Abstract Hyperpycnal (negatively buoyant) river inflow into lakes and oceans often develops three-dimensional (3D) plunging flow patterns when laterally unconfined. To determine the 3D flow pattern characteristics, laboratory experiments of laterally unconfined plunging on a sloping bed were carried out using salinity to control the density difference. The experiments were complemented by numerical modeling based on a high-resolution computational fluid dynamics model. As is the case for confined plunging plumes, it was found that in unconfined plunging, the inflow densimetric Froude number $Fr_{d-0}$ at the river mouth and the bed slope of the receiving water body $\beta$ are the dominant control parameters. However, the results documented that the hydrodynamics of laterally unconfined plunging are fundamentally different: The hyperpycnal plume in unconfined configurations forms a triangle on the surface in the plunge zone due to its convergence near the surface and lateral spreading near the bottom. The triangular pattern extends further into the receiving water when $Fr_{d-0}$ increases or the bottom slope decreases. The unconfined entrainment coefficient, which quantifies the amount of ambient water entrained into the plunging plume, also increases with increasing $Fr_{d-0}$. In general, entrainment is much higher in unconfined than in confined plunging. The plunging densimetric Froude number $Fr_{d-0}$ takes a constant value of $\sim 0.5$ in confined plunging, whereas it increases with increasing $Fr_{d-0}$ and can be $\gg 1$ in unconfined plunging. Complex patterns of secondary currents occur in the plunging plume. A low-velocity zone whose size increases with $Fr_{d-0}$ is observed near the centerline above the bed.

1. Introduction

River inflows carry sediments, contaminants, and nutrients into reservoirs, lakes, or oceans (Branch et al., 2020; Lamb et al., 2010; Pope et al., 2022; Scheu et al., 2018). The present paper focuses on river inflows that have a higher density ($\rho_h$) than the receiving waters ($\rho_a$), hereinafter referred to as hyperpycnal (negatively buoyant) river inflows. The excess density may result from lower temperatures (Hogg et al., 2013; Spigel et al., 2005), suspended sediments (De Cesare et al., 2001; Kostaschuk et al., 2018; Wright et al., 1986), or both (Best et al., 2005). Understanding how hyperpycnal river inflows transport and how they mix with ambient waters is essential for predicting and modeling the fate of fluvial materials (e.g., dissolved salts, heat, chemicals, biological particles, and sediment) and thus for determining how they will affect water quality, local ecosystems, and morphological evolution.

Upon entering the receiving water body, the hyperpycnal discharge displaces ambient water and then plumes below the surface at the plunge location ($x = x_p$), which is determined by a balance between the momentum of the inflow and the baroclinic pressure resulting from the density difference (e.g., Figure 6.18 of Fischer et al., 1979; see also Figures 1 and 2). After plunging, the hyperpycnal plume transforms into an underflow at distance $x_{ud}$ from the river mouth. Thus, the plunge region can be divided into two parts: from the river mouth to the plunge location ($0 < x < x_p$) and from the plunge location to the location where the plunging plume has transformed into an underflow ($x_p < x < x_{ud}$). The underflow progresses along the bottom boundary (e.g., Kostaschuk et al., 2018) and may detach from the bottom at the level of neutral buoyancy (e.g., Cortés et al., 2014).

Sediment-laden hyperpycnal plumes can cause turbidity currents. If the hyperpycnal plume gradually loses momentum, suspended sediment can settle out (Lamb et al., 2010), which reduces the excess density. On the other hand, the hyperpycnal plume can also pick up sediment from the bottom and thereby increase its excess density.
potentially leading to self-acceleration (Parker et al., 1986; Sequeiros et al., 2009). Both sediment deposition and pick-up can induce morphological modifications in the receiving water body.

The dynamics of the hyperpycnal plume are dominated by its buoyancy and momentum. Buoyancy is expressed as the depth-averaged relative density difference $\frac{\rho_d - \rho_a}{\rho_a}$, and momentum by the Froude number $Fr$. From the river mouth to the plunge location, $Rd$ and $Fr$ are defined as:

$$Rd = \frac{\rho_d - \rho_a}{\rho_a} \quad \text{and} \quad Fr = \frac{U}{\sqrt{gH}}.$$ 

Here, $U$, $\rho_d$, and $\rho_a$ are, respectively, the depth-averaged velocity and density of the hyperpycnal current, $H$ is the local water depth and $g$ is the magnitude of gravitational acceleration. Fr and $Rd$ are often combined in the densimetric Froude number $Fr_d$ (e.g., Akiyama & Stefan, 1984; Sequeiros, 2012),

$$Fr_d = \frac{Fr}{Rd} = \frac{U}{\sqrt{gH} (\rho_d - \rho_a)/\rho_a} \bigg|_{y/B_0=0}$$

These parameters are calculated at the central plane ($y/B_0 = 0$; $B_0$ is the width of the river channel at the mouth and $y$ is the distance along the transverse axis in a Cartesian coordinate system, Figure 1a). The subscript “0” denotes initial parameters at the river mouth. Most previous laboratory studies focused on laterally confined receiving waters (Akiyama & Stefan, 1984; Arita & Nakai, 2008; Fleenor, 2001; Lamb et al., 2010; Lee and...
During the plunging process, the hyperpycnal plume entrains ambient waters. As a result, the underflow discharge of again increasing due to the entrainment of ambient water (Lee and Yu, 1997). The location of the local maximum sloping boundary, then reaches a local maximum. Thereafter, it decreases to a local minimum, before finally

\[ E = \left( \frac{Q_{ud} - Q_0}{Q_0} \right) \]

where \( E \) describes the amount of ambient water transported across the density interface into the hyperpycnal plume during plunging:

\[ E = (Q_{ud} - Q_0) / Q_0 \]

Laboratory experiments on confined plunging reported values for \( E \) in the range 0.02–0.2 (Farrell & Stefan, 1988; Fleenor, 2001; Lamb et al., 2010; Lee & Yu, 1997).

In lakes or oceans, river inflow can develop laterally after leaving the inflow channel (Figure 2); thus, the plunging of a hyperpycnal inflow can be three-dimensional (3D). Examples of unconfined plunging are the Lillooet River entering Lillooet Lake (Canada; Best et al., 2005), the Slims River flowing into Klune Lake (Canada; Crookshanks & Gilbert, 2008), and the Rhône River plunging into Lake Geneva (Switzerland; Piton et al., 2022; Soulignac et al., 2021). Figure 2a gives an aerial view of the Rhône River mouth showing a triangular pattern on the water surface. A sketch of the unconfined plunging process is shown in Figure 2b. In unconfined plunging, Hogg et al. (2013) defined the plunge location as the place on the surface where the ambient waters from both sides of the progressively plunging plume meet, that is, the vertex of the surface triangle. Hereinafter, this
location is referred to as the vertex plunge point in the unconfined case to distinguish it from the plunge location in confined plunging. Hogg et al. (2013) presented a theoretical approach to predict the shape of the triangle and the vertex plunge point as a function of the inflow parameters for the case of a horizontal bottom.

Thus far, no detailed measurements of the velocity and density fields in the unconfined plunging zone are available in the literature. Yet, such data are needed to quantify the main characteristics of unconfined plunging, that is, the location of the vertex plunge point, plunging densimetric Froude number, and entrainment coefficient and how they are related to control parameters, such as the inflow densimetric Froude number Fr_{d,0} and bottom slope β. Laboratory experiments were conducted by Hauenstein and Dracos (1984) using dye and fine sediments to visualize the spreading of unconfined plunging plumes over a sloping bottom. They proposed an integral model to estimate the lateral spreading and entrainment of the hyperpycnal plume. Johnson, Ellis, et al. (1987), Johnson, Farrell, et al. (1987), Johnson et al. (1989), and Stefan and Johnson (1989) experimentally investigated plunging currents in diverging channels (3–90°) with a horizontal bottom. They observed that the plunging current separates from the sidewalls and becomes laterally unconfined when the diverging angle exceeds 25°, while Fr_{d,0} depends on Fr_{d,0} and the diverging angle. Chen et al. (2013) and Tseng and Chou (2018) showed numerically that the dynamics of the plunging are substantially modified by a sloping bottom. However, their (Reynolds-averaged) models were validated only with laboratory data from confined experiments.

In this paper, results from a unique set of laboratory experiments and numerical modeling of unconfined plunging are presented. These allow for a systematic characterization of this 3D process. The detailed velocity and density fields obtained from the experiments are used to quantify the main characteristics of the plunging plume and to validate the numerical model. The validated model is then applied to investigate an extended range of initial and boundary conditions for additional quantitative analyses (e.g., to determine the role of control parameters). The results for unconfined 3D plunging are also compared with results from laterally confined, two-dimensional (2D) cases. In particular, we focus on the following questions:

1. How do 3D flow patterns in unconfined plunging differ from 2D-confined plunging patterns?
2. How does the flow inside the unconfined plunging hyperpycnal plume develop? Does flow separation occur near the bottom boundary?
3. What are the control parameters of the unconfined plunging process and how do they affect the plunging dynamics?
4. Do characteristics of confined plunging, such as constant Fr_{d,0} and limited entrainment E < 0.2, also apply to unconfined plunging?

Figures and text with the prefix S, which provide details and clarifications of topics discussed in the main text, are found in the Supporting Information (SI) section.

2. Materials and Methods

2.1. Control Parameters and Their Investigated Range

The dynamics of unconfined plunging depends on g, B_0, H_0, β, ρ_0, ρ_a, U_0, and the kinematic viscosity ν. According to the Buckingham Π theorem (Garrett, 1960), these can be grouped into independent nondimensional parameters, for example, the aspect ratio H_0/B_0, the bottom slope β, the Reynolds number Re_0 = U_0H_0/ν, the Froude number Fr_0, and the relative density excess R_0. The latter two can be combined into Fr_{d,0} (Equation 1). It is important to determine whether Fr_{d,0} is the only dominant control parameter or if both of its constituents Fr_0 and R_0 must be considered. The range of investigated control parameters in the present laboratory experiments and numerical investigations is summarized in Table 1.

This investigation was motivated by ongoing ECOL field studies of the negatively buoyant Rhône River inflow into Lake Geneva (e.g., Piton et al., 2022; Soulignac et al., 2021). The river channel aspect ratio H_0/B_0 = 0.04 and lake bottom slope of β = 8° were reproduced in the laboratory experiments. Four experimental cases were investigated with a relative density difference R_0 ranging between 8 × 10^{-4} and 4 × 10^{-3}, and with two Froude numbers Fr_0 (0.08 and 0.13), resulting in two sets of Fr_{d,0} values (2 and 3, Cases 1–4, Table 1, A). The corresponding inflow Reynolds numbers in laboratory experiments are inherently several orders of magnitude smaller than those under field conditions. The values of Re_0 between 6,000 and 9,000 are, however, large enough to guarantee turbulent flow conditions.
After the numerical model was validated with the experimental data (Table 1, A), it was applied to expanded ranges of control parameters (Table 1, B) and also a confined configuration (Table 1, C):

1. Fr_{d-0} values from 2 to 6 were investigated based on a variety of combinations of Fr_0 and R_0 values. This range of Fr_{d-0} values is representative of the Rhône River inflow into Lake Geneva. Only cases with Fr_{d-0} > 1 were considered since the plunge is expected to occur inside the inlet channel if Fr_{d-0} < 1 (Johnson, Farrell, et al., 1987; Spigel et al., 2005).

2. The influence of the bottom slope angle $\beta$ was investigated numerically by also considering a smaller bottom slope ($\beta = 4^\circ$) and a horizontal bottom ($\beta = 0^\circ$).

3. Confined plunging was simulated using the validated numerical model for the same range of Fr_{d-0} (from 2 to 6) for a comparison with unconfined plunging.

After the numerical model was validated with the experimental data (Table 1, A), it was applied to expanded ranges of control parameters (Table 1, B) and also a confined configuration (Table 1, C):

1. Fr_{d-0} values from 2 to 6 were investigated based on a variety of combinations of Fr_0 and R_0 values. This range of Fr_{d-0} values is representative of the Rhône River inflow into Lake Geneva. Only cases with Fr_{d-0} > 1 were considered since the plunge is expected to occur inside the inlet channel if Fr_{d-0} < 1 (Johnson, Farrell, et al., 1987; Spigel et al., 2005).

2. The influence of the bottom slope angle $\beta$ was investigated numerically by also considering a smaller bottom slope ($\beta = 4^\circ$) and a horizontal bottom ($\beta = 0^\circ$).

3. Confined plunging was simulated using the validated numerical model for the same range of Fr_{d-0} (from 2 to 6) for a comparison with unconfined plunging.

### 2.2. Laboratory Experiments

The laboratory experiments were carried out in the Coriolis Platform, a 13-m diameter by 1.2-m deep circular tank at Laboratoire des Écoulements Géophysiques et Industriels (LEGI), Université Grenoble Alpes, CNRS, Grenoble, France). A sketch of the experimental setup is shown in Figure 3a; more details are given in Text S1 and Figure S1.1 in Supporting Information S1. The Rhône River inflow into Lake Geneva was simulated at a scale of 1:60 by a 2-m wide by 4-m-long straight inflow channel with a rectangular cross-section and horizontal bottom that was positioned 0.67 m above the bottom of the tank. The water depth inside the inlet channel was maintained at $H_0 = 0.08$ m, resulting an aspect ratio $H_0/B_0 = 0.04$. The channel's downstream end was centered with respect to an inclined flat plate ($\beta = 8^\circ$ slope, 8-m wide by 4.75-m long).
During the experiments, the tank was first filled with water with density $\rho_0$. After that, saline water with density $\rho_a$ was fed at the upstream end of the inlet channel via two lateral injectors (Figure 3a). In order to produce a near-uniform velocity distribution across the channel width, a rectangular manifold consisting of an array of full-depth plastic grids (Figure 3a) was installed, followed by a 0.5-m-thick honeycomb placed 1.5-m upstream from the discharge plane. With a constant water discharge $Q_0$, a stable water flow in the inlet channel was established and verified in preliminary tests (Text S1.1 in Supporting Information S1). A constant water depth in the basin was maintained by extracting water (at rate $Q_0$) from outlets in the bottom of the tank. These outlets were positioned at the side and below the sloping boundary to minimize perturbations to the hyperpycnal plume. More details of the experimental procedure are given in Text S1 in Supporting Information S1. The Cartesian coordinate system used in this study ($x$: longitudinal, $y$: transversal, $z$: vertical) has its origin (0, 0, 0) on the centerline of the inlet channel at the beginning of the sloping boundary and at the water surface (Figure 3a). The respective time-averaged ($\overline{u}, \overline{v}, \overline{w}$) and transient velocities ($u, v, w$) are in the ($x, y, z$) directions. A second Cartesian coordinate system ($x_s, y_s = y, z_s$) with corresponding velocities ($\overline{u_s}, \overline{v_s} = \overline{v}, \overline{w_s}$) and ($u_s, v_s = v, w_s$) was applied as shown in Figure 1b. For this “s” coordinate system, the longitudinal and vertical coordinates are, respectively, parallel and perpendicular to the bottom slope of the inclined flat plate.

For Cases 1 and 3 (Table 1), flow visualization was realized by injecting fluorescent dye (Rhodamine 6G) at different times during the experiment. A 25-W Yag laser operating at a wavelength of $\lambda = 532$ nm was set horizontally and moved vertically (from $z = -0.04$ to $-0.29$ m) to scan the whole volume of the hyperpycnal plume. Images were captured with GoPro and Nikon D5 cameras.

**Figure 3.** Sketches of the Coriolis Platform (Laboratoire des Écoulements Géophysiques et Industriels, Université Grenoble Alpes) and the numerical domain. (a) The experimental setup consists of injectors, an inlet channel, a sloping bottom plate (inclination 8°), and three drains. The origin of the coordinate system is at the surface of the inlet channel. The large green triangle represents the particle image velocimetry laser sheet. (b) Numerical domain for unconfined plunging composed of an inlet channel with a horizontal bottom and a receiving domain with a sloping bottom. (c) Numerical domain for confined plunging composed of a 4-m-long inlet channel and a 12-m channelized receiving domain.
Particle image velocimetry (PIV) was used for flow visualization and instantaneous velocity determination. The PIV measurements in the plunge region started when this region reached a steady state, which was 3 min after the onset of the experiment. Velocity fields were computed from PIV measurements using a cross-correlation PIV algorithm encoded with the UVMAT software (http://servforge.legi.grenoble-inp.fr/projects/soft-uvmat). For this purpose, an adaptive multi-pass routine was used, starting with an interrogation window of 45 × 31 pixels and a final window size of 31 × 21 pixels, with a 70% window overlap. Each element of the resulting vector field represents an area of roughly 0.01 × 0.01 m. The maximum instantaneous velocity error is estimated to be ∼3%. Detailed information about the PIV configuration is provided in Text S1.3 in Supporting Information S1.

2.3. Numerical Model

A numerical model based on the open-source CFD package OpenFOAM (De Lorenzis & Düster, 2020; Jasak, 2009; Weller et al., 1998) was developed to simulate the experimental configurations using a transient solver “BuoyantBoussinesqPimpleFoam” for incompressible turbulent flow. The geometry used in the model represents the relevant geometry of the laboratory experiment, consisting of an inlet channel plus a receiving tank with an 8° bottom slope (Figure 3b). The mass and momentum conservation equations are, respectively:

$$\nabla \cdot \langle \mathbf{u} \rangle = 0 \quad (6)$$

$$\frac{\partial \langle \mathbf{u} \rangle}{\partial t} + \nabla \cdot ((\mathbf{u}) \otimes \langle \mathbf{u} \rangle) = -\nabla \left( \frac{\rho}{\rho_a} \right) + \frac{1}{\rho_a} \nabla \cdot (\tau + \tau_t) + (\langle R \rangle + 1) \mathbf{g} \quad (7)$$

where (...) denotes the LES space scale filter, \( \mathbf{u} \) the velocity vector, \( t \) time, \( p \) pressure, \( \tau \) the resolved stress tensor, \( \tau_t \) the sub-grid scale (SGS) turbulent stress tensor, \( \rho \) the local density, \( R = (\rho - \rho_a)/\rho_a \) the relative density difference, and \( \mathbf{g} \) the gravitational acceleration. The momentum equation is based on the Boussinesq approximation, that is, density variations are considered only in the buoyancy term (e.g., Gray & Giorgini, 1976; Mayeli & Sheard, 2021). Transport of salt was computed using the incompressible mass diffusion equation (Cantero et al., 2007),

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = \nabla^2 (\alpha_{eff} \mathbf{u}) \quad (8)$$

where \( \alpha_{eff} = \nu/\text{Sc} + \nu_t/\text{Sc}_t \) is the effective diffusivity with \( \text{Sc} = \nu/D \) being the Schmidt number and \( \text{Sc}_t = \nu/K \) the turbulent Schmidt number. Here, \( \nu \) is kinematic viscosity, \( \nu_t \) is turbulent viscosity, \( D \) is molecular diffusivity, and \( K \) is eddy diffusivity. Following previous studies on density currents (e.g., Cantero et al., 2007; Härtel et al., 2000; Ooi et al., 2009; Özgökmen et al., 2004), \( \text{Sc} \) is assumed to be unity, which has almost no effect on the numerical results if \( R \ll 1 \) (Ooi et al., 2009), since molecular diffusion is negligible. Most previous studies took the turbulent Schmidt number, \( \text{Sc}_t \), in the range 0.7–0.9 (Tominaga & Stathopoulos, 2007). Here, \( \text{Sc}_t = 0.85 \) was applied.

The computational domains for the unconfined and confined geometries are shown in Figure 3. Comparisons of the unconfined and confined plunging were likewise performed with the domain shown in Figure 3c for the latter case. The domain for confined plunging is a 2-m-wide channel with two sections: a 4-m-long inlet with a horizontal bottom and a 12-m-long receiving section with an 8° sloping bottom. Additional details of the numerical model setup (e.g., numerical schemes, treatment of boundary conditions, and grid independence test) are provided in Text S2 in Supporting Information S1.

3. Results and Discussion

3.1. Main Features of Velocity and Density Patterns

In all experimental and numerical cases investigated (Table 1), qualitatively similar results of velocity and density patterns were obtained. In this section, details of the flow field and the density field development will first be shown for Case 3 as a representative example to present the 3D flow patterns of unconfined plunging. Thereafter, results from all cases will be combined to determine the parameters that control the plunging process in Sections 3.2 and 3.3.
3.1.1. Density Field at Different Vertical Levels

Figure 4a shows the dye-visualized images at three depths in experimental Case 3 (Table 1). For comparison, the density distributions at the same planes calculated from the numerical model are illustrated in Figure 4b. Figures 4a and 4b present the changes in the structure of the plunge region below the water surface. With increasing depth, the core of the triangular surface pattern gradually decreases due to buoyancy-induced plunging of the inflow and entrainment of ambient water. The numerical model also provides a more detailed 3D shape of the plunge region for a specific isopycnic surface ($R = 0.2R_0$) as shown in Figure 4c. The hyperpycnal plume converges toward the centerline near the water surface after entering the ambient waters (Figure 4). It forms a triangle at the surface, but spreads laterally close to the bottom (Figure 4c). This behavior is markedly different from confined plunging.

3.1.2. Comparison of Measured and Modeled Mean Velocity Fields

Figures 5a–5c presents the time-averaged (over 50 s) velocity distributions on different planes for Case 3. The location of the vertex plunge point ($x_p$) and the location where the plunging plume transforms into an underflow ($x_{ud}$) are discussed in more detail in Section 3.2. Since the inlet flow and the plunging process can be assumed to be symmetrical (Hauenstein, 1982; Hauenstein & Dracos, 1984), the symmetry of each panel in Figure 5 illustrates the good agreement between the numerical model results and the experimental data. The distribution of longitudinal velocities at $z = -0.5H_0$ is also triangular (Figure 5a). The boundary of the triangle extracted from the dye-visualized images (uppermost layer in Figure 4a) is plotted for comparison (red stars; for details refer to Text S3 in Supporting Information S1). In the deeper section at $z = -2H_0$ (Figure 5b), a larger triangle is identified. Inside this triangle, a region with reduced velocity (low-velocity region) exists, marked by the brown-dashed lines. Close to the bottom (Figure 5c), this low-velocity region is still evident in the plunging region ($0 < x < x_{ud}$). In the underflow region after plunging ($x \geq x_{ud}$) (Figure 5c), the largest longitudinal velocities are located at the centerline ($y/B_0 = 0$) and the current spreads laterally outward on both sides.
Figures 6a and 6b compare the velocity along the centerline on the plane a-a (z = −0.5H₀) and 0.04 m above the sloping bottom on plane c-c. On plane a-a, the horizontal velocity decreases with distance from the end of the inlet channel due to loss of momentum and eventually reaches zero. Near the bottom, the centerline current velocity parallel to the bottom slope first decreases rapidly and then increases again, indicating the zone with reduced velocity inside the plunging plume, marked by brown-dashed lines in Figure 5c. In the underflow region (x ≥ xₐ), the longitudinal velocity uₓ near the bottom at the centerline tends toward a constant value (Figures 5c and 6b) due to the combined effect of acceleration (Rg sin β) and entrainment.

Transversal profiles of the longitudinal, transversal, and vertical velocity components at x = 0.5xp and z = −0.5H₀ are plotted in Figure 6c. In this panel, the longitudinal velocity has a nearly constant value inside the triangular region and decreases quickly outside it. On each side, the transversal velocity points inward toward the centerline.
with maximum (positive) and minimum (negative) values located near the edge of the surface triangle. This inward transversal velocity results from the transverse lock-exchange-type flow generated by the lateral pressure gradient between the hyperpycnal plume and ambient water as discussed in Hogg et al. (2013) and Tseng and Chou (2018). The superposition of the longitudinal and inward transversal velocity components results in a velocity direction that follows the edge of the surface velocity triangle at the interface (Figure 5a). The vertical velocity (green line, Figure 6c), obtained from the numerical model, is directed downward in the whole transect with two peaks near the edges of the surface triangle. Figure 6d presents the near-bottom downslope velocity profiles (plane c-c) at $x = 0.5x_p$ and $x = x_{ud}$. At $x = 0.5x_p$, inside the plunging region (purple), two local velocity maxima delimit a lower velocity region near the centerline. Again, this behavior is due to the low-velocity zone observed in Figures 5b and 5c. At $x = x_{ud}$ (orange), however, the current is an underflow and the velocity profile only has one maximum at the centerline. The 3D shape of the low-velocity zone can be visualized by the iso-surface of $\bar{u} = 0.6U_0$ based on the numerical results. Note that the axes have different ranges in the panels.

Figure 6. Comparison of numerical results (lines) and experimental results (circles and squares) for Case 3: (a) Centerline longitudinal velocity at $z = -0.5H_0$. (b) Centerline velocity parallel to and 0.04 m above the sloping bottom. The locations of the vertex plunge point ($x_p$) and where the plunging plume transforms into an underflow ($x_{ud}$) are marked by the black dashed lines. (c) Transversal profiles of velocities at ($y/y_p = 0.5$; $z/H_0 = -0.5$). Red and blue present the longitudinal and transversal velocities, respectively. For the vertical velocity, only numerical data are available (green line). (d) Transversal profiles of experimental and numerical $\bar{u}$ at 0.04 m above the bottom (plane c-c, Figure 1) inside the plunge region at $x = 0.5x_p$ (purple) and in the underflow region at $x = x_{ud}$ (orange). (e) 3D shape of the low-velocity zone defined by the iso-surface of $\bar{u} = 0.6U_0$ based on the numerical results.
3.1.3. Modeled Mean Velocity Fields in the Central Plane and Cross Sections

Model results for the velocity distribution clearly show a low-velocity zone around the centerline (Figures 7a and 7b). However, the time-averaged relative density field ($\tilde{R}$) in the corresponding sections indicates that the density in this low-velocity zone is uniform ($= R_0$; Figures 7c and 7d). The low-velocity zone is created by flow separation that occurs when the slope changes at the junction of the inlet channel and the sloping bed of the receiving waters. Blanckaert (2015) divided the flow separation process into two stages: In the first stage, the velocity profile develops a deficit but remains oriented downward, followed by the second stage where flow reversal occurs near the boundary and a recirculation zone develops. Only the first-stage separation occurs in the cases considered here. The density distribution remains uniform within the plunging flow, whereas it is diluted due to entrainment of ambient water across the interface (Figures 7c and 7d). Figure 7b presents the transverse and vertical velocities at $x = 0.5x_p$. Near the bottom, the density difference between the hyperpycnal plume and ambient water causes a lateral pressure gradient. This results in an outward transversal flow on both sides near the bottom (red dashed-lined boxes). As a consequence, similar to lock-exchange flow (e.g., Shin et al., 2004), an inward transversal flow toward the centerline is generated near the surface (red dotted-lined boxes) to keep the mass balance. Interestingly, transverse velocities converging toward the center of the plunging flow are also observed in the region $-0.3 < y/B_0 < 0.3$ near the bottom as already reported in the numerical study of Tseng and Chou (2018) and confirmed by our experimental data in Figure 5c. In the area $0.25 < x/B_0 < 0.5, -0.3 < y/B_0 < -0.1$, the quiver plot shows transverse velocities directed toward the centerline. These near-bottom converging velocities occur due to the much higher downward velocity at the two sides ($y/B_0 \approx \pm 0.3$) compared with the centerline.

After plunging, the hyperpycnal plume flows down the slope in the underflow region. Figures 7e and 7f present the density and velocity fields at $x = x_{ud}$. Most of the dense fluids are found in a thin layer at the bottom (Figure 7e).
contrast to the plunging region (Figure 7d), only downward-outward secondary velocities were observed inside the hyperpycnal plume (Figure 7f), which explains the lateral spreading of the underflow (Figure 5c).

In both cross sections, at $x = 0.5 x_p$ and $x = x_{ud}$, secondary circulations at the dense/ambient flow interfaces are observed, highlighted by the circles in Figures 7b and 7f (clockwise on the left side and counterclockwise on the right). Figures 7g and 7h present the time-averaged vorticity field, $\omega_i = \partial w / \partial y - \partial v / \partial z$, in these two sections. High values on both sides of the hyperpycnal plume indicate rotating secondary circulations.

3.2. Determination of Parameters $x_p$, $x_{ad}$, $Fr_{d-p}$, and $E$

Although the location of the vertex plunge point can be estimated from specific contours of velocity and/or density at the surface, the results will depend on the threshold value used in the definition. In confined plunging, Lee and Yu (1997) suggested that $x_p$ and $x_{ad}$ can be determined from variation of the layer-averaged thickness of the hyperpycnal plume $h_i(x)$ along the central plane ($y/B_0 = 0$) (details in Section 1). In the present study, this method is also applied to the numerical unconfined cases. Figure 8 illustrates the variation of $h_i(x)$ in the unconfined numerical Case 3. The local maximum of $h_i(x)$ gives the value of $x_p$, while the local minimum gives the location where the plunging plume transforms into an underflow ($x_{ad}$). After $x_p$ and $x_{ad}$ are determined, the plunging densimetric Froude number is calculated using Equation 1 and the entrainment coefficient is obtained by Equations 4 and 5 using $R = 0.2 R_0$ to determine the cross-sectional area $A$.

3.3. Parameters Dominating the Plunging Process

Since the results obtained for all cases were similar to those of Case 3 discussed above, they were combined in order to determine their dependence on $Fr_0$, $R_0$, $Fr_{d-p}$, $\beta$, and the lateral confinement, which are assumed to be the main controls.

3.3.1. Influence of $Fr_0$, $R_0$, and $Fr_{d-p}$

Figure 9a shows half of the modeled density contour ($\bar{R} = 0.95 R_0$) at $z = -0.5 H_0$ for cases with different values of $Fr_{d-p}$, $Fr_0$, and $R_0$ (Table 1). Experimental data from the dye-visualized images are also depicted in this figure for comparison (gray scales of the dye images are approximately linked to the density; see Text S3 in Supporting Information S1 for details). Figure 9b presents half of the velocity contour ($\bar{u} = 0.3 U_0$) at $z = -0.5 H_0$ in the

---

Figure 8. Modeled variations of layer-averaged hyperpycnal current thickness in the central section of Case 3. The red cross indicates the vertex plunge point ($x_p$) and the blue cross marks the location where the plunging plume transforms into an underflow ($x_{ad}$).

Figure 9. (a) Points on the density contours ($\bar{R} = 0.95 R_0$) at $z = -0.5 H_0$ for Cases 1–14 (Table 1). (b) Points on the velocity contours ($\bar{u} = 0.3 U_0$) at $z = -0.5 H_0$ for Cases 1–4. In both panels, each case is identified by Case, $Fr_0$ and $Fr_{d-p}$ values in the legend (corresponding $R_0$ values are given in Table 1). Open and filled symbols present the numerical and experimental data, respectively. Symbols indicate cases with different $Fr_0$ and colors give cases with different $Fr_{d-p}$. 

experiments compared with the corresponding numerical cases. It is evident that the size of the triangle strongly depends on $\text{Fr}_d$. As $\text{Fr}_d$ increases, the vertex plunge point moves further away from the river mouth, resulting in a larger $x_p$.

Although different combinations of $\text{Fr}_0$ and $R_0$ can result in the same $\text{Fr}_d$, the size of the surface triangle does not change (Figure 9) for given values of $\text{Fr}_d$. Figure 10 presents the measured and modeled centerline longitudinal velocity at $z = -0.5H_0$ for Cases 1–4. Similar to the surface triangle size, the variation of this centerline velocity is again dependent only on $\text{Fr}_d$ rather than $\text{Fr}_0$ and $R_0$. Furthermore, the length of the low-velocity zone inside the plunging plume also increases with $\text{Fr}_d$ (Figure 11).

### 3.3.2. Influence of the Bottom Slope

Figure 12 presents the modeled surface density contour $\overline{A}(R_A = 0.95 R_0)$ for three numerical cases with the same inlet condition ($\text{Fr}_0 = 0.08$, $\text{Fr}_d = 2$), but with different bottom slopes ($\beta$). Investigated bottom slopes include a horizontal bottom, a bottom slope of 4°, and the experimentally investigated bottom slope of 8°. A large difference between the surface triangles is apparent in Figure 12, which shows that the unconfined hyperpycnal plume plunges closer to the river mouth when the bottom boundary slope is larger, as was previously observed by Tseng and Chou (2018). A similar result was reported in confined cases (Arita & Nakai, 2008). The results of the numerical simulation of the horizontal case were compared with the analytical prediction of the surface triangle by Hogg et al. (2013):

$$y = \pm \left( \frac{B_0}{2} - \frac{x \sqrt{g^0 H_0}}{2 \overline{u}_0} \right)$$

(9)

where $\overline{u}_0$ denotes the inlet velocity at the surface. The numerical results of this study agree well with their model (Figure 12). Equation 9 is based on the assumptions that the centerline velocity on the water surface remains almost constant up to the vertex plunge point and that the lateral converging velocity of the surface triangle follows the law obtained from lock-exchange density currents: $\overline{v} = \sqrt{g^0 H_0}/2$. Both of these assumptions are invalid if the bottom boundary is inclined. A comparable analytical solution to Equation 9 for a nonzero bottom slope is not available.

### 3.3.3. Influence of Lateral Confinement

Figure 13a presents the variation of $\text{Fr}_d$ in confined numerical cases with an 8° bottom slope and $\text{Fr}_0 = 0.08$. $\text{Fr}_d$ is calculated based on the velocity and density data in the central plane (Equation 1). In the longitudinal direction, $\text{Fr}_d$ decreases due to the bottom slope following Equation 2 as suggested by Arita and Nakai (2008). The numerical simulations indicate that the plunge occurs when $\text{Fr}_d$ decreases to a critical value close to 0.5, which is consistent with the value obtained by Lamb et al. (2010) using the theoretical model of Parker and Toniolo (2007). When $\text{Fr}_d$ increases, the plunge occurs further away from the river mouth. The decrease of $\text{Fr}_d$ is slower in unconfined
they further assumed that $q = 0$ for the numerical cases. The black dashed-dotted lines are the prediction of Equation 9 for the horizontal bottom Case 16.

Figure 12. Surface density contours ($\bar{R} = 0.95R_0$) for the numerical cases with the same $F r_0 = 0.08$ and $F r_{d-o} = 2$, but with different bottom slopes (i.e., $0^\circ$, $4^\circ$, and $8^\circ$ for Cases 16, 15, and 1 (Table 1), respectively, as indicated by the colors in the legend). The colors in the legend). The black dashed-dotted lines are the prediction of Equation 9 for the horizontal bottom Case 16.

plunging than in confined plunging (Figures 13a and 13b), implying that Equation 2 is not valid in unconfined cases. Equation 2 is based on the assumption that the discharge per unit width in the central plane ($q_c$) remains constant before the plunge location, that is, $U_0H_0 = U_0(x)H(x)$. This is valid in confined plunging, for example, in Case 21, where $q_c/q_{c-o}$ remains nearly constant at around unity (Figure 13c, black circles). However, in unconfined plunging, $q_c$ increases longitudinally since the transversal secondary velocity is directed toward the centerline as shown in Figure 7b. The increase of $q_c$ slows down the decrease of $F r_p$. As a result, $F r_p$ at the location where the confined hyperpycnal plume plunges is still greater than 0.5 in the corresponding unconfined case (same value of $F r_{d-o}$, compare Figures 13a and 13b). Thereafter, $F r_p$ continues to decrease in the unconfined case. At the vertex plunge point, $F r_{d-o}$ in the unconfined cases is still substantially greater than the critical value of ~0.5 that is characteristic of confined plunging. Moreover, $F r_{d-o}$ is found to increase with $F r_{d-o}$ and can be larger than unity. These results indicate that the unconfined plunge is not only controlled by a critical value of $F r_{d-o}$ but also by the three-dimensional flow patterns inside the plunge region. Indeed, the plunge occurs where the two sides of the hyperpycnal plume meet at the centerline on the surface even though $F r_p$ is still greater than the critical value for confined cases.

Figure 14a presents the increase of discharge in the plunge region (from $x = 0$ to $x = x_p$) due to entrainment in four unconfined numerical cases with the same $F r_0 = 0.08$ and $F r_{d-o} = 3$, but different combinations of $F r_0$ and $F r_{d-o}$. For the cases considered, $F r_0$ and $F r_{d-o}$ have no influence on the entrainment since $F r_{d-o}$ does not change. Figure 14b shows the variation of the entrainment coefficient $E$ with $F r_{d-o}$ in confined and unconfined numerical cases with $F r_0 = 0.08$. In confined plunging, $E$ values are found within a narrow range (0.05–0.15), which are similar to results reported in previous experimental studies ranging from 0.02 to 0.2 (Farrell & Stefan, 1988; Fleenor, 2001; Lamb et al., 2010; Lee & Yu, 1997). In unconfined plunging, however, $E$ values are not only significantly larger, but also increase with increasing $F r_{d-o}$ from 0.4 to 0.7 (Figure 14b). The increase of $E$ with $F r_{d-o}$ in unconfined cases can be explained by the downstream shift of the vertex plunge point with increasing $F r_{d-o}$. This results in a larger interface area along which the entrainment between the riverine inflow and the ambient water occurs.

### 3.4. Generalization of Results

Field measurements of unconfined temperature-induced plunging were made in the Canale Ital sider mouth (Lake Iseo, Italy) by Hogg et al. (2013) and in the Tokaanu Tailrace mouth (Lake Taupo, New Zealand) by Spigel et al. (2005). The related geometry and inlet conditions are listed in Table 2. Numerical simulations for Lake Iseo and Lake Taupo were performed using simplified geometries similar to Figure 3b based on geometric (1:20 scale) and Froude similarity (Table 2). The numerical model predicts $x_p/B_0 = 0.8$ for the Canale Ital sider mouth, consistent with the range of 0.6–1.0 reported by Hogg et al. (2013). Hogg et al. (2013) applied Equation 9 to estimate the vertex plunge point ($x_p = \bar{u}_oB_0/\sqrt{g'H_0}$; they further assumed that $\bar{u}_o = U_0$), resulting in $x_p/B_0 = 2.4$, which is more than double the measured value. This overestimation of $x_p$ is due to the simplifying assumption that the lake bottom is horizontal. For the Tokaanu Tailrace mouth, the numerical model gave $x_p/B_0 = 1.0$, which agrees with the range ($x_p/B_0 = 0.8–1.0$) reported by Spigel et al. (2005). They calculated an entrainment coefficient $E = 1.9$, which is about double the value ($E = 1.1$) determined numerically using Equation 4 to calculate $Q_{sat}$. Spigel et al. (2005) assumed that $Q_{sat} = \text{discharge per unit width}$ in the central plane $\times$ plume width, which overestimates $Q_{sat}$ since the velocity in the central plane of the underflow region is considerably higher than on the two sides as shown in Figure 5c. If their method is applied to the numerical data, $E = 1.7$ is obtained that is quite close to the value ($E = 1.9$) they reported.

The inflow of the Rhône River (Lake Geneva) is sediment-laden and both the suspended sediment and temperature contribute to the excess density of the hyperpycnal plume. Figure 2a shows the surface triangle at the Rhône River mouth. This image was taken on a day when $F r_{d-o} \approx 3.2$ and gives an estimation of the vertex plunge point as $x_p/B_0 \approx 1.0$. The numerical and experimental Case 3 have an $F r_{d-o}$ value close to this and further that $x_p/B_0 = 0.75$. The underestimation of $x_p$ may result from sediment deposition that is not included in the experiments.
or the numerical model. As the hyperpycnal plume develops, it loses momentum, which leads to the deposition of larger-sized suspended sediment, reducing the relative density difference (Piton et al., 2022). Sedimentation may also reduce the bottom slope angle. Both of these mechanisms can lead to a larger \( x_p \) in hyperpycnal plunging.

4. Summary and Conclusions

By combining detailed laboratory measurements of the velocity fields and 3D numerical modeling, this study allowed the first characterization of 3D unconfined plunging of a hyperpycnal river plume over a sloping bed and its lateral spreading. The numerical modeling was based on a computational fluid dynamics (CFD) model, which was validated with the experimental results, thus demonstrating that the model is suitable for realistically simulating the unconfined plunging process.

The results of this study reveal that the 3D unconfined plunging process is different from confined (essentially 2D) plunging. In the unconfined plunging process, 3D flow structures are observed: As the hyperpycnal plume is advected longitudinally, currents in the cross sections are directed downward and form transversal lock-exchange type flows on each side of the plunge. This causes the current to converge toward the centerline on the surface creating a triangular shape of velocity/density fields, while spreading laterally near the bottom. The near-bottom lateral spreading further generates secondary circulations on both sides of the hyperpycnal plume.

Inside the unconfined plunging plume, a low-velocity zone exists due to flow separation induced by the transition from the horizontal bottom of the inflow channel to the sloping bed of the receiving waters.

Similar to confined plunging, the inflow densimetric Froude number \( Fr_{d-0} \) and the bottom slope \( \beta \) in the receiving water body are the dominant control parameters in unconfined plunging. The same value of \( Fr_{d-0} \) can be obtained from different combinations of its constituents \( Fr_0 \) and \( R_0 \). The results show that plunging characteristics only depend on \( Fr_{d-0} \) irrespective of \( Fr_0 \) and \( R_0 \).

Decreasing \( Fr_{d-0} \) or increasing the bottom slope causes plunging to occur closer to the river mouth.

In confined plunging, the plunge occurs when the densimetric Froude number \( Fr_{d-0} \) decreases to a critical value close to 0.5 and the amount of ambient water entrained into the hyperpycnal plume is quite limited. In unconfined plunging, however, the vertex plunge point is where the two sides of the hyperpycnal plume meet at the centerline on the surface even if \( Fr_{d-0} \) is still larger than the critical value of unconfined plunging. Since ambient waters can be entrained from both sides into the hyperpycnal current, the entrainment coefficient \( E \) in unconfined plunging is found to be much larger than in confined plunging.

This study has made evident the following similarities and differences between confined and unconfined plunging:

Similarities:

1. From the river mouth, the layer-averaged thickness \( h_c \) of the hyperpycnal current in the central section first increases and then decreases rapidly after the initiation of plunging, followed by another increase due to entrainment. The variations of \( h_c \) can be applied to determine \( x_p \) and \( x_{ud} \).
2. The distance from the river mouth to the plunge location (or the vertex plunge point) increases with increasing \( Fr_{d-0} \) and decreasing bottom slope \( \beta \).
Differences:

1. Unconfined (3D) plunging flow patterns are different from those of confined (2D) cases.
2. The discharge per unit width at the central section $q_c$ increases longitudinally in unconfined plunging but is constant in confined cases.
3. In confined plunging, the plunge occurs when $Fr_d$ decreases to the critical value (i.e., $Fr_d - p \approx 0.5$). In unconfined cases, however, the vertex plunge point is located where the two sides of the hyperpycnal plume meet at the centerline on the surface.
4. In unconfined plunging, much more entrainment takes place resulting in significantly larger entrainment coefficient $E$ values than in confined cases.

The numerical model results agreed well with previous field observations of unconfined plunging flow. This unique combination of laboratory experiments, numerical modeling, and previous field observations improves the understanding and the characterization of unconfined hyperpycnal river plunging dynamics.

Unconfined hyperpycnal river plume plunging is often observed in lakes. Taking into consideration unconfined plunging processes allows for better understanding of how plunging inflows transport materials and how they mix with ambient waters, and as a result, how they affect water quality, local ecosystems, and morphological evolution. Therefore, the results of the present study can contribute to the development of effective lake management concepts. These findings can also be expected to be applicable to other water bodies where unconfined hyperpycnal river-plume plunging occurs.
