**Abstract:** The linear trinuclear complex cation  $[\text{Fe}_3(\text{DpyF})_4]^{2+}$  was prepared as  $[\text{Fe}_3(\text{DpyF})_4](\text{BF}_4)_2 \cdot 2\text{CH}_3\text{CN}$ . With large Fe–Fe distances of 2.78 Å, this complex demonstrates intramolecular ferromagnetic coupling between the anisotropic  $\text{Fe}^{\text{II}}$  centers ( $J/k_{\text{B}} = +20.9(5)$  K) giving an  $S_{\text{T}} = 6$  ground state and exhibits single-molecule magnet properties.

The pursuit of molecule-based magnetic storage units has inspired enormous scientific activity, with a key challenge being the conception of new single-molecule magnets (SMMs) working at liquid nitrogen temperatures or above.<sup>1</sup> One approach has been to increase the thermal energy barrier of the Orbach-like relaxation by maximizing the ground spin state. Although very high spin polynuclear complexes can be obtained,<sup>2</sup> negligible magnetic anisotropy often results in a poorly isolated ground state. To overcome this, one strategy is to increase the intramolecular magnetic coupling using, for example, radical-based spin mediators to promote the parallel alignment of the metal spins (i.e. an effective ferromagnetic coupling which is independent of the nature of the magnetic interaction between the bridging radical and metal centers).<sup>3</sup>

Ferromagnetic coupling (FM) can also be observed in direct metal-metal interactions, particularly for valence-delocalized iron clusters,<sup>‡</sup> which often exhibit maximal ground spin states.<sup>4</sup> The simplest examples include di-iron paddlewheel complexes, such as an  $\text{Fe}^{\text{I}}\text{-Fe}^{\text{I}}$  complex with an intermetallic distance of 2.127 Å ( $S_{\text{T}} = 3$ ),<sup>5</sup> mixed-valent  $\text{Fe}^{\text{II}}\text{-Fe}^{\text{I}}$  complexes<sup>6</sup> with distances of *ca.* 2.2 Å ( $S_{\text{T}} = 7/2$ ), and two  $\text{Fe}^{\text{II}}\text{-Fe}^{\text{II}}$  complexes with distances of 2.287 and 2.462 Å ( $S_{\text{T}} = 4$ ).<sup>7</sup> The face-sharing bioctahedral  $S_{\text{T}} = 9/2$  complex  $[(\text{Me}_3\text{tacn})_2\text{Fe}_2(\mu^2\text{-OH})_3]^{2+}$ , has yet a longer Fe–Fe distance of 2.510 Å.<sup>8</sup> Eventually, the Fe–Fe distance becomes too large to mediate spin coupling; as in  $\text{Fe}_2(\mu\text{-DPhBz})_2(\eta^2\text{-DPhBz})_2$  ( $d_{\text{Fe-Fe}} = 3.124$  Å), with a magnetic moment compatible with non-interacting  $S_{\text{Fe}} = 2$  centres.<sup>7a</sup>

Clusters with three iron ions can adopt a triangular or, more rarely, a linear arrangement of atoms. Examples of high-spin triangular complexes include the mixed-valent  $S_{\text{T}} = 11/2$   $\text{Fe}_3$  (and related  $S_{\text{T}} = 19/2$   $\text{Fe}_6$ ) clusters, with Fe–Fe distances ranging from *ca.* 2.4 to 2.7 Å.<sup>9</sup> Maximal spin states have also been predicted for linear iron clusters,<sup>10</sup> although only four such compounds have been reported. Recently, a trinuclear compound with three bridging 2,6-bis[(trimethylsilyl)amido]pyridine ligands was obtained with FM coupling between the  $\text{Fe}^{\text{II}}$  centers (2.442 Å).<sup>11</sup> Additionally, the tetranuclear complexes  $\text{Fe}_4(\text{tpda})_3\text{Cl}_2$ <sup>12</sup> and  $\text{Fe}_4(\text{tpda})_3\text{Br}_2$ ,<sup>13</sup> with mixed bridging-chelating tripyridyldiamido modes and long Fe–Fe distances of > 2.9 Å, were modelled as consisting of two FM coupled  $\text{Fe}_2$  pairs, with antiferro-

**Figure 1.** Thermal ellipsoid (50%) diagram of the cation in **1** at 270 K from single crystal X-ray diffraction data.

prepared the  $\text{BF}_4^-$  analogue  $[\text{Fe}_3(\text{DpyF})_4](\text{BF}_4)_2$  to study its static and dynamic magnetic properties.  $[\text{Fe}_3(\text{DpyF})_4](\text{BF}_4)_2 \cdot 2\text{CH}_3\text{CN}$  (**1**, Figure 1) was synthesized using an adaptation of the literature protocol,<sup>14</sup> by refluxing  $\text{LiDpyF}$ ,  $\text{FeCl}_2$  and  $\text{TlBF}_4$  in THF and recrystallizing the ensuing pale yellow precipitate from the diffusion of diethyl ether into an acetonitrile solution (ESI). It crystallizes in the space group  $I4/m$  (Table S1) such that the four fold axis is co-linear with the metal axis and the central  $\text{Fe}^{\text{II}}$  ion is bisected by a glide plane perpendicular to the metal axis, giving one unique  $\text{Fe}(1)\text{--Fe}(2)$  distance of 2.7838(5) and 2.7742(6) Å at 270 and 100 K, respectively. The cation displays distorted octahedral terminal  $\text{Fe}^{\text{II}}$  sites and a tetrahedrally distorted square planar central  $\text{Fe}^{\text{II}}$  ion (Table S3). The terminal  $\text{Fe}(1)\text{--N}$  distances average 2.191[2] Å for both temperatures, while the central  $\text{Fe}(2)\text{--N}(2)$  distance is 2.1436(18) and 2.1431(18) Å (Table S2), consistent with HS  $\text{Fe}^{\text{II}}$  centres and similar to those reported for  $[\text{Fe}_3(\text{DpyF})_4](\text{PF}_6)_2$ .<sup>14</sup> One of the  $\text{BF}_4^-$  anions and the solvent molecules could not be modelled atomistically; solvent masking in Olex 2<sup>16</sup> suggested the presence of two acetonitrile molecules per formula unit.

The static magnetic susceptibility,  $\chi$ , was measured on a polycrystalline sample of **1** mixed with mineral oil (Figure 2). The  $\chi T$  value at 300 K is  $15.3 \text{ cm}^3 \text{ K mol}^{-1}$ , significantly higher

**Figure 2.** Temperature dependence of the  $\chi T$  product (where  $\chi$  is the molar magnetic susceptibility ( $M/H$ ) per complex and  $T$  the temperature) in an applied dc magnetic field of 0.1 and 1 T for **1**. Inset: Field dependence of the magnetization for **1** below 8 K. Solid lines are the best fits to the model described in the text.

magnetic (AF) inter-pair interactions. In 1998, a tri-iron cluster with a similar mixed coordination mode,  $[\text{Fe}_3(\text{DpyF})_4](\text{PF}_6)_2$ , ( $\text{DpyF}$  = dipyritylformamide), was reported to have a room-temperature  $\chi T$  value of  $16 \text{ cm}^3 \text{ K mol}^{-1}$ , much higher than that expected for three isolated  $\text{Fe}^{\text{II}}$  centers, once again suggesting FM coupling between the  $\text{Fe}^{\text{II}}$  spins.<sup>14</sup>

Motivated by our interest in the magnetic properties of linear clusters,<sup>15</sup> we have

than the sum of Curie constants for three uncoupled high-spin  $\text{Fe}^{\text{II}}$  centers ( $9.0 \text{ cm}^3 \text{ K mol}^{-1}$  for  $g = 2$ ). Upon decreasing the temperature, the  $\chi T$  value increases continuously, reaching a maximum value of  $25.8 \text{ cm}^3 \text{ K mol}^{-1}$  at 22 K, revealing dominant FM coupling between the three  $\text{Fe}^{\text{II}}$   $S = 2$  spins. The maximum value is higher than that expected from an  $S_T = 6$  system ( $21.0 \text{ cm}^3 \text{ K mol}^{-1}$ ,  $g = 2$ ), suggesting the contributions from orbital momentum, leading to a  $g$  factor higher than 2 (as expected for high-spin octahedral  $\text{Fe}^{\text{II}}$  centers). Below 20 K, the  $\chi T$  value at low field (0.1 T) decreases slightly to reach a minimum value of  $21.7 \text{ cm}^3 \text{ K mol}^{-1}$  at 1.85 K, likely due to magnetic anisotropy

and/or AF interactions between cation moments. Variable field magnetization data below 8 K (Figure 2, inset and Figure S1), do not saturate even at 7 T, reaching a maximum value of  $10.7 \mu_B$ , lower than the  $12 \mu_B$  expected for an  $S_T = 6$  species. This high field feature, and the non-superposition of the  $M = f(HT^{-1})$  curves (Figure S1), strongly suggest the presence of a significant magnetic anisotropy. In the literature, magnetic data for linear iron clusters have been treated either using an exchange-coupled model, when FM exchange is weak ( $|J/k_B| < 50$  K)<sup>7b,12</sup> or a delocalized macrospin model in the strong coupling limit ( $|J/k_B| > 300$  K).<sup>9a,9c</sup> In the present case, a simple macrospin model would not capture the temperature dependence of the  $\chi T$  product (Figure 2), and therefore the experimental data were fitted numerically (PHI<sup>17</sup>) considering the following anisotropic Heisenberg Hamiltonian:

$$\hat{H} = -2J(\hat{S}_{\text{Fe}-1} \cdot \hat{S}_{\text{Fe}-2} + \hat{S}_{\text{Fe}-2} \cdot \hat{S}_{\text{Fe}-3}) + 3D_{\text{Fe}}\hat{S}_{\text{Fe},z}^2$$

where  $J$  denotes the intramolecular interaction between  $\text{Fe}^{\text{II}}$  spins,  $\hat{S}_{\text{Fe}-i}$  is the spin operator for each metal ion centre ( $S_{\text{Fe}} = 2$ ) and  $D$  is the axial ZFS parameter. The best fit parameters,  $J/k_B = +20.9(3)$  K,  $D/k_B = -6.2(2)$  K and  $g = 2.23(5)$ , reproduce well the experimental data shown in Figures 2 and S1. Notably, the fit was not significantly improved by incorporating a rhombic ZFS parameter or intermolecular interactions in the model and degraded strongly upon forcing  $D$  to be positive. The estimated FM interaction in  $[\text{Fe}_3(\text{DpyF})_4](\text{BF}_4)_2 \cdot 2\text{CH}_3\text{CN}$  ( $J/k_B = +20.9$  K) is slightly larger than in  $\text{Fe}_4(\text{tpda})_3\text{X}_2$  ( $J/k_B = +10.1$  to  $+15.4$  K),<sup>12,13</sup> which possess longer Fe–Fe distances ( $> 2.9$  Å vs.  $2.78$  Å).

Further insight into the ground state electronic structure on the cation in **1** was obtained using density functional theory (DFT) as implemented in ORCA v.4.2.1,<sup>18</sup> using X-ray coordinates adjusted to  $D_{2d}$  symmetry without further optimization. The performance of DFT in describing exchange coupling has been reviewed extensively,<sup>19</sup> and the choice of functional has a substantial impact, particularly in cases where the ground state involves FM exchange. Following recommendations from Illas et al.,<sup>20</sup> we discuss here results obtained with the hybrid B3LYP functional,<sup>21</sup> and the sensitivity of the results to other choices is discussed in ESI. We have identified a number of different FM configurations with  $S_T = 6$ , along with a broken-symmetry (AF) state which is an approximate quintet with  $M_S = 2$ . The lowest-energy configuration does indeed prove to be FM ( ${}^{13}\text{B}_2$ ,  $S_T = 6$ ): The  $\text{Fe}^{\text{II}}$  manifold of Kohn-Sham orbitals is shown in Figure 3, with only the  $\square$ -manifold shown here for simplicity. The orbital array shows the 15 metal-based orbitals split into a lower band of 10 that are approximately Fe–N non-bonding and a higher band of 5 that are Fe–N antibonding. The very different local coordination environments of the terminal and inner  $\text{Fe}^{\text{II}}$  ions (octahedral and distorted square-planar, respectively), lead to different high-spin electronic configurations: for the two terminal  $\text{Fe}^{\text{II}}$  ions, the 6<sup>th</sup> (spin- $\beta$ )  $3d$  electron occupies a  $d_{z^2}$  orbital ( $1a_1$  and  $1b_2$  in Figure 3), while for the inner  $\text{Fe}^{\text{II}}$  ion, the 6<sup>th</sup> electron occupies a  $d_{xy}$  orbital ( $1b_1$ ), with Fe–Fe  $\delta$  character. The  $\sigma$  manifold therefore makes a FM contribution to exchange coupling through a spin delocalization/double exchange mechanism (see inset in Figure 3), while the  $\delta$  manifold makes an AF superexchange contribution according to the Goodenough-Kanamori rules, albeit a weak one due to the limited  $\delta$  overlap. The sum of the two components, FM coupling in the  $\sigma$  manifold and weak AF coupling in  $\delta$ , gives rise to the FM alignment observed in the magnetic measurements.

**Figure 3.** Kohn-Sham orbital energy diagram for the  $^{13}B_2$  ground state of  $[Fe_3(DpyF)_4]^{2+}$ . Interactions with  $\sigma$ ,  $\pi$ ,  $\delta$  and  $\delta'$  symmetry are mediated by  $d_{z^2}$ ,  $d_{xz/yz}$ ,  $d_{xy}$  and  $d_{x^2-y^2}$  orbitals, respectively. Eigenvalues and eigenfunctions shown are for the spin- $\beta$  manifold. Isosurfaces are shown only for the orbitals of  $\sigma$  and  $\delta$  symmetry that are involved in Fe-Fe exchange coupling. The schematic configurations shown in the inset illustrate the FM and AF contributions of double- and superexchange in the  $\sigma$  and  $\delta$  manifolds, respectively.

external dc-field led to appearance of frequency and temperature dependent ac signals (Figures 4 and S2, ESI), revealing the slow dynamics of the magnetization and consequently, its SMM properties. The  $\chi'$  vs.  $\nu$  and  $\chi''$  vs.  $\nu$  data at 1.9 K in different dc-fields (Figure S2, ESI) and at different temperatures under 0.2 T (Figure 4) were fit to the generalized Debye model<sup>23</sup> to obtain the field and temperature dependence of the magnetization relaxation time ( $\tau$ ) characteristic of this  $S_T = 6$  SMM (Figure S5). To analyse the paramagnetic relaxation, four mechanisms are usually invoked: quantum tunneling of the magnetization (QTM),<sup>24,25</sup> Orbach-type (i.e., thermally activated, Arrhenius behavior),<sup>25-27</sup> Raman<sup>27</sup> and direct<sup>28</sup> processes. The paramagnetic relaxation rate ( $\tau^{-1}$ ) can be then decomposed in four terms:

$$\tau^{-1} = \tau_{Raman}^{-1} + \tau_{Direct}^{-1} + \tau_{Arrhenius}^{-1} + \tau_{QTM}^{-1}$$

possessing their own thermal and dc-field dependences with a collection of eight independent parameters:

The electronic structure can be mapped onto the Heisenberg ladder using a broken-symmetry state with  $M_S = 2$ , where the spin moment on the central Fe ion is inverted relative to the FM ground state. While the near orbital degeneracy of the Fe<sup>II</sup> ion complicates the mapping of spin-state energies onto a simple Heisenberg-type Hamiltonian,<sup>22</sup> we can use the computed energies of the  $S_T = 6$  and  $M_S = 2$  states to extract an estimate of the exchange coupling constant,  $J/k_B = +43.2$  K (ESI). While this number is higher than the experimental value of +20.9 K, it is within the normal range of accuracy shown by DFT in the FM regime.

The dominance of FM coupling, the detection of magnetic anisotropy and a negative  $D$  value led us to investigate potential SMM properties. In the absence of an external dc-field, no frequency dependence in either the in-phase ( $\chi'$ ) or out-of-phase ( $\chi''$ ) component of the ac susceptibility was observed above 1.8 K with ac frequencies up to 10 kHz (ESI). The application of an

$$\tau^{-1} = C \frac{1 + C_1 H^2}{1 + C_2 H^2} T^n + A T H^m + \tau_0^{-1} \exp\left(-\frac{\Delta}{k_B T}\right) + \frac{B_1}{1 + B_2 H^2}$$

Considering that the magnetization relaxation is observed in a small experimental window (0.02-1 T, 1.8-3 K, 0.115-10 kHz; Figure S5), it is unreasonable to try to extract accurately the whole set of parameters. Nevertheless, a few hypotheses can be formulated by a simple analysis of the relaxation time. At low dc-field (Figure S5a), the characteristic frequency decreases from 10 kHz at 0.02 T down to 140 Hz at 0.3 T suggesting the presence of QTM relaxation, even if a Raman process cannot be completely excluded with  $C_2 > C_1$ . Above 0.3 T, the relaxation time is only weakly field dependent, in disagreement with direct (in  $H^4$  or  $H^2$ ) or Raman (in  $H^{-2}$  with  $C_2 \ll C_1$ ) mechanisms. Therefore, the paramagnetic relaxation in **1** seems to be dominated by Orbach-type and QTM pathways. Between 1.8 and 3 K, the  $\ln(\tau)$  vs.  $T^{-1}$  plot

Figure 4. ac frequency (left) and temperature (right) dependence of the real ( $\chi'$ , top) and imaginary ( $\chi''$ , bottom) parts of the ac susceptibility for **1** at 0.2 T, for ac frequencies of 10-10000 Hz and 1.8-10 K. Solid lines on the  $\chi'$  and  $\chi''$  vs.  $\nu$  plots are generalised Debye fits<sup>23</sup> of the ac data used to extract the temperature dependence of the relaxation time (Figure S5) as well as  $\alpha$ ,  $\nu$ ,  $\chi_0'$ ,  $\chi_\infty'$  and  $\chi_0''$ - $\chi_\infty''$  (Fig. S4.)

(Figure S5b) is linear and thus compatible with a thermally activated relaxation with a pre-exponential factor,  $\tau_0$ , of  $9(1) \times 10^{-9}$  s and an energy gap,  $\Delta_{\text{eff}}/k_B$ , of 22(1) K. Nevertheless, this value is ten times lower than that expected ( $\Delta/k_B = DS_T^2/k_B = 223$  K) from the estimated magnetic anisotropy ( $D/k_B = -6.2$  K) and the spin-ground state ( $S_T = 6$ ) suggesting that our experimental window may cover a crossover regime between these two relaxation pathways.

In conclusion,  $[\text{Fe}_3(\text{DpyF})_4](\text{BF}_4)_2 \cdot 2\text{CH}_3\text{CN}$  contains a rare example of a linearly-disposed trinuclear cluster cation, with ferromagnetically coupled  $\text{Fe}^{\text{II}}$  ions and an  $S_T = 6$  ground state, consisting of singly-occupied nearly degenerate metal-based molecular orbitals. The Fe-Fe distance (2.8 Å) is amongst the longest observed to mediate FM coupling. The magnetic data was modeled with an anisotropic Heisenberg Hamiltonian, giving  $J/k_B = +20.9(3)$  K and  $D/k_B = -6.2(2)$  K. The combination of the strong magnetic anisotropy and the energetically well-separated ground state likely yield the SMM properties, which appear to involve QTM and Orbach-like relaxations.

Electronic Supplementary Information (ESI) available: Synthesis, crystallography, Shape analysis, magnetic measurements and theoretical calculations. See DOI: 10.1039/D1CC05043E. Structures of **1** at 270 and 100 K can be found in the Cambridge Structural Database CCDC 2025912-2025913.
