimental and theoretical studies have determined S_e^{th} for this synergistic effect nor the
6
7 dependence of S_e^{th} on pre-damage levels in KTaO_3 .
8
9

10 Although the synergistic coupling of S_e dissipation with pre-existing defects may
11
12 dramatically enhance damage accumulation in some ABO_3 oxides, as revealed by the
13
14 measured rapid amorphization driven by track formation, this defect-stimulated track
15
16 formation may also have beneficial applications, such as the change in refractive index
17
18 relative to the pristine bulk crystal [3,35–37] that enables fabrication of waveguides and other
19
20 optical functionalities in the near-surface of defective KTaO_3 [17,18,38]. Since the electronic
21
22 conductivity of ion tracks (conducting material) may be enhanced relative to the bulk
23
24 insulating material, these conductive ion tracks may also be employed as durable field
25
26 emission cathodes [39]. Further development of these applications requires an improved
27
28 understanding of the spatial distribution, radial structure and radial stress of the ion tracks [4].
29
30 A precise determination of how ion track creation depends on S_e and initial damage-state may
31
32 offer new possibilities to better control the properties of ion tracks and their interfaces with
33
34 the surrounding matrix [40]. Therefore, the determination of the S_e^{th} value for track formation
35
36 and how it depends on initial pre-damage state can facilitate the selective design of ion tracks
37
38 in the near-surface of KTaO_3 by ion beams, which may provide new flexible approaches to
39
40 tailor the properties or functionality of perovskite materials for electro-optical applications.
41
42
43
44
45

46 In this study, the synergistic coupling of pre-existing defects with S_e dissipation is
47
48 explored in pre-damaged KTaO_3 irradiated with 18 MeV Si ions and 91.6 MeV Xe ions at 300
49
50 K, and the results are compared with those previously obtained using 21 MeV Ni ions [33]. In
51
52 this work, all ions are in the low velocity regime (i.e., below the peak in S_e) and the ion
53
54 energies yield S_e values below and above those reported for ionization-induced track creation
55
56 in pre-damaged KTaO_3 irradiated at a flux of 6×10^{10} ions/cm²·s with 21 MeV Ni ions [33]. As

aforementioned, accurate information on the S_e^{th} value is still missing and thus, a combined experimental and computational evaluation is employed to determine the S_e^{th} values for this synergistic effect and the dependence of S_e^{th} on the pre-damage level.

2. Experimental Procedures and Modelling

2.1. Irradiation and characterization

One set of three epi-polished, $\langle 100 \rangle$ -oriented, single crystal KTaO_3 wafers were pre-damaged at 300 K via irradiation with 2.0 MeV Au^{2+} ions to ion fluences of 6.4×10^{12} , 1.1×10^{13} , and 1.6×10^{13} ions/cm², with an average particle flux of 1.6×10^{10} ions/cm²·s, using the 3 MV Tandatron Cockcroft-Walton accelerator at IFIN-HH [41]. Irradiations with Au ions were carried out along a random-equivalent direction by tilting the sample 7° off the $\langle 100 \rangle$ orientation. A 2 MeV He beam was employed to perform ex-situ Rutherford backscattering spectrometry in a channeling configuration (RBS/C) along the $\langle 100 \rangle$ direction and along a random (off-channel) direction on the pristine KTaO_3 and on each irradiated area to evaluate the corresponding change in level of fractional disorder. The RBS/C measurements were performed with the silicon detector positioned at 165° from the direction of the incident beam. The disorder depth profile associated with each RBS/C spectrum was determined based on an iterative method that was originally applied to SrTiO_3 [42] and later used to quantify the irradiation-induced disorder in KTaO_3 [25]. In this analysis, a fractional disorder level of 0.0 refers to the unirradiated or pristine state, and a fractional disorder level of 1.0 corresponds to a random or completely amorphous structure. The initial maximum disorder fractions, f_0 , created in 2 MeV Au-irradiated KTaO_3 to fluences of 6.4×10^{12} , 1.1×10^{13} , and 1.6×10^{13} ions/cm² were 0.08, 0.30 and 0.53 on the Ta sublattice, respectively. In a previous study [25], we have shown that for KTaO_3 irradiated with low-energy noble gases at 300 K the damage accumulation exhibits a slow damage accumulation rate at low fluences (often referred to as step 1) and followed by a sharp rise of the accumulated damage (often referred to as step 2)

1
2
3 with ion fluence before amorphous state is achieved. In other word, these damage
4 accumulation curves exhibit sigmoidal behavior that was well described by a comprehensive
5 damage accumulation model. The model curve fits to the experimental data, have
6 demonstrated that point defects (and small point defect clusters) and amorphous nuclei are
7 produced in step 1 (relative disorder level ≤ 0.08) and 2, respectively. One should note that
8 the formation of larger defect clusters is disregarded in this model fits because their formation
9 is inhibited due to the nucleation of amorphous seeds at very early stages of damage
10 accumulation. Since the sample with $f_0 = 0.08$ corresponds to the end of step 1 just before the
11 sharp increase of the accumulated damage, only point defects (and small point defect clusters)
12 are expected to form in the sample irradiated to 1.6×10^{13} ions/cm². The sample with $f_0 = 0.3$
13 and 0.53 corresponds to the beginning and middle of step 2, respectively. Thus, a larger
14 amorphous fraction is to be expected in the sample irradiated to 1.6×10^{13} ions/cm² than in the
15 sample irradiated to 1.1×10^{13} ions/cm². Afterwards, these pre-damaged KTaO₃ samples were
16 subjected to irradiation at 300 K with 18 MeV Si⁶⁺ ions to fluences ranging from 1.0×10^{12} to
17 1.0×10^{13} ions/cm². The average ion flux was 2.1×10^9 ions/cm²·s to prevent macroscopic
18 heating and maintain the 300 K irradiation temperature. Pristine KTaO₃ was also irradiated
19 with 18 MeV Si ions under identical conditions for reference. The evolution of disorder with
20 increasing ion fluence in these irradiated samples was evaluated by RBS/C utilizing a 2.0
21 MeV He beam, as described above.

1
2
3 during the irradiations, all irradiations were implemented along a random direction by tilting
4 the crystal 7° off the surface normal. In-situ RBS/C, which were performed with 2.0 MeV He
5 ions and with the silicon detector positioned at 155° from the incident beam direction,
6 determined the damage profile and a peak disorder fraction of 0.08 on the Ta sublattice in the
7 pre-damaged KTaO_3 . A higher level of disorder was also produced at 300 K in another two
8 KTaO_3 wafers by 2.0 MeV Au ion irradiation to a fluence of 1.2×10^{13} ions/cm², which
9 resulted in a peak disorder fraction of about 0.33 for these pre-damaged samples. The pristine
10 and four pre-damaged samples were then irradiated at the GANIL facility (Caen, France) on
11 the IRRSUD beamline using 91.6 MeV ^{129}Xe ions to ion fluences of 1.0×10^{11} and 1.0×10^{12}
12 ions/cm². As in the case of the 18 MeV Si ion irradiations, the ion flux was 2×10^9 ions/cm²·s
13 to prevent sample heating. Disorder modifications in these SHI irradiated samples at each
14 fluence were determined utilizing RBS/C with a 2.0 MeV He beam, as described above.

31 The mean projected range of 2 MeV Au ions in KTaO_3 has been determined based on
32 SRIM simulations [44], which yielded a projected ion range, R_p , of ~ 260 nm and range
33 straggling, ΔR_p , of ~ 82 nm. Based on SRIM calculations, the ion fluences of 6.4×10^{12} to
34 1.6×10^{13} ions/cm² result in a peak concentration of implanted Au ions of ~ 0.0006 to ~ 0.001
35 at. %, respectively. Consequently, under these conditions, the damage evolution processes in
36 KTaO_3 are not expected to be significantly affected by changes in chemistry or local strain
37 associated with the implanted Au ions. In the case of the higher energy ions, the ion ranges
38 are substantially much larger (i.e., 4.5 and 7.85 μm in the case of 18 MeV Si and 91.6 MeV
39 Xe ions, respectively). Therefore, the high energy ions come to rest substantially past the pre-
40 damaged layer and do not add to measurable change in pre-damage disorder. The
41 corresponding depth profile of damage dose, in displacements per atom (dpa), in KTaO_3 for 2
42 MeV Au irradiation has been ascertained by summing the K, Ta, and O vacancies and atomic
43 replacements at each depth, which have been calculated using full-cascade SRIM simulations,

Table 1: SRIM predicted electronic energy loss (S_e), nuclear energy loss (S_n), and ratio S_e/S_n at a depth of 170 nm in KTaO_3 for each high energy ion used. The specific energy (E) is also included.

Ion/energy	S_e (keV/nm)	S_n (keV/nm)	S_e/S_n	E (MeV/u)
18 MeV ^{28}Si	6.16	0.018	342	0.64
21 MeV ^{58}Ni	10.16	0.121	84.0	0.36
91.6 MeV ^{129}Xe	23.18	0.220	105	0.71

as recently recommended [45]. In all SRIM calculations, the theoretical density for KTaO_3 (7.015 g/cm^3) was used, and a 25 eV displacement energy was assumed for all elements [23,24]. Additionally, the depth dependence of the projected energy losses, S_n and S_e , as well as the ratio S_e/S_n , were predicted using the SRIM code, and the values at the depth of the pre-damage peak are summarized in Table 1.

Both a pristine sample and a pre-damaged sample of KTaO_3 irradiated with 91.6 MeV Xe ions were also analyzed by transmission electron microscopy (TEM). A focused ion beam approach, followed by ion milling with low-energy Ar, was used for preparing the cross-sectional samples for TEM. The TEM results are provided in the Supplementary material.

2.2. Computer simulations of track evolution

Molecular dynamics simulations have been integrated with a model for the inelastic thermal spike [46] in order to evaluate the dissipation of S_e and evolution of ion tracks from irradiation with 18 MeV Si, 21 MeV Ni and 91.6 MeV Xe ions in pre-damaged KTaO_3 . The model for the evolution of the inelastic thermal spike has its foundation in the two-temperature description of heat dissipation in the electronic and atomic subsystems, which describes the transfer of S_e to the atomic subsystem via electron-phonon coupling. As reported previously for KTaO_3 [32,34], the electronic energy dissipation profile transferred to the atomic structure for a given ion and energy is established by the inelastic thermal spike model. This calculated energy dissipation profile for each ion is incorporated as input to the

1
2
3 MD simulations to determine the response to each thermal spike event. For the thermal spike
4 calculations in pre-damaged KTaO_3 , we used lattice and electronic thermal conductivity
5 reduced by a factor of ten compared to the values for pristine KTaO_3 , as discussed previously
6 [20]. The mean free electron path used for KTaO_3 with 11% pre-existing Frenkel pairs (FPs)
7 is 2.2 nm and for KTaO_3 with 30% pre-existing FPs is 1.9 nm [20].
8
9

10
11
12
13
14 The DL_POLY code [47] was used for the MD simulations, with empirical potentials
15 [48] smoothly merged to the ZBL scattering (repulsive) potentials [44] for close interatomic
16 distances. The systems have a size of $26.5 \text{ nm} \times 26.5 \text{ nm} \times 60 \text{ nm}$ and periodic boundaries.
17
18 The initial disorder levels of 11 and 30% FPs were generated by randomly introducing FPs
19 into the simulation cell, which is intended to qualitatively reproduce the presence of an initial
20 fractional disorder peak, f_0 , of ~ 0.11 and 0.30 , respectively (see RBS/C results). The
21 simulation cells with FPs were equilibrated under a constant temperature and pressure
22 ensemble before injecting the thermal spike in the z direction of the simulation cell. The
23 thermal-spike simulations were performed in the microcanonical ensemble. Energy scaling at
24 the boundaries of the simulation cell along the x and y dimensions was applied using a
25 Langevin thermostat with a width of 10 \AA . A simple geometric criterion based on small
26 sphere, with a cut-off radius of 0.75 \AA , was used to distinguish defects [49] in the simulation
27 cell.

48
49 The distributions of relative disorder with depth for the Au-irradiated KTaO_3 , with and
50 without subsequent irradiation with 18 MeV Si^{6+} ions, are shown in Figs. 1(a-c). These
51 damage depth distributions were derived, using an iterative procedure [42], from the RBS/C
52 spectra provided in Figs. S1(a-c) (supplementary material). Only best-fit curves to the actual
53 data are provided for visual lucidity. In Fig. 1(b), the depth profile of local damage dose (dpa)
54

1
2
3 derived from full-cascade SRIM simulations for KTaO_3 irradiated with 2 MeV Au ions to
4
5 1.1×10^{13} ions/cm² is included for reference, and the peak in damage dose occurs at depth of
6
7 about 170 nm. For the low initial disorder level of ~ 0.08 (Fig. 1a), subsequent 18 MeV Si ion
8
9 irradiation to a relatively low fluence of 1.0×10^{12} ions/cm² causes a small decrease in the
10
11 amount of disorder. Upon further irradiation to higher fluences, 1.0×10^{12} ions/cm² to 1.5×10^{12}
12
13 ions/cm², the measured disorder slightly increases, but is still lower than the initial damage
14
15 level of 0.08. Surprisingly, the measured disorder again starts to decrease slightly with
16
17 increasing Si fluence from 1.5×10^{12} to 8.0×10^{12} ions/cm². On the other hand, for the higher
18
19 initial levels of pre-existing disorder, f_0 , in KTaO_3 (i.e., about 0.30 (Fig. 1b) and 0.53 (Fig.
20
21 1c)), subsequent irradiations with 18 MeV Si^{6+} ions dramatically enhance damage
22
23 accumulation, as evidenced by the increase of fractional disorder over the entire damage
24
25 profile with increasing Si fluence. This accelerated damage accumulation clearly indicates a
26
27 synergistic coupling between energy dissipation by highly ionizing ions and pre-existing
28
29 defects, which triggers ion track formation within the pre-damaged region [30,33]. One can
30
31 note that the Ta disorder peak in the pre-damaged samples shifts slightly to deeper depths
32
33 with increasing Au ion fluence or level of disorder. This is generally due to some relaxation of
34
35 the irradiation-induced normal tensile strain and formation of defect clusters at the damage
36
37 peak [50–53] in conjunction with the potential chemical effects of the implanted ion species
38
39 [54]. Since the SRIM calculations indicate that the peak Au concentration does not exceed
40
41 0.001 at.%, the chemical effects of the implanted ions may be ruled out [55]. It is, however,
42
43 important to also note that the peaks in increased disorder due to the 18 MeV Si ions are
44
45 nearly at all the same depths (as predicted by the SRIM damage peak), independent of the Au
46
47 ion fluence. This clearly suggests that the actual irradiation-induced pre-damage profiles are
48
49 responsible for the synergistic effects. The oscillating changes in the relative disorder level
50
51 with Si fluence at low initial disorder level, as shown in Fig. 1(a), indicates that for the sample
52
53
54
55
56
57
58
59
60

1
2
3 with the lowest initial damage level (~ 0.08), the synergistic effect is not active, and may in
4 fact be competing with a damage annealing process, as observed in SrTiO_3 [56]. In other
5 words, a threshold disorder level above 0.08, but below 0.30, is required to stimulate track
6 formation in pre-damaged KTaO_3 with 18 MeV Si ions.
7
8
9

10
11
12 While there is no evidence for damage production in pristine KTaO_3 irradiated with 18
13 MeV Si ions (see inset of Fig. S1a), there is obvious evidence for disorder production in the
14 pristine KTaO_3 following irradiation with 91.6 MeV Xe ions (see Fig. S2(a) in the
15 supplementary material). Similar disorder production was also previously observed in pristine
16 SrTiO_3 irradiated with SHIs (629 MeV Xe and 946 MeV Au) [40]; whereas in pristine SrTiO_3
17 irradiated with lower energy and lighter mass ions (i.e., lower S_e), no measurable damage was
18 produced [30]. Following the approach of Xue et al. [40] for analysis of the RBS/C spectra
19 from pristine and pre-damaged SrTiO_3 irradiated with SHIs, the net growth in RBS yield,
20 $\chi(n)_{\text{net}}$, for channel number, n , has been determined for the pre-damaged KTaO_3 following
21 subsequent irradiation with 91.6 MeV Xe ions utilizing the expression:

35
36
37

$$\chi(n)_{\text{net}} = \chi(n)_{\text{df}} - \chi(n)_{\text{ps}} + \chi(n)_{\text{vg}} \quad (1)$$

38
39
40
41
42 where $\chi(n)_{\text{df}}$, $\chi(n)_{\text{ps}}$ and $\chi(n)_{\text{vg}}$ are the RBS/C yields measured from a defective (i.e., pre-
43 damaged) region following subsequent irradiation with 91.6 MeV Xe ions, from a pristine
44 region that was irradiated with only 91.6 MeV Xe ions, and from the reference virgin region,
45 respectively. Since disorder production (i.e., ion tracks) is observed in the pristine KTaO_3
46 following irradiation with 91.6 MeV Xe ions, the amount of this disorder should be subtracted
47 from the disorder in pre-damaged KTaO_3 following irradiation with SHIs using Eq. (1) in
48 order to accurately evaluate the actual dechanneling fraction. This approach allows better
49 quantitative correlation of ion track dimensions with the amount of pre-damage and was

2
3 applied to determine $\chi(n)_{\text{net}}$ from the RBS/C spectra provided in Figs. S2b and S2c
4 (supplementary material). Figures 2(a,b) show the fractional Ta disorder with depth extracted
5 from $\chi(n)_{\text{net}}$ by the same iterative procedure as above. In this procedure, the dechanneling
6 contribution of disorder in the irradiated crystals is determined and subtracted from $\chi(n)_{\text{net}}$ to
7 ascertain the fractional Ta disorder, f_a , with depth for pre-damaged KTaO_3 with and without
8 subsequent irradiation with 91.6 MeV Xe ions. By default, this procedure does subtract the
9 background contribution of tracks for a given fluence to the disorder, consistent with Eq. (1)
10 over the whole depth of analysis, and this contribution is accounted for in subsequent analysis
11 below. In the sample with an initial fractional disorder peak, f_0 , of ~ 0.08 (Fig. 2a), the results
12 reveal no significant change, beyond experimental uncertainty, in the disorder profiles of the
13 pre-damaged KTaO_3 samples prior to and after 91.6 MeV Xe ion irradiation to 1.0×10^{11}
14 ions/cm², which also does not produce significant disorder in the pristine KTaO_3 (Fig. S2a)
15 With increase in ion fluence to 1.0×10^{12} ions/cm², the relative disorder increases significantly
16 in the pristine sample (Fig. S2a) and in the pre-damage sample (i.e., from ~ 0.08 to 0.4), both
17 of which agree with the high track densities recorded in the TEM micrographs provided in
18 Fig. S3. In the case of KTaO_3 with $f_0 = 0.33$, subsequent irradiation with 91.6 MeV Xe ions to
19 1.0×10^{11} ions/cm² increases the relative disorder from 0.33 to 0.36. Unfortunately, the sample
20 with the highest pre-damage level ($f_0 = 0.33$) and subsequently irradiated with 91.6 MeV Xe
21 ions to 1.0×10^{12} ions/cm² exhibited some microcracking on the surface, and thus it was
22 impossible to perform meaningful RBS/C analysis on this sample. Similar cracks have been
23 reported in BaTiO_3 irradiated with 635 MeV $^{238}\text{U}^+$ ions to 1.4×10^{12} ions/cm² and were
24 ascribed to volumetric swelling associated with amorphous tracks or lattice stresses from an
25 irradiation-induced phase transition [57]. Cracking due volume swelling associated with
26 amorphous tracks may explain the observed cracking in the present study, since the density of
27 amorphous tracks and volume swelling should increase with Xe fluence and full

4 5 *3.2 Thermal spike model results*

6
7
8 Figure 3 (a) shows the calculated radial profiles of lattice temperature in KTaO_3 with
9
10 11% and 30% FPs for thermal spikes corresponding to 18 MeV Si ions, 21 MeV Ni ions and
11
12 91.6 MeV Xe ions. In Fig 3 (a), the melting temperature, T_m , of KTaO_3 is indicated by a
13
14 horizontal line. The maximum lattice temperature during the inelastic thermal spike increases
15
16 with ion energy (i.e., S_e), as illustrated in Fig. 3(a). The lattice temperature depends on both
17
18 the pre-damage level and the magnitude of the electronic energy loss (S_e). The pre-damage
19
20 level affects the electron-phonon coupling strength and the heat conductivity, and S_e
21
22 level affects the electron-phonon coupling strength and the heat conductivity, and S_e
23
24 determines the amount of energy available to transfer to the lattice. The defects increase
25
26 electron-phonon coupling and, consequently, the profile of energy transferred to the atomic
27
28 structure [20]. For example, given the same disorder level of 30% FPs, but different energy
29
30 loss due to 18 MeV Si (green curve) and 91.6 MeV Xe (red curve), the lattice temperature is
31
32 higher for the higher energy loss, and the heat dissipates within a cylinder along the ion path
33
34 with larger radius (10 nm vs 15 nm for the 18 MeV Si and 91.6 MeV Xe ions, respectively).
35
36 As shown in Fig. 3b, the ion track diameter is affected accordingly, and depends on both the
37
38 pre-damage level and the electronic energy loss. The synergistic effect between the pre-
39
40 damage and the electronic energy loss depends on the combination of the level of the pre-
41
42 existing damage and the electronic energy loss.
43
44
45

46
47 Figures 3(b-e) show cross-sectional areas (15 nm \times 15 nm in size) of the simulation
48
49 cell at the end of each thermal spike simulation (80 - 180 ps). The track shown in Fig.3(b) is
50
51 formed in KTaO_3 containing 30 % FPs due to a thermal spike corresponding to an 18 MeV Si
52
53 ion. This is the smallest track obtained, with a diameter of 2.6 ± 0.1 nm, and corresponds to
54
55 the lowest temperature profile shown in Fig. 3(a). Figures 3(c, d) show the tracks due to
56
57 thermal spikes, equivalent to 21 MeV Ni ions, in KTaO_3 with 11% and 30 % FPs,
58
59
60

1
2
3 respectively; the corresponding track diameters are 3.3 ± 0.2 nm and 5.7 ± 0.2 nm [20]. In
4
5 Figs. 3(e,f), the amorphous ion tracks due to 91.6 MeV Xe in KTaO_3 with 11% and 30 % FPs
6
7 are shown, with track diameters of 7 ± 0.1 nm and 9.7 ± 0.2 nm, respectively.
8
9

10 **4. Discussion**

11
12 Based on the disorder profiles in Figs. 1 and 2, the dependence of relative Ta disorder, f_a , on
13
14 fluence in pre-damaged KTaO_3 samples irradiated with 18 MeV Si ions or 91.9 MeV Xe ions
15
16 has been ascertained at several depths (i.e., 50, 75, 100, and 170 nm). The results are shown in
17
18 Figs. 4 and 5, as a function of ion fluence (ions/nm² = 10^{14} ions/cm²), for 18 MeV Si and 91.6
19
20 MeV Xe irradiation, respectively. At each depth, the value of f_a has a minimum value, f_0 , that
21
22 corresponds to the initial pre-damaged level and increases with depth until a maximum value
23
24 of f_0 is achieved at the damage peak (i.e., 170 nm). Thus, each fit of the direct-impact model
25
26 (see dash lines in Figs. 4 and 5) has its own f_0 value. As shown in Figs. 4 and 5, the
27
28 synergistic coupling between electronic energy dissipation from highly ionizing ions with pre-
29
30 existing damage dramatically enhances damage accumulation in KTaO_3 . Previous studies of
31
32 pre-damaged ABO_3 perovskites (e.g. KTaO_3 [33,34], SrTiO_3 [30], LiTaO_3 [58], and LiNbO_3
33
34 [59,60]) that were subsequently subjected to highly-ionizing ion irradiation have
35
36 unambiguously established that the growth of any pre-existing defect clusters or amorphous
37
38 domains due to elastic collisional processes is negligible because of the very low S_n of the
39
40 ions while traversing the pre-damaged region. Thus, the effects of any collisional-induced
41
42 defects due to S_n are negligible in this region. In other words, point defect production and
43
44 aggregation do not contribute to the enhanced damage accumulation observed in KTaO_3 (see
45
46 Figs. 4 and 5). Consequently, the S_e -induced formation of continuous or discontinuous
47
48 amorphous ion tracks is the primary process responsible for the enhanced disordering rate in
49
50 KTaO_3 with pre-existing damage. It is well established [28,61] that indirect methods (i.e.,
51
52 RBS/C) are more powerful in quantifying the size of discontinuous ion track than direct
53
54
55
56
57
58
59
60

1
2
3 observation methods (i.e., TEM), as well as quantifying the size of continuous ion tracks in
4
5 the presence of high pre-existing damage levels. It should also be mentioned that indirect
6
7 methods are particularly useful for determining S_e^{th} values, which are difficult to assess by
8
9 TEM [61] because track radii are often lower than 2 nm for low S_e values and are obscured by
10
11 the presence of high pre-damage levels, such as in the present study. Therefore, a direct-
12
13 impact model [62,63] is utilized to describe the increase in relative disorder at constant depth
14
15 with increasing ion fluence for both 18 MeV Si and 91.6 MeV Xe ions. In this direct-impact
16
17 description, the amorphous fraction, f_a , at a specific depth from the defect-stimulated
18
19 component of track formation is given by:
20
21
22
23
24
25

$$26 \quad f_a = 1 - (1 - f_0) \times \exp(-(\sigma_a - \sigma_p) \times \Phi) \quad (2)$$

27
28
29
30 where σ_a is the cross-sectional area of the tracks in the pre-damaged region, σ_p is the cross-
31
32 sectional area of the tracks in pristine KTaO_3 , which is subtracted in the analysis of RBS/C
33
34 spectra, Φ is the ion fluence, and f_0 is the initial fractional disorder level in pre-damage
35
36 KTaO_3 . Here, σ_p is determined by implementing a direct-impact model to describe the ratio, r ,
37
38 which is the fractional disorder induced in pristine material by ion tracks [40] (discussed in
39
40 supplementary material) and is therefore given by:
41
42
43

$$44 \quad r = 1 - \exp(-\sigma_p \times \Phi) \quad (3)$$

45
46 If the creation of amorphous latent ion tracks in pristine KTaO_3 is disregarded ($\sigma_p = 0$), the
47
48 amorphous fraction from track formation given by Eq. (2) is simplified [see Eq. (4)].
49
50
51

$$52 \quad f_a = 1 - (1 - f_0) \times \exp(-\sigma_a \times \Phi) \quad (4)$$

Eq. (4) has been previously used to evaluate the dependence of σ_a on pre-damage level in KTaO_3 following 21 MeV Ni ion irradiation [33]; however, that study revealed that no measurable damage was produced in pristine KTaO_3 , as in the present work for 18 MeV Si ions (see Figs. S1a-c). This is not surprising because the S_e values for both Si (6.16 keV/nm) and Ni (10.16 keV/nm) ions are significantly lower than the recently measured S_e^{th} value for discontinuous track formation in pristine KTaO_3 (~ 13.8 keV/nm) [18]. Thus, in the present study, Eq. (4) is fit to the measured change in disorder with increasing ion fluence for 18 MeV Si ions, as shown in Figs. 4(a,b) by the dashed curves, and the dependence of the derived model parameter, σ_a , on initial disorder level is given in Fig. 4(c). Below an initial disorder levels of 0.35, σ_a exhibits a linear dependence on initial disorder level for 18 MeV Si ions that shows an initial disorder level threshold of 0.1 for track creation under these conditions. which is consistent with the observation of no evidence for synergistic track creation in pre-damaged KTaO_3 with an initial peak disorder level of 0.08 and subsequently irradiated with 18 MeV Si ions. The disorder profiles shown in Fig. 1(a) support linear correlation between σ_a and initial disorder. The initial disorder level threshold of 0.1 for creation of tracks in KTaO_3 with 18 MeV Si ions is larger than that previously reported for KTaO_3 irradiated with 21 Ni ions (0.03) [33]. This finding unambiguously establishes that the threshold disorder level for track formation in KTaO_3 increases with decreasing values of S_e for incident ions. A similar linear correlation between σ_a and initial disorder has been previously observed in SrTiO_3 [30]. In previous MD simulations [32,34], it has been shown that this linear increase in σ_a with initial disorder is consistent with increases in electron-phonon coupling and decreases in thermal conductivity due increased electron and phonon scattering from the defects. Consequently, the radial thermal spike profile is notably affected, which directly influences the depth dependence of amorphous track size. The current MD simulations validate the track

1
2
3 sizes, determined by an indirect method (i.e., RBS/C), in pre-damaged KTaO_3 irradiated with
4
5 18 MeV Si ions.
6

7
8 Wesch et al. [64,65] and Kamarou et al. [66–69] have previously reported on SHI
9
10 irradiation effects in pristine semiconductors and showed that the ratio, r , at depths beyond a
11
12 narrow surface layer (tens of nanometer) is nearly constant. This indicates that the track size
13
14 is relatively uniform for a nearly constant S_e over a large depth region. These studies
15
16 suggested that the thin surface layer remains almost undamaged because the charge state of
17
18 the incident ion is significantly less than the mean equilibrium charge state in the sample, and
19
20 r was determined only at one depth behind the undamaged narrow surface layer [67,68]. Thus,
21
22 in this study, the values of r in pristine KTaO_3 were determined from the RBSC spectra (Fig.
23
24 S2) at a depth of 70 nm using the Kamarou et al. method [68,69], and the dependence of r on
25
26 91.6 MeV Xe ion fluence is given in Fig. 5(a). The particulars of this analysis are provided in
27
28 the supplementary material. Furthermore, Eq. (3) has been fit to the increase in r with fluence
29
30 in Fig. 5(a), and the value of σ_p for 91.6 MeV Xe ions in pristine KTaO_3 was determined. This
31
32 cross section, σ_p , for track formation in pristine materials is used in Eq. (2) to fit the change in
33
34 disorder in pre-damaged KTaO_3 with increasing Xe ion fluence, as illustrated in Figs. 5(b,c),
35
36 where the dashed curves represent the best fits of Eqs. (2) and (3) to the data, which yield σ_a .
37
38 Considering a nearly circular amorphous cross-section, an equivalent ion track diameter, d , is
39
40 given by:
41
42
43
44
45
46
47
48

$$49 \quad d^2 = 4\sigma_a/\pi \quad (5)$$

50
51
52
53
54 The properties and conditions for track formation in pre-damaged KTaO_3 at 300 K are
55
56 now discussed in more detail. The effective track diameters as functions of initial disorder for
57
58 18 MeV Si and 91.6 MeV Xe ions in KTaO_3 are illustrated in Fig. 6(a); along with data for 21
59
60

1
2
3 MeV Ni ions [33]. The curves in Fig. 6 are just polynomial or spline fits to the data. In
4
5 KTaO₃ with an initial disorder level of $f_0 = 0.33$, the tracks formed by irradiation with 18
6
7 MeV Si ions, have an average diameter of 2.7 ± 0.3 nm. This experimentally determined track
8
9 diameter is consistent with that obtained from MD simulations (2.6 ± 0.1 nm for 30 % FPs).
10
11 With an increase in level of pre-existing disorder to $f_0 = 0.53$ in KTaO₃, the average diameter
12
13 of the tracks due to 18 MeV Si ions increases to 5.9 ± 0.6 nm. Similar to the 18 MeV Si
14
15 irradiation, an increase of ion track diameter with increasing pre-existing disorder level has
16
17 been reported for 21 MeV Ni ions [33], and the experimentally determined track diameters for
18
19 91.6 MeV Xe ions are 3.3 ± 0.2 nm, 8.0 ± 0.4 nm, and 14.3 ± 0.7 nm, for initial disorder
20
21 levels, f_0 , of 0.0, 0.08 and 0.33, respectively. While there is some difference in the ion fluxes
22
23 for these ions, the ion fluxes ($< 6 \times 10^{10}$ ions/cm²·s) are not expected to increase the
24
25 temperature or affect track size. The MD simulations reveal that for increasing pre-existing
26
27 damage level, the lattice temperature within the thermal spike increases because the defects
28
29 increase the electron-phonon coupling leading to more radially confined energy dissipation to
30
31 the lattice, as shown in Fig.3(a). In general, higher temperatures form larger track sizes [4].
32
33 The results further show that, for low levels of initial disorder, track size exhibits a linear
34
35 relationship with the pre-existing disorder level in KTaO₃. As the initial disorder level
36
37 increases in KTaO₃, the track diameters tend to saturate, which agrees with previous results
38
39 obtained at 300 K for 21 MeV Ni ions [33] and previous MD simulations [32]. For the same
40
41 initial disorder level, the results in Fig. 6(a) reveal that smaller average track sizes are created
42
43 for 18 MeV Si ions than for either 21 MeV Ni and 91.6 MeV Xe ions. In other words, the
44
45 average track size increases as S_e increases, which is consistent with the increasing thermal-
46
47 spike temperature with increasing S_e , as observed in the MD simulations.
48
49
50
51
52
53
54
55

56 To better highlight this effect, track cross sections for pristine and defective KTaO₃,
57
58 irradiated with Si, Ni and Xe ions, are depicted versus S_e in Fig. 6(b), along with results for
59
60

1
2
3 358 MeV Ni ion irradiation of pristine KTaO_3 [18]. Note that the value of f_0 is labeled for
4 each irradiation condition in Fig. 6(b). As shown in Fig. 6(b), for pristine KTaO_3 ($f_0 = 0.0$) and
5
6 for a low initial peak disorder level ($f_0 = 0.08$), the measured track cross sections increase
7
8 linearly with S_e . With an increase in level of pre-existing disorder to $f_0 = 0.33$ in KTaO_3 , the
9
10 track cross section increases linearly for S_e values below 10 keV/nm, but tends to saturate for
11
12 higher S_e values. As evidenced in Fig. 6(b), no tracks are detected in pristine KTaO_3 irradiated
13
14 with ions having S_e less than 10 keV/nm (i.e. 21 MeV Ni ions); whereas swift heavy ions
15
16 (e.g., 91.6 MeV Xe ions) produce ion tracks in pristine KTaO_3 . It has been reported that S_e
17
18 values above 12.0 keV/nm may be required to form ion tracks in pristine KTaO_3 [18]. The
19
20 threshold value, S_e^{th} , for track creation at different pre-damage levels can be extracted from
21
22 the results in Fig 6(b), and the values of S_e^{th} are provided in Fig. 6(c) as a function of initial
23
24 level of disorder. It is obvious that the value of S_e^{th} shifts to higher values with decreasing
25
26 initial disorder level. For example, while a minimum value of S_e^{th} is achieved for a high initial
27
28 disorder level (i.e., ~ 5.02 keV/nm for $f_0 = 0.53$), a maximum value is achieved for pristine
29
30 KTaO_3 (i.e., ~ 10.81 keV/nm for $f_0 = 0.0$). It is also striking to note that the value of S_e^{th}
31
32 decreases slowly from 6.68 keV/nm to 5.02 keV/nm as f_0 increases from 0.08 to 0.53,
33
34 respectively; while on the other hand, S_e^{th} increases rapidly for f_0 values below 0.08, up to a
35
36 value of 10.81 keV/nm for pristine KTaO_3 . These results indicate that this synergistic track
37
38 formation has a strong dependence on both the initial level of pre-damage in KTaO_3 and the
39
40 values of S_e for the incident ions. Experimental [70,71] and theoretical [72] studies have
41
42 determined that for the same values of S_e , measured track radii are larger in the low velocity
43
44 regime than in the high velocity regime [73]. Although similar dependencies are predicted for
45
46 KTaO_3 [18], additional studies are required for a comprehensive understanding of the
47
48 relationship between S_e^{th} and ion velocity.

3 As aforementioned, the current MD simulations validate the observed trends for
4 experimentally determined track sizes in pre-damaged KTaO_3 irradiated with highly ionizing
5 ions. An example is provided in Fig. 7, which compares the track sizes determined via RBS/C
6 and MD in pre-damaged KTaO_3 with an initial disorder level of $f_0 = 0.33$ and 30 %
7 preexisting FPs, respectively. The MD results confirm that the track size increases linearly for
8 S_e values below 10 keV/nm, but tends to saturate for higher S_e values. However, this
9 comparison indicates that the experimentally determined track sizes are larger compared to
10 the ones determined by MD. As discussed previously [34], the main sources of this
11 discrepancy are the estimated values of the e-ph coupling parameter and an inaccurate
12 correlation between disorder (measured by ion channeling) and the MD FP concentration.
13 Additionally, the ion channeling measurements determine an average size of a large number
14 of tracks, while the MD values are an average of measurements along one track.

30 Finally, this study reveals that a threshold disorder level above 0.08 (i.e., 0.1) is
31 required to stimulate track formation in pre-damaged KTaO_3 with 18 MeV Si ions (see Fig.
32 4c). Below this value, an equilibrium between damage recovery and damage production
33 processes is observed (see Fig .1a). In other word, the synergistic effect is not active. These
34 findings indicate the existence of two processes for a low initial damage level ($f_0 \sim 0.10$): (1)
35 $S_e > 6.16$ keV/nm, where the synergistic effect is active, and (2) $S_e < 6.16$ keV/nm, where
36 athermal annealing from the thermal spike associated with S_e competes with damage
37 production. Highly ionizing ions with $S_e < 6.16$ keV/nm may promote defect recovery in
38 KTaO_3 by enhancing the mobility of point defects via thermal spikes that do not achieve
39 melting or ionization-induced diffusion [74], as observed in SrTiO_3 [56]. A more quantitative
40 understanding of these processes requires additional investigation of this competitive
41 (recovery) effect on defect production and evolution in defective KTaO_3 .

58 **5. Conclusions**

59
60

1
2
3 Improved understanding and advanced models of electronic energy loss (S_e) effects on
4 ion track creation in defective solids may provide new pathways to control ion track creation and
5 properties and thus more flexibility to tailor properties and functionalities of complex oxides for
6 a range of applications. In this regard, the synergy of pre-existing damage states with the
7 dissipation of S_e from highly ionizing ions has been studied for single crystal KTaO_3 . The results
8 demonstrate that this synergistic interaction enhances formation of amorphous ion tracks, and the
9 dimensions of these amorphous tracks exhibit a strong dependence on S_e and the level of pre-
10 existing disorder. The results further reveal the threshold values, S_e^{th} , for this synergistic effect
11 and their dependence on pre-damage level, which was the research goal. The values of S_e^{th}
12 increase from 5.02 keV/nm for a pre-existing fractional disorder of 0.53 to 6.68 keV/nm for a
13 pre-existing fractional disorder level of 0.08 and to 10.81 keV/nm for pristine KTaO_3 . Above
14 these thresholds, amorphous latent tracks are produced due to local melting and rapid quenching
15 processes. Below a disorder fraction of 0.08 and $S_e \leq 6.68$ keV/nm, this synergistic effect is not
16 active and may in fact be in equilibrium with a damage annealing process. While there is no
17 evidence for ion track creation in pristine KTaO_3 for ions with $S_e < 10$ keV/nm, swift heavy ions
18 with $S_e > 11$ keV/nm (e.g., 91.6 MeV Xe ions) create ion tracks in pristine KTaO_3 . Moreover, for
19 a given level of pre-existing damage, the average track size increases with S_e . These findings
20 indicate that it is possible to tune track size and location in a material by selective control of
21 initial pre-damaged level and the electronic energy loss deposited by highly ionizing ions.

Fig.1. Relative Ta disorder as a function of depth for pre-damaged KTaO_3 irradiated with 18 MeV Si ions at 300 K to different ion fluences: (a) maximum initial disorder fraction $f_0 = 0.08$; (b) $f_0 = 0.30$ and (c) $f_0 = 0.53$. In (b), the SRIM-derived damage dose (dpa) profile (right axis) for a fluence of 1.1×10^{13} Au ions/ cm^2 , is included for comparison. The experiment uncertainty for the curves is estimated to be $\sim 15\%$, which is mainly attributed to the statistics of the backscattering spectra [75] and to the standard deviation in fitting the experimental disorder profiles.

Fig. 2. Relative Ta disorder as a function of depth for pre-damaged KTaO_3 irradiated with 91.6 MeV Xe ions at 300 K to different fluences: (a) maximum initial disorder fraction $f_0 = 0.08$ and (b) $f_0 = 0.33$. The experiment uncertainty is estimated to be $\sim 15\%$, which is mainly attributed to the statistics of the backscattering spectra [51] and to the standard deviation in fitting the experimental disorder profiles.

Fig. 3. (a) Radial profiles of lattice temperature in KTaO_3 with 11 % and 30 % pre-existing Frenkel pairs for ions and energies in this study. (b-f) Cross sections of the irradiated systems at the end of each simulation, at times 180 ps, 80 ps, 98 ps, 100 ps, and 112 ps, respectively. All cross-sectional areas shown have size 15×15 nm. K atoms are shown in red, Ta atoms in grey and O atoms in purple.

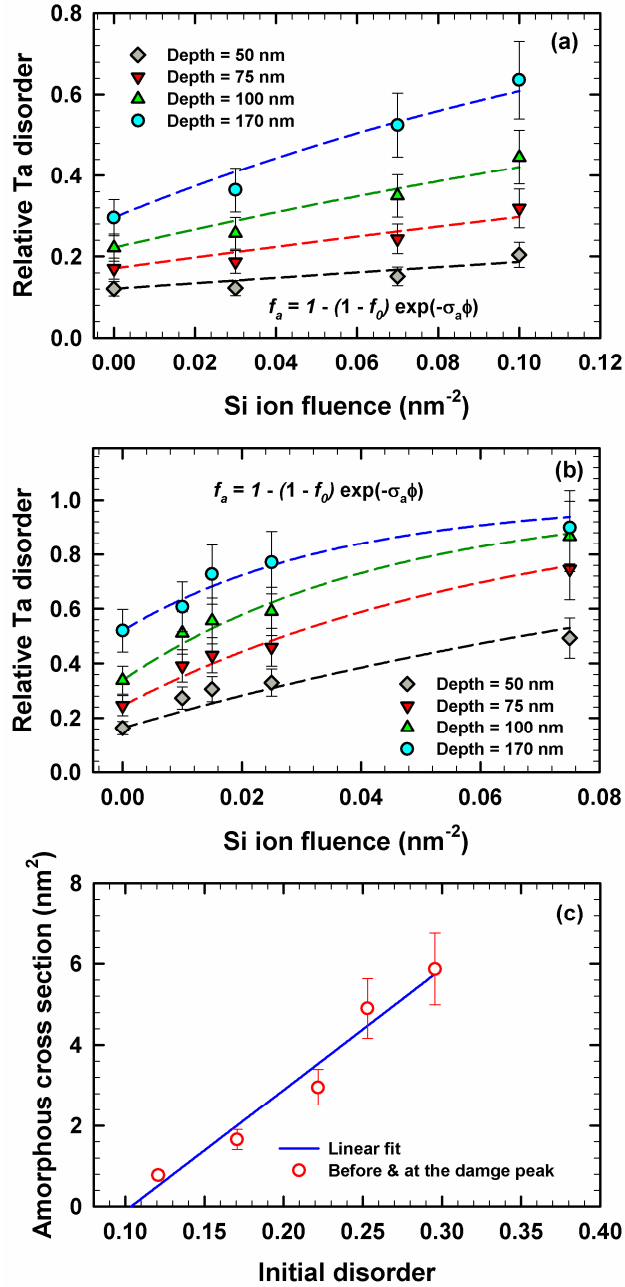

Fig. 4. Relative Ta disorder in pre-damaged KTaO₃ as a function of Si ion fluence (ions/nm² = 10¹⁴ ions/cm²) at different depths, along with curve fits of direct-impact model (Eq. 4): (a) maximum initial disorder fraction $f_0 = 0.30$ and (b) $f_0 = 0.53$. (c) Dependence of amorphous cross-section on initial level of disorder in KTaO₃.

Fig. 5. Relative Ta disorder in KTaO_3 as a function of Xe ion fluence ($\text{ions}/\text{nm}^2 = 10^{14} \text{ ions}/\text{cm}^2$) at different depths: (a) pristine or $f_0 = 0.00$, (b) $f_0 = 0.08$ and (c) $f_0 = 0.33$. Eq. (3) has been fit to data in (a), while Eq. (2) has fit to data in (b) and (c).

Fig. 6. Track formation in pre-damaged KTaO₃ at 300 K: (a) dependence of track diameter on initial disorder; (b) track cross section as a function of electronic energy loss; and (c) dependence of S_e^{th} for track formation on initial disorder. The error bars in determining track diameter is estimated to be $\sim 10\%$, which is mainly attributed to the standard deviation in track cross section from fit of direct impact model [31].

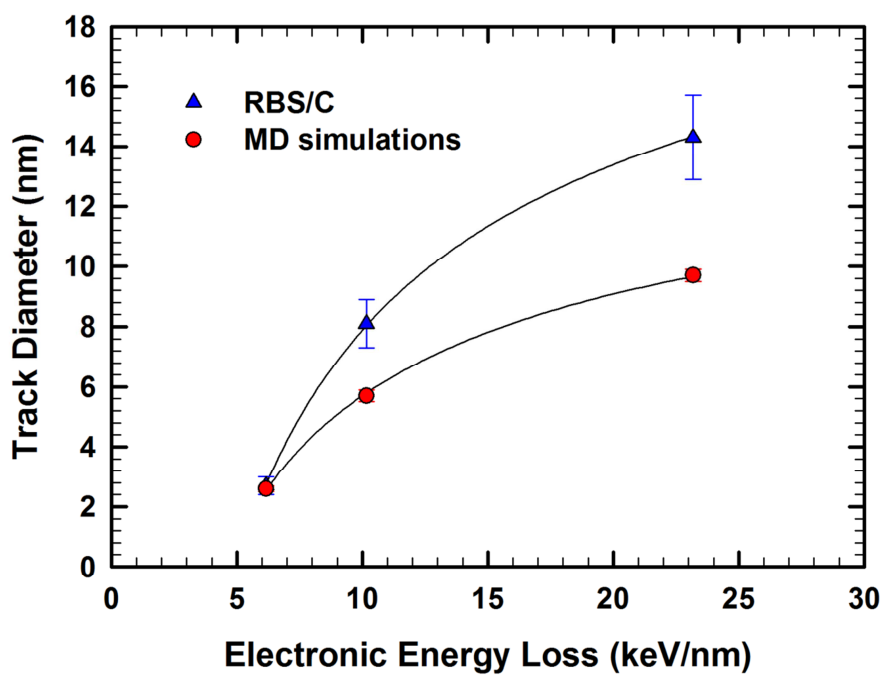

Fig. 7. Comparison of the determined track sizes via RBS/C and MD in pre-damaged KTaO_3 with an initial disorder level of $f_0 = 0.33$ and 30 % preexisting FPs, respectively (the error bars are $\sim 10\%$ [31]). The curves in Fig. 7 are just polynomial fits to the data.

RBS/C spectra

The RBS/C spectra for 18 MeV Si irradiated single crystal KTaO₃, with an initial damage created by 2 MeV Au ions, are shown in Fig. S1, along with the random equivalent and channeling spectra from the pristine sample. As shown in Fig. S1a, 18 MeV Si ions do not produce significant damage in KTaO₃ when a very low initial pre-damage state (relative disorder peak of 0.08) is present. The inset of Fig. S1a presents the RBS/C spectra recorded before and after irradiation with 18 MeV Si ions to a fluence of 8.0×10^{12} ions/cm². These spectra do not exhibit any perceptible difference in yield, beyond the uncertainty of the experimental measurements, indicating that 18 MeV Si irradiation did not induce any significant damage in the near surface region (≤ 1 μm) accessible to RBS/C. Similar results have been previously reported for 21 MeV Ni ions [1]. In contrast, the RBS/C spectra in Fig. S1b clearly exhibit enhanced damage accumulation under 18 MeV Si irradiation when a higher pre-existing damage state (relative disorder peak of 0.3) is present, as evidenced by rapid increase in the Sr and Ti yields with increasing Si ion fluence. The damage accumulation is accelerated with increasing level of pre-existing disorder in KTaO₃, as shown in Fig. S1c (relative disorder peak of 0.53).

The high-channel region of the ion channeling spectra (i.e., the Ta sublattice) from the 91.6 MeV Xe irradiated pristine KTaO₃ single crystals is shown in Fig. S2a,

Supplementary Material

together with the random and channeling spectra from a pristine crystal. The spectra recorded in the $\langle 100 \rangle$ -axial direction on the Xe-irradiated crystals exhibit, as compared to those for pristine samples, an increase in the backscattering yield with increasing ion fluence due to the accumulation of ionization-induced damage. The ion channeling spectra recorded from Au-irradiated KTaO_3 with and without subsequent irradiation with 91.6 MeV Xe ions, are shown in Fig. 2b and c. As shown in Fig. S2b and c, the presence of pre-existing damage states accelerates the increase in the backscattering yield, which suggests that substantially more damage is produced in the defective lattice than in the pristine region. This rapid increase in backscattering yields at low Xe ion fluences indicate direct impact amorphization along the ion path. The irradiation-induced fractional disorder due to 91.6 MeV Xe ions in KTaO_3 is quantified by the ratio, r , of the relative backscattering yield to the amorphous level: $r = (\chi_d - \chi_p) / (\chi_a - \chi_p)$, where χ_d , χ_p and χ_a are the backscattering yields at 170 nm (channel 1718) in the irradiated region, in the pristine reference sample without ion irradiation and in amorphous KTaO_3 , respectively. This procedure has been previously used to quantify the high energy ion irradiation-induced disorder in other ABO_3 (e.g., SrTiO_3 [R2] and LiTaO_3 [R3]) and semiconductors (e.g., InP [4,5], InSb [R4], GaAs [R4], GaP [5], Ge [5], and Si [R4]). The measured damage profiles, shown in Fig. 1 and 2 for the Au ion irradiations, exhibit a nearly Gaussian shape with the damage maximum appearing at a depth of about 170 nm, i.e. very close to the maximum of the SRIM-predicted damage peak (Fig. 1b); this is why the ratio, r , is calculated at 170 nm. The RBS/C spectra plotted in Fig. S2a reveal that irradiation of pristine KTaO_3 with 91.6 MeV Xe to an ion fluence of 1.0×10^{11} ions/cm² leads to a small, but measurable, increase in the value of r (from 0.0 % to ~ 0.21 %). As 91.6 MeV Xe ion fluence increases from 1.0×10^{11} to 1.0×10^{12} ions/cm², the value of r increases significantly from ~ 0.21 to 10.4 %. As shown in Fig. S2b, the presence of a low initial level of damage (~ 0.08) enhances the increase of the ratio r (from ~ 12 to 59 %). This suggests that the average amorphous cross-sections are larger in the pre-damaged regions than in the pristine regions.

Supplementary Material

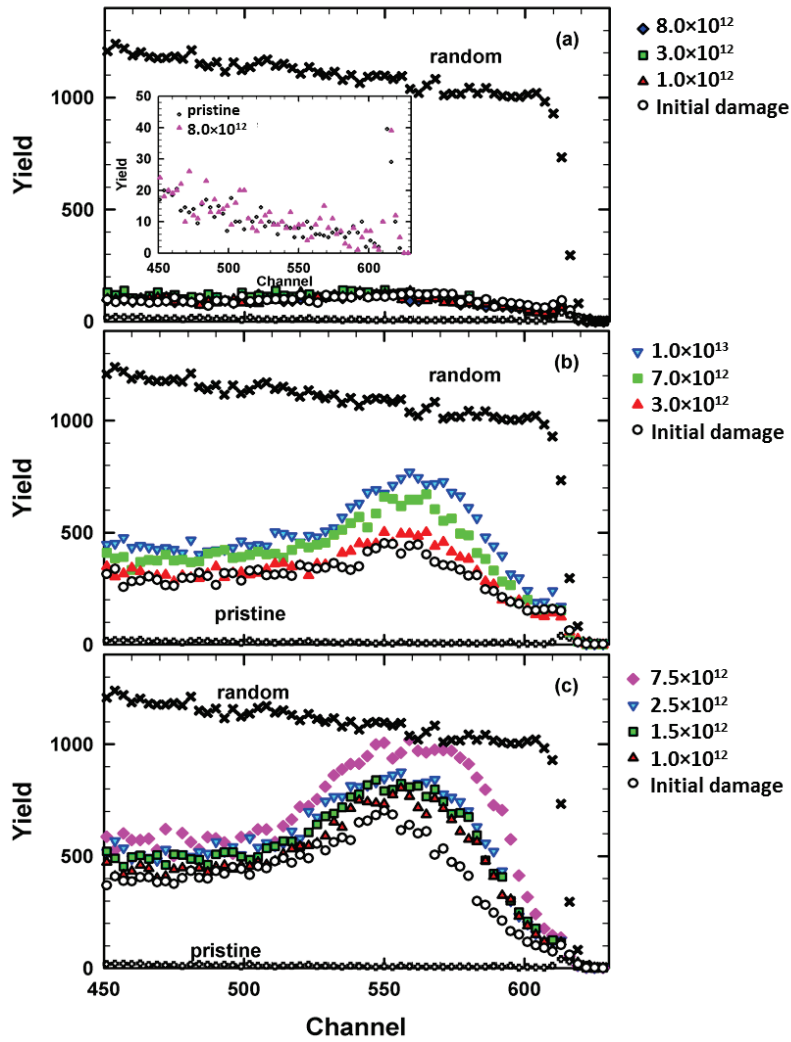

Figure S1: Several RBS/C spectra, after irradiation with 18 MeV Ni for defective KTaO₃ with a maximum disorder level of: (a) 0.08, (b) 0.3, and (c) 0.53. The inset shows the RBS/C results for 18 MeV Si irradiations on pristine KTaO₃ for an identical ion fluence of 8.0×10^{12} ions/cm². Random and channeling spectra from a pristine KTaO₃ sample are also included.

Supplementary Material

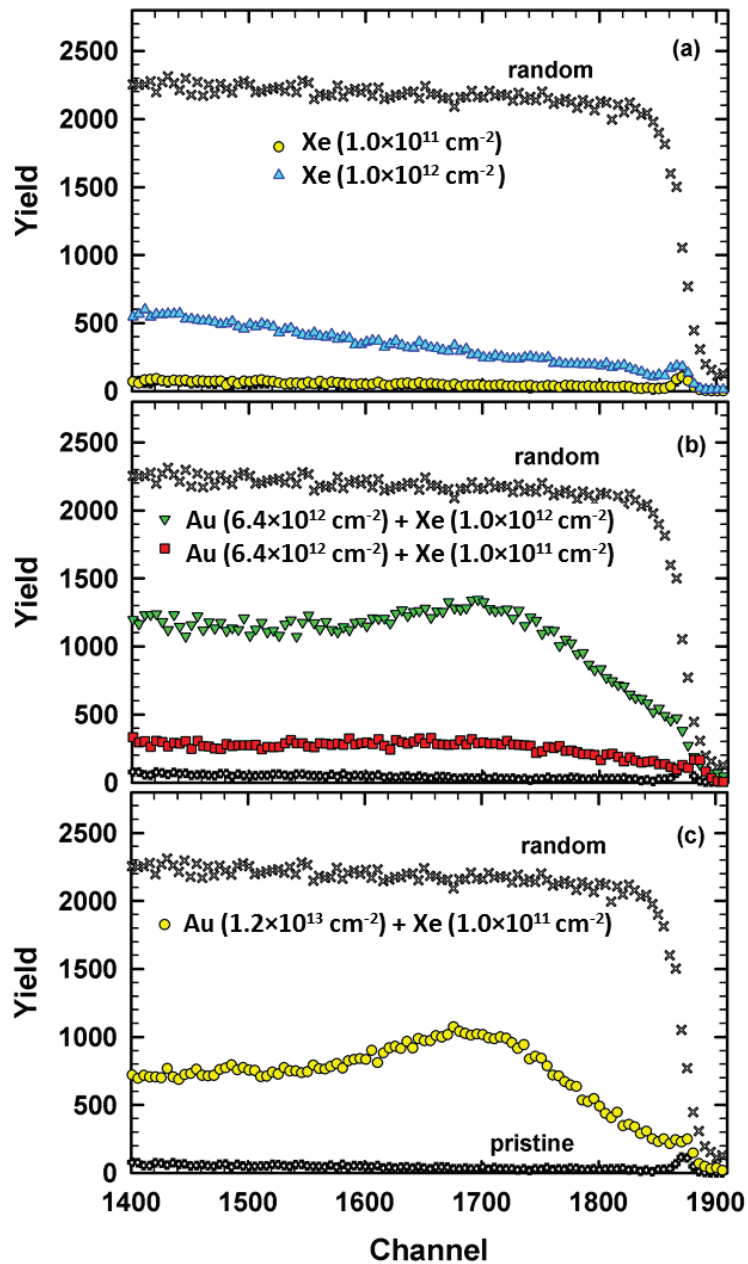

Figure S2: Several RBS/C spectra, after irradiation with 91.6 MeV Xe for: (a) pristine KTaO_3 without pre-damage, (b) defective KTaO_3 with a maximum disorder level of 0.08, and (c) defective KTaO_3 with a maximum disorder level of 0.33. Random and channeling spectra from a pristine KTaO_3 sample are also included.

Supplementary Material

Fig. S3. KTaO_3 irradiated with 91.6 MeV ^{129}Xe ions to a fluence of 10^{12} ions/ cm^2 : (a) pristine sample; (b) sample pre-damage with 2 MeV Au ions to a fluence of 6.4×10^{12} ions/ cm^2 . The yellow arrow indicates the depth of the pre-damaged peak.

TEM results

The irradiated samples were fragile and beam sensitive. The cross-sectional TEM images for pristine and pre-damaged KTaO_3 are shown in Fig. S3. The high density of tracks in the pristine irradiated sample is visible in Fig. S3(a) and consistent with the ion fluence. These observations of high track densities in KTaO_3 for a high value of S_e (23.18 keV/nm) are consistent with the discontinuous track formation reported by Han et al. [6] in pristine KTaO_3 irradiated with 358 MeV Ni ions at lower values of S_e (13.8 keV/nm), which is close to the threshold for track formation. In the pre-damaged sample, there is some evidence for individual ion tracks near the surface, but in the highly pre-damaged region, individual tracks are obscured by the pre-existing damage, as shown in Fig. S3(b).
