#### Abstract

In February and March 2022, the eastern coast of Australia recorded 17 an unprecedented amount of precipitation with extended floods and 18 damages to properties amounting at least to AUD 2.3 billions. In this 19 paper we use both reanalysis and observations to perform a statisti-20 cal and dynamical attribution of this precipitation event to climate 21 change. We define 1948-1977 as the counterfactual period and 1990-22 2019 as the factual one. The statistical attribution is based on fitting 23 the generalized extreme value distribution for 3-days averaged pre-24 cipitation annual maxima for the two periods, while the dynamical 25 attribution aims at looking at the recurrence properties of sea-level 26 pressure and geopotential height patterns in both periods. We find 27 that the dynamics of the event consists in an unprecedented combi-28 nation of several factors: a tropical atmospheric river, the presence 29 of the Coral low pressure system and a blocking anticyclone offshore 30 Eastern Australia. Our main finding is that no clear attribution state-31 ments can be made, both because of the unprecedented nature of this 32

event, the lack of long high quality available data and the dependence of the results on the La Nina phase of El Nino Southern Oscillation.

35 Keywords: Climate Change, Extreme Precipitation, Attribution, Australia

# <sup>36</sup> 1 Introduction

In the latest IPCC report (Masson-Delmotte et al. 2021), researchers confirm 37 the role that human activity plays in the climate upheavals of recent decades. 39 The scientists also confirm the role of anthropogenic greenhouse gases emis-39 sions in modifying frequency and intensity of extreme weather events that we 40 experience today. The IPCC scientists warn in particular about the effects that 41 climate change is having on the water cycle. Studies have shown that rising 42 temperatures are leading to more intense rainfall, flooding but also to more 43 severe droughts (Cook et al, 2018) in some regions of the world. The distribu-44 tion, frequency and intensity of precipitations are changing significantly across 45 the globe, especially in subtropical regions accustomed to monsoons (Dou-46 ville et al. 2021). In the 21st century, coastal areas are already experiencing 47 and will increasingly experience flooding due to heavy precipitations and sea 48 level rise (Wilby and Keenan, 2012). Flooding from rising seas, which was 49 only occasional a few decades ago, could occur every year by the end of the 50 century (Hirabayashi et al, 2013). 51

Australian average land temperatures have risen by 1.44°C since 1910. 52 according to the recent study by Grainger et al (2022). The oceans surround-53 ing the continent have also warmed by an average of one degree over the same 54 period, leading to more frequent marine heat waves. Half of the corals in Aus-55 tralia's Great Barrier Reef have died since 1995 because of this rise in water 56 temperature in conjunction with increased acidification (Wolff et al. 2018; Hol-57 land et al, 2020). There is a wide consensus on the fact that sea levels will rise 58 in future climates, affecting Australian coasts (Church et al, 2006; Woodruff 59 et al. 2013; Church et al. 2017). As in other regions, this will likely increase the 60 hazards linked to storm surges associated with tropical cyclones. Other authors 61 have also pointed out that rainfall has decreased in southwestern Australia as 62 well as in the fire-rayaged southeast, while increasing in the north, which has 63 been hit by major floods and destructive cyclones in recent years (Dey et al, 64 2019; Abram et al, 2021). 65

If climate change projections for Australia are worrying, the country is 66 already experiencing severe extreme weather events. Indeed, climate change 67 has already taken its toll on Australia (Head et al, 2014; Abram et al, 68 2021; Canadell et al, 2021), which has been hit by fires, drought and 69 intense cyclones. In 2019-2020 the country was already ravaged by wildfires 70 of exceptional proportions after experiencing the hottest and driest year on 71 record (Borchers Arriagada et al, 2020; Jetten et al, 2021). The fires destroyed 72 an area almost the size of the United Kingdom, killed several people and killed 73

or displaced nearly three billion animals, costing the Australian economy about 7/ 7 billion AUD (Filkov et al, 2020). In the current 2022 year, both high and low 75 temperature records have been broken in Australia. On one hand, on the 13/01. 76 the coastal town of Onslow reached an unprecedented 50.7°C, the hottest tem-77 perature ever recorded in Australia for sixty-two years (The Guardian, 2022). 78 On the other hand, on the 02/06, the temperature at the Thredbo Top weather 70 station reached -6.9°C and historic snowfalls for this time of year (The New 80 Daily, 2022). Future projections of climate-related disasters for the coastal 81 areas as well as the vast island-continent report an increasing risk of extreme 82 events capable of heavily damaging natural ecosystems and impact health and 83 agriculture (Hobdav et al. 2018; Dev et al. 2019; Ukkola et al. 2020). 84

Here we will focus on the record-breaking extreme precipitation event which 85 occurred from the last week of February to mid-March 2022, in the eastern 86 coast of Australia. Heavy precipitations - 345mm of rain were recorded at 87 Brisbane on the 28th of February - met soils already close to saturation from 88 the recent rains in the end of 2021. This lead to severe and enduring flooding 89 in March. This event caused 22 recorded casualties, rendered uninhabitable 90 25,000 homes and businesses, forced 200,000 people to evacuate and produced 91 massive power and transports outages for a total of  $\sim 2.32$  billion AUD of 92 damage (Foreign Policy, 2022). 93

In order to explain this rain bomb event, we have identified two main 94 ingredients: i) an atmospheric river, formed north the continent around the 95 22nd of February, in the upper atmosphere – between eight and 10 kilometres 96 up – moved from the ocean to the south reaching the continent and produc-97 ing a continuous flux of precipitation originating from the tropics, and ii) a 98 dipolar structure consisting of a low pressure system in the Coral Sea and a 99 blocking anticyclone further east. The combination of these elements allowed 100 to transport moist air from the tropics to the Coral Sea, and then condense 101 the moisture that has then fallen as rain thanks to the low pressure, while 102 winds were pushing rain over Queensland's south east. Precipitation was fur-103 ther enhanced by orographic effects. At an even larger scale, the phenomena 104 were embedded in a strong La Nina phase, which induces additional air mois-105 ture in the south west Pacific and wind circulation patterns that could have 106 played a role in the intensity of the event. 107

Preliminary results of the University of Melbourne reported by national 108 and international newspapers (see, e.g. The Guardian (2022)) showed that on 109 the 26th and 27th of February, the two days with heaviest rain, 16 times the 110 water held by Sydney harbour (500 bn liters) flowed in the atmospheric river 111 above Queensland. Indeed, during those days rainfall of over 400 millimetres 112 was recorded across the greater Brisbane area. This would add up on the 28th 113 February to a total of 676.8 millimetres of rainfall, the largest three, and seven, 114 day total ever recorded in Brisbane. Another record breaking amount of rain-115 fall was recorded in Mount Glorious which received rainfall in excess of 1770 116 millimetres in the week until 28th of February. More than 30 locations across 117 the south-east recorded rainfall in excess of 1000 millimetres, resulting in the 118

4 Challenges in 2022 Australian rain bombs Attribution

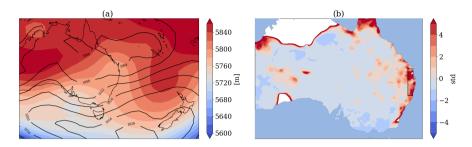

Fig. 1 Description of the rain bomb event. (a) Geopotential height at 500hPa (colors) and sea level pressure (contours) averaged over the 26th, 27th and 28th of February 2022. (b) Standardized anomaly of accumulated precipitations for the period 20th February - 20th March with respect to the 1990-2019 period. Regions in white correspond to standardized anomaly above 15 standard deviations.

floods being more intense than that of 1974. The unprecedented flooding that raised many rivers above record highs moved south, leaving towns underwater. The area of Sydney was more affected on the 3rd and the 8th of March with the city's chief reservoir, spilling at a rate in excess of 70 gigalitres a day on March 3. Residents in parts of western Sydney were told to evacuate for the second year in a row as the city's Warragamba Dam overflowed. But the system stalled before it passed over Sydney.

Damage from floods is only partially estimated at this stage, but is expected to reach almost AUD 2.3 billion (Foreign Policy, 2022), an estimate that exceeds that of the Insurance Council of Australia, which also summed-up the cost of claims from the disaster to AUD 1.45 billion (ClimateCouncilAustralia, 2022). However, this is only a lower bound, as the estimates are still expected to grow.

Figure 1 (a) presents the synoptic situation averaged over the 26th, 27th 132 and 28th of February over the region. We see the dipole structure with an 133 upper level low pressure system centered above the Brisbane region and a high 134 pressure system over the Coral sea. Figure 1 (b) presents the standardized 135 anomaly of accumulated precipitations for a one month period (20/02-20/03)136 with respect to the 1990-2019 period. The standardized anomaly was computed 137 by considering the series of accumulated precipitations for the 20/02-20/03138 period for each year over 1990-2019 and removing the mean and dividing by 139 the standard deviation. The Eastern coast of Australia saw extremely strong 140 precipitations, with many locations exceeding 5 standard deviation anomalies 141 with respect to the climatology. 142

We study whether this event can be attributed to climate change using dynamical systems theory to target the concurrent atmospheric circulation patterns and search for pattern recurrences in the far (1948-1977) and recent past (1990-2019). Our working hypothesis is that the far past acts as a counterfactual world where the Earth climate was not influenced by anthropogenic forcing when compared to the recent past (the factual world). Additionally, we assume that the 30-year period is long enough to average out the interannual variability of the atmospheric motions (as that caused, for example, by
El-Niño - Southern Oscillation). Finally we verify that these events produce
similar impacts on the targeted regions.

The paper is organized as follows: section 2 describes the data and methods used in this study. This is followed by the results (Section 3) providing both a statistical a dynamical attribution analysis. We conclude with a discussion and perspectives in Section 4.

# <sup>157</sup> 2 Data and Methods

## 158 2.1 Data

<sup>159</sup> In order to detect significant changes in the circulation associated with Aus-<sup>160</sup> tralian Rain bombs, we use daily sea level pressure (slp), 500hPa geopotential <sup>161</sup> height (z500) and 2m air temperature (t2m) data from the NCEP/NCAR <sup>162</sup> reanalysis (Kalnay et al, 1996) over the period 01/01/1948 – 31/03/2022. The <sup>163</sup> data have a horizontal resolution of  $2.5^{\circ} \times 2.5^{\circ}$ .

The precipitation data are taken from the high resolution daily rainfall gridded datasets of the Bureau of Meteorology of Australia. The data have a horizontal resolution of  $0.05^{\circ} \times 0.05^{\circ}$ . Daily precipitation data from the Alderley station, close to Brisbane, is also used solely. The gridded data set will be used for the dynamical attribution (section 3.2) and the station data for the statistical attribution (section 3.1). For the ENSO index, we used the Nino3.4 detrended index as in Van Oldenborgh et al (2021).

## 171 2.2 Methods

Extreme Value Theory (EVT) has been introduced in the study of atmospheric 172 flows a decade ago (Freitas et al. 2008) and has gained a considerable amount 173 of attention in both the applied mathematics and the climate science communi-174 ties (Lucarini et al, 2012, 2016; Faranda et al, 2019). It can be used to compute 175 recurrence times statistics for meteoroloical observables, but also gives access 176 to important information on the stability and the predictability of a partic-177 ular climatic state. We can apply this framework to the study how weather 178 extremes are influenced by anthropogenic-driven climate change conditioned 179 to the occurrence of a specific atmospheric circulation pattern (Faranda et al, 180 2020). Indeed weather extremes are associated with synoptic objects, i.e. a 181 cyclone, an anticyclone, or a couple of these structures. During this identifica-182 tion, we select a region (a longitude/latitude box) that fits the synoptic objects 183 that we want to examine. Once fixed the day of interest  $\zeta$ , we scan all the 3-184 days rolling averaged sea-level pressure (slp) and 500hPa geopotential (z500) 185 maps of the selected region in two periods: 1948-1977 (counterfactual world) 186 and 1990-2019 (factual world). For both periods, we select the best 35 ana-187 logues as the slp and z500 maps minimizing the pointwise euclidean distance 188 with the target day  $\zeta$ . We verified that the results are not sensitive to the 189

choice of the number of analogues provided that we extract between 25 and 50 analog maps. 30 years long factual and counterfactual periods ensure a large enough statistical sample of *slp* and *z*500 maps to be able to select sufficiently authentic analogues. Furthermore, it is short enough to satisfy the assumption of climate stationarity, with respect to anthropogenic climate change, while still long enough for the interannual and interdecadal natural variability of the atmospheric circulation to be averaged over.

Once obtained the two sets of analogues for the factual and counterfactual 197 periods, we average them out to search for significant differences  $\Delta slp$  and 198  $\Delta z500$ . To determine significant changes, we apply a two-tails Welch's t-test 199 (Welch, 1947) with different variance at each grid point. We mark as signifi-200 cant only grid point changes for which the *p*-value of the test is below 0.05. 201 Conditioning to the dates determined for slp or z500 maps, we also study the 202 associated 2 meters temperatures t2m and total precipitation maps tp. The 203 Welch's t-test procedure is repeated on these ensembles to identify significant 204 changes. 205

Using the dynamical systems framework described above, we then introduce a few metrics to determine the recurrence properties of the map in the counterfactual and factual worlds. These metrics are computed twice, once with the set of analogues obtained in each period. The formulas for computing these metrics are given in appendix A. For more information, please refer to Faranda et al (2022).

• Analogs Quality Q: We can study the typicality of  $\zeta$  by comparing the 212 euclidean distance of  $\zeta$  from its analogues with the distances of the analogues 213 from their own analogues. If the value of Q belongs to the same distribution 214 of the values of Q analogues, then the typicality of the event is ensured and 215 attribution of  $\zeta$  can be performed. If instead the Q for the chosen day is 216 larger than that of the analog days, then this is an unprecedented slp or z500217 configuration and the results for attribution must be taken more carefully. 218 A difference in Q between the counterfactual and factual periods indicate a 219 change in typicality of the event due to climate change. 220

Predictability Index D: Also called instantaneous dimension. For an atmo-221 spheric state  $\zeta$ ,  $D(\zeta)$  measures the density of similar configurations. We can 222 compute  $D(\zeta)$  in both the periods to detect a climate-change induced shift 223 in predictability. Indeed, D is a proxy for the number of degrees of freedom 224 of the map, meaning that the higher the dimension the more unpredictable 225 the next slp or z500 maps will be. If the dimension D of the chosen day is 226 higher or lower than that of the analogues, then the day will be less or more 227 predictable than its closest dynamical situations. 228

• Persistence Index  $\Theta$ : Another information derived from the dynamical systems theory is the persistence of a given configuration. The persistence counts for how many days we are likely to observe a map that will resemble  $\zeta$ . Once again we will compute  $\Theta$  for the two different periods and using the analogs as well to detect shifts from the factual to the counterfactual worlds. Seasonality of Analogs: We can also simply count the number of analogs in
 each month to detect whether a given circulation shifts towards earlier or
 later months. This can have strong thermodynamic implications.

We also provide results of the attribution conditional not on the past and 237 present climate, but on the El-Niño - Southern Oscillation (ENSO) mode. 238 ENSO is known to be a major factor in the variability of tropical and sub-239 tropical regions around the Pacific and likely played a role in the February 240 2022 event for which the mode was strongly negative. Therefore, we decided 241 to run the attribution analysis conditional on the Nino3.4 index being above 242 the 75% percentile (ENSO+) and below the 25% percentile (ENSO-) for the 243 period 1948-2019. Analogues are then computed in those two pools of data 244 using either 3-days rolling averaged slp or z500 maps. 245

## 246 **3** Results

## 247 3.1 Statistical attribution

In order to assess the possible changes in the probability of occurrence for the 248 event due to climate change, we use the rapid statistical attribution method 249 described in Section 2. We fit the 3-days averaged precipitation yearly maxima 250 to a Generalized Extreme Value (GEV) law for the factual and counterfac-251 tual periods for three stations, namely the Alderley station (Brisbane) at the 252 epicentre of the 26th-28th February event, the Sydney Botanic garden station 253 and the Cairns Aero station. We repeat the same analysis over the region 254 152°-154°W, 25.5°-31°S centered on Brisbane where the event was the most 255 extreme (see, e.g. Figure 1b). 256

Figure 2 shows the resulting GEV fits for Brisbane (a), Brisbane region (b), 257 Sydney (c) and Cairns (d). In both the factual and counterfactual worlds the 258 event of April 2022 in Brisbane was exceptional, with return periods estimated 259 of more than a thousand years. The event was also a 100-year precipitation 260 event in the Brisbane region in both periods. The 26th-28th February event 261 was less extreme in Sydney and Cairns, with return periods of less than a 262 decade in both stations for the factual and counterfactual periods. In Alderley 263 station return levels are slightly higher in the counterfactual period. We can 264 explain this by the occurrence of an extreme precipitation events in January 265 1974, that also produced floods in Brisbane. However, the 95% confidence 266 intervals are too wide to conclude to any detectable effect of climate change 267 with this method. 268

Figure 3 shows the same analysis but conditioned to the phases of El Niño Southern oscillation. In particular, we condition using Nino 3.4 index, sampling ENSO+ phases and ENSO- phase, defined respectively as the first and last quartile of the index. Results show a stronger effect of the la Niña phase (ENSO-) on precipitation rates at both Brisbane stations (3a). The 2022 26th to 28th February event is very rare during ENSO+ phases with a return period of over 400 years. Instead, it has a return period of 120 years in ENSO- phases.

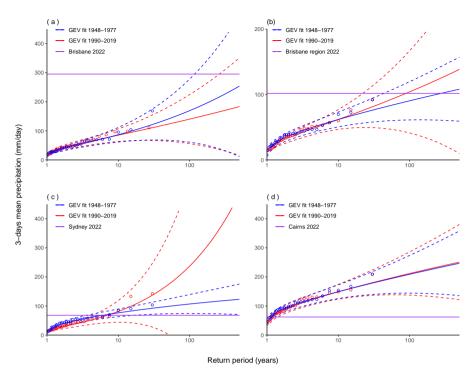

Fig. 2 Fit of the annual maximum of 3-days averaged precipitation running means at Brisbane (Alderley station) (a), the Brisbane region (152°-154°W, 25.5°-31°S) (b), Sydney (Sydney Botanic gardens station) (c) and Cairns (Cairns Aero station) (d) to a GEV in the factual and counterfactual periods. Gumbel plot of the GEV fit over 1948-1977 (blue lines with 95% confidence intervals), and 1992-2021 (red lines) using the maximum likelihood estimation. The purple line shows the value of intensity of the observed event at the station or area of interest in 2022.

This is in agreement with the influence of the strong la Niña phase currently ongoing on the intensity of the 2022 event suggested in 1. This effect is less clear if we consider the Brisbane region (3b): in this case the confidence intervals are so wide that it is difficult to draw any conclusion. The same procedure applied to Sydney (3c) and Cairns (3d) station data does not allow to draw any conclusion because of the wide confidence intervals, wich prevent to obtain statistical significant differences, at least at the 95% level chosen in this study.

## <sup>283</sup> 3.2 Dynamical attribution

To identify the dynamical and thermodynamic factors which may have played
a role in the intensity of the event, we ran the dynamical attribution framework
presented previously.

Figures 4 and 5 present the results using respectively slp and z500 analogues. These figures display the slp/z500 (a–d), t2m (e–h) and prate (i–l) maps and, from left to right, the maps of the event (a,e,i), the composites of

9

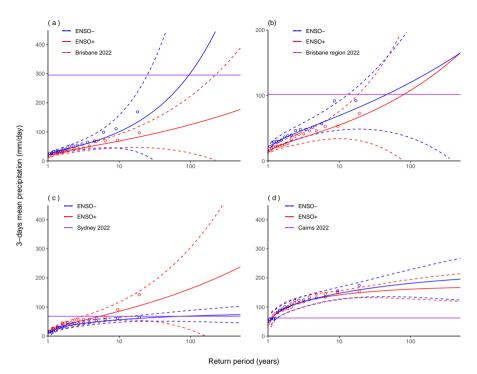

Fig. 3 Fit of the annual maximum of 3-days averaged precipitation running means at Alderley station (a) and over the Brisbane region (152°-154°W, 25.5°-31°S) (b) to a GEV, depending on El Niño 3.4 detrended index. Gumbel plot of the GEV fit over years in the 1st quartile (red lines) and 4th quartile (blue lines) of NINO3.4 index average over JFM from 1948 to 2021, with 95% confidence intervals. The purple line shows the value of intensity of the observed event at Alderley station in 2022.

counterfactual (b,f,j) and factual (c,g,k) analogs and the difference between 290 the factual and counterfactual analogs (d,h,l) where hashed-filled areas show 291 significant differences. Distributions of additional metrics comparing the 292 counterfactual and factual periods, namely analogs quality, predictability, 293 persistence and distribution by season are shown in panels m-p, respectively. 294 For the *slp* analogues, we firstly notice that the analogues quality (Q) is not 295 good and therefore results must be interpreted carefully (panel (m)). In the 296 factual period, there is a signal of intensified high-pressures over New Zealand, 297 which may be related to the stronger advection of moist air from the Coral 298 sea. When we look at the precipitation difference map (Fig. 4 (l)), there are 299 indeed stronger precipitations on the Eastern coast of Australia in the factual 300 period but only few regions are significantly different than the counterfactual 301 period and do not fully correspond to the regions where the precipitations 302 are maximum during the February 2022 event. There is moreover no strong 303 temperature signal as depicted in panel (h) using 2m air temperature which 304 does not display significant differences between the factual and counterfactual 305 periods on the Eastern coast and in the Coral sea. However, panel (o) and (p) 306

## Springer Nature 2021 LATEX template

## 10 Challenges in 2022 Australian rain bombs Attribution

show that the predictably is lower and the persistence is higher in the factual
period. The event is particularly persistent compared to its analogues in the
factual period which may explain the intensity of the event.

This results are confirmed when using the z500 analogues (Fig. 5), which are better as shown in panel (m). The factual period displays stronger high z500 over the northern region but also almost no significant temperature signal (panel (h)). The low predictability D (panel (n)) but high persistence  $\Theta$ (panel (p)) of the event is also noticed using z500 analogues. When it comes to precipitations, even though they are stronger during the factual period (panel (l)), this difference is not significant.

These results are coherent with the statistical attribution in so far as the 317 temperature signal associated with climate change is weak. There is however 318 a noticeable dynamical signal in the two periods as represented in the slp and 319 z500 analogues difference maps. One may indeed notice that ENSO, which is 320 the major driver of variability in the region, was in a strong and persistent La 321 Nina phase during the event, which is not fully represented using analogues 322 (see figure 6). We therefore decided to run the same dynamical attribution 323 analysis using the Nino3.4 index to define ENSO- phases and factual ENSO+ 324 phases. 325

The results of this analysis are presented in figures 7 and 8 using respec-326 tively slp and z500 analogues. On the dynamical side, there is a significant 327 stronger upper level low during ENSO- phases (Fig. 8 panel (d)) analogues. 328 Using both analogues, the temperature signal is much stronger during ENSO+ 329 phases, which may explain the absence of signal when doing the analysis during 330 past and present periods: the natural variability is stronger than the climate 331 change signal on this region. When it comes to precipitations, there is a strong 332 positive signal on the Eastern coast and Brisbane regions during La Nina 333 phases using slp analogues but the quality of analogues is low and these results 334 are not significant using z500 analogues. 335

# 336 4 Conclusions

In this paper we have performed a statistical and dynamical attribution of the 337 Australian rain bomb event of February 2022. We have used both reanalyses 338 and historical records of daily precipitations in the past (1948-1977, counterfac-339 tual) and present (1990-2019, factual) periods. From a statistical point of view, 340 this extreme precipitation event was unprecedented in the Brisbane region and 341 very intense with respects to previous historical records in the broader East-342 ern coast of Australia. The statistical attribution suggests that this event has 343 a low probability to happen both in the past and present climate (less than 344 one in a century). There is no clear signal of a climate change influence (high 345 uncertainty) which translates in a low evidence for the attribution of this event 346 to climate change. 347

The dynamical attribution, performed using the method of analogues circulation patterns proposed in Faranda et al (2022) to those observed during the

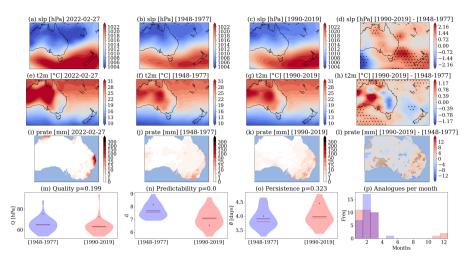

Fig. 4 Dynamical attribution using slp analogues for the Australian rain bomb on 27-02-2022. 3-days rolling mean sea-level pressure slp (a), 2-meter temperatures t2m(e) and total precipitation *prate* (i) centered on the 27-02-2022. Average of the 35 sea-level pressure analogs found for the counterfactual [1948-1977] (b) and factual [1990-2019] (c) periods and corresponding 2-meter temperatures (f,g) and daily precipitation rate (j,k).  $\Delta slp$ (d),  $\Delta t2m$  (h) and  $\Delta prate$  (i) between factual and counterfactual periods: hashed-filled areas show significant differences. Violin plots for counterfactual (blue) and factual (red) periods for the Analogs Quality Q (m) the Predictability index D (n), the Persistence index  $\theta$  (o) and the distribution of analogs in each month (p). Values for the selected day are marked by a black dot. Black (resp. red) lines represent the empirical mean (resp. median) of the distribution.

events suggest the exceptional characteristics of the event which appears to be 350 unprecedented in both the factual and counterfactual distributions of weather 351 patterns: it has arisen as the combination of ingredients: the tropical moisture 352 was deflected to the subtropics, collected and lifted by a low pressure system 353 which stationed over Eastern Australia blocked by an high pressure offshore 354 the Coral sea. This combination created an atmospheric river capable of trans-355 porting several gigaliters of water towards the Queensland and the South West 356 of the continent. Finally, La Niña phase of the El-Niño-Southern-Oscillation 357 likely played a significant role in the intensity of the event. 358

The main limitation of this study is that we do not use climate models: 359 the rational for doing so comes from the evidence that both large, regional 360 and local phenomena contributed to this event. In order to perform an attri-361 bution study based on models, we would need a large ensemble of convection 362 permitting models resolving at least the region shown in Fig. 1, with specific 363 runs capable to evaluate also the contribution of la Nina to the event. Even 364 with such models, the detailed physics of the precipitation could still depend 365 on the microphysics introduced in the model as shown by Ban et al (2021). 366 A further limitation of this study is the use of factual and counterfactual peri-367 ods consisting of only 30 years. While we could in principle consider the whole 368 period twice, as in the protocol described by Philip et al (2020), we cannot 369

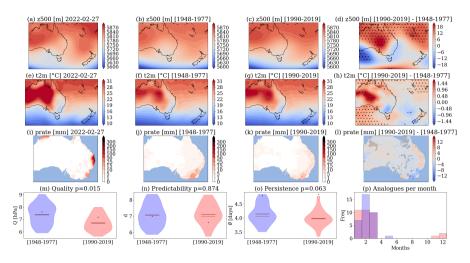

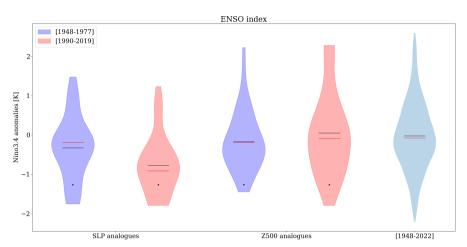

Fig. 5 Dynamical attribution using z500 analogues for the Australian rain bomb on 27-02-2022. 3-days rolling mean 500hPa geopotential height z500 (a), 2-meter temperatures t2m (e) and total precipitation prate (i) centered on the 27-02-2022. Average of the 35 500hPa geopotential height analogs found for the counterfactual [1948-1977] (b) and factual [1990-2019] (c) periods and corresponding 2-meter temperatures (f,g) and daily precipitation rate (j,k).  $\Delta z500$  (d),  $\Delta t2m$  (h) and  $\Delta prate$  (i) between factual and counterfactual periods: hashed-filled areas show significant differences. Violin plots for counterfactual (blue) and factual (red) periods for the Analogs Quality Q (m) the Predictability index D (n), the Persistence index  $\theta$  (o) and the distribution of analogs in each month (p). Values for the selected day are marked by a black dot. Black (resp. red) lines represent the empirical mean (resp. median) of the distribution.

here use the implicit assumption of stationarity of the variability of the rainfall extremes that is underlying the protocol. While this is a limitation on the
available data, it is a fair way to account for the variability of extremes, allowing for a larger uncertainty and a conservative estimates on the role of climate
change to triggering this event.

To frame our results in a more general framework, we observe that they 375 are in line with what the IPCC report AR6, WG1, Chapter 11.4, states about 376 rainfall over the region, namely that "Available evidence has not shown an 377 increase or a decrease in heavy precipitation over Australasia as a whole 378 (medium confidence), but heavy precipitation tends to increase over North-379 ern Australia (particularly the north-west) and decrease over the eastern and 380 southern regions." (Senevirate et al. 2021). We however observe that the 381 compounding dynamical elements driving this event are also observed in a 382 series of unprecedented extreme weather events occurred in the last few years, 383 including the 2021 Canada heat dome, the Antarctica atmospheric rivers, the 384 2022 Indian, Chines, Western European and North American heatwaves. Such 385 series of record breaking events raise the question of the emergence of new phe-386 nomena linked to global warming, a field to explore statistically, e.g. by using 387 the concept of time of emergence introduced in Hawkins and Sutton (2012)388

# 418 A Predictability and Persistence Indices

The attractor of a dynamical system is a geometric object defined in the space 419 hosting all the possible states of the system (phase-space). Each point  $\zeta$  on the 420 attractor can be characterized by two dynamical indicators: the local dimen-421 sion D, which indicates the number of degrees of freedom active locally around 422  $\zeta$ , and the persistence  $\Theta$ , a measure of the mean residence time of the system 423 around  $\zeta$  (Faranda et al, 2017). To determine D, we exploit recent results from 424 the application of extreme value theory to Poincaré recurrences in dynami-425 cal systems. This approach considers long trajectories of a system — in our 426

case successions of daily SLP latitude–longitude maps — corresponding to a sequence of states on the attractor. For a given point  $\zeta$  in phase space (e.g., a given SLP map), we compute the probability that the system returns within a ball of radius  $\epsilon$  centered on the point  $\zeta$ . The Freitas et al (2010) theorem, modified by Lucarini et al (2012), states that logarithmic returns:

$$g(x(t)) = -\log(\operatorname{dist}(x(t),\zeta)) \tag{1}$$

432 yield a probability distribution such that:

$$\Pr(z > s(q)) \simeq \exp\left[-\vartheta(\zeta)\left(\frac{z - \mu(\zeta)}{\sigma(\zeta)}\right)\right]$$
(2)

where z = q(x(t)) and s is a high threshold associated to a quantile q 433 of the series g(x(t)). Requiring that the orbit falls within a ball of radius 434  $\epsilon$  around the point  $\zeta$  is equivalent to asking that the series g(x(t)) is over 435 the threshold s; therefore, the ball radius  $\epsilon$  is simply  $e^{-s(q)}$ . The resulting 436 distribution is the exponential member of the Generalized Pareto Distribution 437 family. The parameters  $\mu$  and  $\sigma$ , namely the location and the scale parameter 438 of the distribution, depend on the point  $\zeta$  in phase space.  $\mu(\zeta)$  corresponds 439 to the threshold s(q) while the local dimension  $D(\zeta)$  can be obtained via the 440

relation  $\sigma = 1/D(\zeta)$ . This is the metric of predictability introduced in Sect. 2.2.

When x(t) contains all the variables of the system, the estimation of D 443 based on extreme value theory has a number of advantages over traditional 444 methods (e.g. the box counting algorithm (Liebovitch and Toth, 1989; Sarkar 445 and Chaudhuri, 1994)). First, it does not require to estimate the volume of 446 different sets in scale-space: the selection of s(q) based on the quantile provides 447 a selection of different scales s which depends on the recurrence rate around 448 the point  $\zeta$ . Moreover, it does not require the a priori selection of the maximum 449 embedding dimension as the observable q is always a univariate time-series. 450

The persistence of the state  $\zeta$  is measured via the extremal index 0 < 451  $\vartheta(\zeta) < 1$ , an adimensional parameter, from which we extract  $\Theta(\zeta) = \Delta t/\vartheta(\zeta)$ . 452 Here,  $\Delta t$  is the timestep of the dataset being analysed.  $\Theta(\zeta)$  is therefore the 453 average residence time of trajectories around  $\zeta$ , namely the metric of persis-454 tence introduced in Sect. 2.2, and it has unit of a time (in this study days). 455 If  $\zeta$  is a fixed point of the attractor, then  $\Theta(\zeta) = \infty$ . For a trajectory that 456 leaves the neighborhood of  $\zeta$  at the next time iteration,  $\Theta = 1$ . To estimate 457  $\vartheta$ , we adopt the Süveges estimator (Süveges, 2007). For further details on the 458 the extremal index, see Moloney et al (2019). 459
