21 **Abstract**

22 Studies on the impact of ocean acidification on marine organisms involve exposing
23 organisms to future acidification scenarios which has limited relevance for coastal
24 calcifiers living in a mosaic of habitats. Identification of tipping points beyond which
25 detrimental effects are observed is a widely generalizable proxy of acidification
26 susceptibility at the populational level. This approach is limited to a handful of studies
27 that focus on only a few macro-physiological traits, thus overlooking the whole organism
28 response. Here we develop a framework to analyze the broad macro-physiological and
29 molecular responses over a wide pH range in juvenile oyster. We identify low tipping
30 points for physiological traits at pH 7.3-6.9 that coincide with a major reshuffling in
31 membrane lipids and transcriptome. In contrast, a drop in pH affects shell parameters
32 above tipping points, likely impacting animal fitness. These findings were made possible
33 by the development of an innovative methodology to synthesize and identify the main
34 patterns of variations in large -omic datasets, fitting them to pH and identifying molecular
35 tipping-points. We propose the broad application of our framework to the assessment of
36 effects of global change on other organisms.

41 **Introduction**

42 The exponential increase in the atmospheric emission of carbon dioxide (CO₂)
43 from anthropogenic activities is mitigated by ocean absorption that leads to decreasing
44 ocean pH and changes in carbonate chemistry, a phenomenon known as ocean
45 acidification (OA) (Caldeira & Wickett, 2003; Orr et al., 2005). This represents a
46 tremendous challenge for marine organisms, especially for calcifiers that produce calcium
47 carbonate (CaCO₃)-based exoskeletons. OA not only induces internal acidosis that
48 impacts metabolism, behavior, growth and reproduction, but also decreases carbonate ion
49 (CO₃²⁻) concentration in the ocean, the elemental constituent of calcifier exoskeletons
50 (Gazeau et al., 2013; IPCC, 2019; Kroeker et al., 2013; Tresguerres & Hamilton, 2017
51 for reviews).

52 OA has been the most-studied topic in marine science in recent times (Browman,
53 2017). As such, many OA experiments have been conducted, usually exposing organisms
54 to experimental conditions based on scenarios modelled for open ocean waters, typically
55 simulating present and near-future surface ocean pH levels. However, many calcifying
56 species thrive in coastal areas where pH levels vary far more than in the open ocean on
57 both daily and seasonal scales (Vargas et al., 2017; Waldbusser & Salisbury, 2014). As a
58 result, several authors have applied pH offsets or conditions that are more locally relevant
59 (Dineshram et al., 2015; Gazeau et al., 2014; Ko et al., 2014), but the results cannot be
60 extrapolated to populations or species that are distributed in a mosaic of habitats. We need
61 to implement experimental approaches whose results can be applied in a wide range of
62 environments at the scale of species (Vargas et al., 2017).

63 Reaction norm, i.e. the response of an organism to changing environmental
64 parameters, allows the identification of tipping points that beyond small variations will
65 have major impacts. According to the last IPCC reports, identification of tipping-points

66 is a key knowledge gap in environmental change research (IPCC, 2019, 2021). Tipping-
67 point is valid for a whole population regardless of habitat. Also, this is a single, easily
68 communicable value that reflects susceptibility to OA (Bednaršek et al., 2019, 2021). To
69 date, only four studies have experimentally established reaction norms for marine
70 calcifiers in relation to pH. These studies focused on the assessment of tipping points for
71 a few selected traits measured at the organism level (i.e. growth, survival) and provide a
72 limited view of the whole organism response, ignoring molecular responses (Comeau et
73 al., 2013; Dorey et al., 2013; Lee et al., 2019; Ventura et al., 2016). We therefore identify
74 the need to integrate macro-physiology and omics together with reaction norms, for
75 understanding the mechanisms responsible for individual organism success under a
76 changing environment. This however requires developing an innovative methodology to
77 synthesize and identify the main patterns of variations in large -omics datasets (Strader et
78 al., 2020) and fit them to reaction norms.

79 Lipidomic and transcriptomic approaches provide complementary and holistic
80 views of organismal responses to environmental changes at the molecular and
81 biochemical levels. Membrane lipids modulate exchanges between the intracellular
82 milieu, which is highly-regulated, and the extracellular milieu which reflects
83 environmental changes, and therefore play a key role in metabolic regulation and ion
84 exchanges (Hazel & Williams, 1990; Hochachka & Somero, 2002; Hulbert & Else, 1999).
85 However, the role of membrane lipids in the regulation of acid-base equilibrium and
86 biomineralization under OA has never been investigated. Here we expect that membrane
87 lipids play a key role in the maintenance of electrochemical gradient across membranes,
88 a parameter that is essential for organism's persistence under OA (Cyronak et al., 2016).

89 The transcriptomic response is one of the first level of metabolic regulation that
90 determine shifts in acid-base ion regulation, metabolic processes, calcification and stress

91 response mechanisms (Matz, 2018; Strader et al., 2020). Although an increasing number
92 of studies investigate the transcriptomic responses of marine calcifiers under OA, they
93 generally focus on a few targeted genes that play a central role in physiological processes
94 and they assume that gene functions are conserved among taxa (Strader et al., 2020). This
95 creates a vicious cycle limiting the opportunities to uncover new mechanisms and cellular
96 pathways involved in organism responses to OA. New methodologies are therefore
97 required to provide new insight on organism's response to OA at the transcriptional level
98 (Rajan et al., 2021; Yarra et al., 2021).

99 Here we determine the reaction norm of juvenile Pacific oyster *Crassostrea gigas*,
100 one of the most cultivated invertebrate species in the world (FAO, 2020), over a wide
101 range of pHs for macro-physiological traits, membrane lipids and gene expression.
102 Although the impacts of OA on this model species have been intensively studied using
103 scenario approaches, there is currently no consensus on its robustness to low pH (Ducker
104 & Falkenberg, 2020). The establishment of reaction norm with biochemical and
105 molecular data is a novel approach that provides new insights on the sensitivity of marine
106 calcifiers to OA.

107 **Material and methods**

108 **Animals and maintenance**

109 The oysters were produced at the Ifremer hatchery facilities in Argenton (Brittany,
110 France) in late August 2018 according to Petton et al. (2015). The broodstock consisted
111 of 139 females and 40 males originating from six different cohorts collected in the natural
112 environment between 2011 and 2016, off Fouras (Ile d'Aix, France). At 40 days old, the
113 juveniles were moved to the Ifremer growing facilities in Bouin (Vendée, France). On
114 January 10th 2019, oysters were returned to Argenton and kept for 8 d in a 500 L flow-

115 through tank. Seawater temperature was gradually increased from 7 °C to 22 °C, the
116 optimal temperature for *C. gigas* (Bayne, 2017), at a rate of *ca.* 2 °C d⁻¹. During the
117 experiment, oysters were continuously supplied with natural seawater originating from
118 a pool (~9000 m³) which is renewed with each spring tide, filtered at 5 µm and UV-
119 treated. The oysters were fed continuously on a mixed diet of *Isochrysis affinis galbana*
120 (CCAP 927/14) and *Chaetoceros gracilis* (UTEX LB2658) (1:1 in dry weight). Food
121 concentration was maintained at 1500 µm³ mL⁻¹ of phytoplankton cells at the outlet
122 of the tank – *ad libitum* (Rico-Villa et al., 2009) – and controlled twice daily using an
123 electronic particle counter (Multisizer 3, Beckman Coulter, USA) equipped with a 100
124 µm aperture tube. On the eve of the experiment on January 14th 2019, at which point
125 they were 5-month-old, oysters were divided into 15 batches containing 292 ± 20
126 individuals (95.2 ± 0.2 g).

127 **Experimental design**

128 Each batch of oysters was exposed to one constant nominal pH condition ranging from
129 pH 7.8 to 6.4 with a step of 0.1 between two levels. The upper pH condition (pH ~7.8)
130 was obtained by running seawater with oysters without pH regulation. The lowest pH
131 values encountered by oysters today are presumably between pH 7.4 and 7.0
132 (Frankignoulle et al., 1996; Melzner et al., 2013; Proum et al., 2017; Wallace et al., 2014).
133 Geochemical models using the record of atmospheric CO₂ levels over the last 300 Myr
134 suggest that the ocean pH was at most 0.6 units lower than today (Caldeira 2003).
135 Continued release of CO₂ from fossil fuels into the atmosphere (worst case scenario)
136 could result in a reduction in pH of 0.7 units at the ocean surface (Caldeira 2003).

137 Therefore, the lowest pH values used in our study are probably unrealistic but expand the
138 reaction norms and increase the statistical power of the tipping point.

139 The experimental system consisted of 18 experimental units that were
140 randomly assigned to one pH condition (n = 15, no pH replication) or to control blanks
141 without animals (n = 3) (Supplementary Figure 1). Each experimental unit consisted
142 of a header tank in which seawater was acidified (except for the ambient pH and
143 blanks) and then delivered by a pump to a holding tank containing the oysters. These
144 tanks were 45 L and their entire volume was renewed every 82 min. pH was regulated
145 by means of pure-CO₂ bubbling, controlled by a pH-regulator (ProFlora® u403 JBL).
146 The pH-regulator was connected to pH-probes installed in each header tank (pH-
147 sensor+Cal, JBL), checked at the start of the experiment using Certipur® Merck NBS
148 buffers (pH = 4.00, pH = 7.00). pH electrodes from the pH-regulator were inter-
149 calibrated twice daily against a pH probe (Sentix® 940-3 WT) connected to a
150 Multiline® Multi 3630 IDS-WTW. The pH-probe was checked once a week using
151 Certipur® Merck NBS buffers (pH = 4.00, 7.00, and 9.00) and calibrated twice a week
152 on the total scale with a certified Tris/HCl buffer (salinity 35; provided by A. Dickson,
153 Scripps University, USA). Throughout the text, pH levels are therefore expressed on
154 the total scale (pH_T). In each experimental tank, air bubbling and a small
155 homogenisation pump (3 W) ensured an efficient mixing of seawater surrounding the
156 oysters. Photoperiod was 10 h light: 14 h dark. During the entire experimental period,
157 oysters were fed as described above.

158 On January 18th 2019, each batch of oysters was randomly assigned to one tank.
159 Oysters were first held at ambient pH for 3 d. Then, pH was progressively decreased in
160 each pH-regulated tank at a rate of 0.2 unit d⁻¹. The decrease in pH lasted for 7 d for the
161 lowest condition. Experimental pH conditions were all reached on January 27th 2019.
162 The pH exposure lasted 23 days, the time required for critical shell alteration
163 (bleaching, perforation, and dissolution) under the lowest pH conditions. No mortality
164 was recorded during the experiment.

165 **Seawater carbonate chemistry**

166 In each oyster tank, temperature, salinity, dissolved oxygen (O₂) saturation
167 levels and pH were measured twice a day using a Multiline® Multi 3630 IDS-WTW
168 (pH probe Sentix® 940-3 WTW, O₂ probe FDO® 925 WTW, salinity probe TetraCon®
169 925 WTW). Seawater samples were collected weekly, filtered through 0.7 µm (GF/F,
170 Whatman®) and poisoned with 0.05% mercury (II) chloride. Total alkalinity (TA) was
171 then measured in triplicate 50 mL subsamples by potentiometric titration at 22 °C,
172 using a Titrand 888 (Metrohm®) titrator coupled to a glass electrode (ecotrode plus,
173 Metrohm®) and a thermometer (pt1000, Metrohm®). TA was calculated following the
174 protocol described in Dickson et al. (2007). At the time of sampling, pH, salinity and
175 temperature were measured, and then used together with TA value to determine
176 carbonate chemistry parameters using the package seacarb v 3.2.16. of the R software.

177 **Biometry**

178 The total fresh weight (shell + tissue) of each batch of oysters was measured
179 twice weekly and interpolated between measurements to estimate daily weight. In

180 addition, shell length and total fresh weight were measured individually on 30 oysters
181 from each condition at the onset (1 d) and at the end of the experiment (23 d). The
182 measurements relate to different individuals taken over time. These oysters were then
183 dissected and pooled to determine the total weight of shell and tissue, separately. The
184 tissues were then lyophilized and weighted to obtain dry weight. Growth rate was
185 calculated as:

$$186 \quad G = (\overline{X}_{23} - \overline{X}_1) \div 23,$$

187 where G is growth rate as expressed as increase in shell length or total body weight
188 per day (mm d^{-1} , mg TW d^{-1}), \overline{X}_1 and \overline{X}_{23} are the average parameter values for shell
189 length and total weight measured at the onset (1 d) and the end of the experiment (23
190 d).

191 Shell thickness was measured on the left valve of five individuals collected per
192 pH condition at the end of the experiment. The left valve was more susceptible to
193 acidification than the right valve. We observed holes in the shell under low pH
194 condition ($\text{pH} < 6.6$) that always occurred on the left valves, close to the umbo. Shells
195 were dried for 24 h at 45 °C, embedded in polyester resin and cross-sectioned from
196 umbo to opposite shell margin along the longitudinal growth axis using a precision
197 saw (Secotom-10 Struers). Sections were glued on a microscope slide and polished
198 with silicon carbide abrasive disks (1200 and 2500 grains cm^{-2}). Images of the section
199 were captured under a Lumar V12 stereoscope (Zeiss) at 30x magnification, and the entire
200 section was reconstructed using an image acquisition software (AxioVision SE 64 –

201 v4.9.1, Zeiss). The minimal shell thickness was measured within the first third of the
202 shell starting from umbo using ImageJ software (Schneider et al., 2012).

203 **Physiological rates**

204 Seawater was sampled twice a day at the inlet and outlet of each oyster tank
205 and phytoplankton cell concentrations were measured using an electronic particle
206 counter (see previous section). No pseudofaeces production was detected throughout
207 the experiment. Ingestion rate was determined as:

$$208 \quad I = \frac{\Delta_{\text{phyto}} \times \text{flow rate}}{W},$$

209 where I is the ingestion rate expressed as $\text{cm}^3 \text{min}^{-1} \text{g}^{-1}$, Δ_{phyto} is difference in
210 phytoplankton concentrations between the inlet and the outlet of the oyster tanks
211 ($\text{cm}^3 \text{min}^{-1}$), flow rate is the water flow at the inlet of the oyster tanks (mL min^{-1}), and
212 W is the total fresh weight of oyster batch (g). The three control blanks were used to
213 check that there was no sedimentation of algae (no differences in cell concentrations
214 between the inlet and the outlet, data not shown).

215 Net calcification and respiration rates were measured after 22 d of exposure.
216 Food supply was stopped 17 h before the assay and tanks were emptied, cleaned and
217 refilled. Again, 1 h before the assay, the tanks were emptied, cleaned and refilled. At
218 the onset of the incubation, water flow and air bubbling were stopped. Gentle mixing
219 of the seawater was maintained by homogenization pump but air bubbling was
220 stopped. Incubations lasted for 90 min. This duration allowed to keep the pH close to
221 the setpoint (< 0.1 pH unit variation) despite oyster respiration. At the onset and at
222 the end of the incubation period, temperature, salinity, pH and O_2 concentration (mg

223 L⁻¹) were measured, and seawater samples were filtered and poisoned for TA analyses
224 (see above) or were immediately frozen at -20 °C for ammonium (NH₄⁺) measurements
225 (Aminot & K  rouel, 2007) (see Supplementary Table 1). Empty tanks were used as
226 controls to check that there was no change in any of the parameters due to
227 evaporation or other potential biological processes in the water itself. Net calcification
228 rate was determined following a modified procedure from Gazeau et al. (2015) using
229 the alkalinity anomaly technique (Smith & Key, 1975):

$$230 \quad NC = \frac{(\Delta_{TA} \times \rho - \Delta_{NH_4^+}) \times V}{2 \times t \times W \times \frac{DW}{TW}},$$

231 where *NC* is the net calcification rate expressed as $\mu\text{mol CaCO}_3 \text{ h}^{-1} \text{ g}^{-1}$, Δ_{TA} and $\Delta_{NH_4^+}$
232 are differences in TA ($\mu\text{mol Kg}^{-1}$) and NH₄⁺ ($\mu\text{mol L}^{-1}$) between the onset and the end
233 of the incubation period, ρ is seawater density (kg L^{-1}) calculated based on temperature
234 and salinity during the incubation, *V* is the volume of the tanks (L), *t* is the duration
235 of the incubations (h), $\frac{DW}{TW}$ is the ratio of dry weight and total weight determined after
236 lyophilization of a pool of tissues from 30 oysters (see above).

237 Respiration rate was determined following:

$$238 \quad R = \frac{(\Delta_{O_2} - \Delta_{O_2 \text{ Control}} \times \rho) \times V}{t \times W \times \frac{DW}{TW}},$$

239 where *R* is the respiration rate expressed as $\text{mg O}_2 \text{ h}^{-1} \text{ g}^{-1}$, Δ_{O_2} and $\Delta_{O_2 \text{ Control}}$ are
240 differences in O₂ concentration (mg L^{-1}) between the onset and the end of the
241 incubation period in the oyster tank and in the three control tanks (average)
242 respectively. Negative values mean that oxygen consumption was negligible and
243 similar to control blanks.

244 **Biochemistry**

245 Soft-tissues of five individuals from each pH condition were collected at 23 d,
246 flash-frozen in liquid nitrogen, pooled, grounded with a ball mill and stored at -80 °C
247 pending analyses. Oyster powder was diluted with chloroform/methanol (2:1, v/v) for
248 the determination of neutral lipids (triacylglycerol: TAG, and sterols: ST) using high
249 performance thin layer chromatography. TAG-ST ratio was used as a proxy of the
250 relative contribution of lipid reserve to structure (membrane). Polar lipids were
251 purified on silica gel micro column, transesterified using methanolic H₂SO₄ at 100 °C,
252 and the resulting fatty acid methyl esters (FAME) were analyzed using a gas-
253 chromatography flame ionization detection system equipped with a DB-Wax capillary
254 column. Peaks were analyzed by comparison with external standards. Each fatty acid
255 was expressed as the peak area percentage of total polar fatty acids. Carbohydrate
256 content ($\mu\text{g mg}^{-1}$) was determined according to the colorimetric method described in
257 DuBois et al. (1956).

258 **Transcriptomics**

259 Soft-tissues of five individuals from each tank were collected at 23 d, flash-
260 frozen in liquid nitrogen and individually grounded (n = 75). Total RNA was then
261 extracted with Extract-All (Eurobio) at a ratio of 5 mL per 100 mg of tissue. RNA
262 quantity/integrity and purity were verified with a NanoDrop 2000 spectrophotometer
263 (Thermoscientific®) and a Bioanalyzer 2100 (Agilent Technologies®) respectively.
264 Samples were then DNase-treated using a DNase Max™ Kit (MO BIO Laboratories,
265 Inc.) and analyzed at the Genotoul sequencing platform (INRAE US 1426 GeT-PlaGe,

266 Centre INRAE de Toulouse Occitanie, Castanet-Tolosan, France). TruSeq RNA
267 libraries were multiplexed and sequenced on a single lane of NovaSeq6000 Illumina
268 S4 150-bp paired-end.

269 Raw reads were first filtered using Trimmomatic v.0.36 for a minimum length (60 bp),
270 a minimum quality (trailing = 20, leading = 20) and the presence of potential
271 contaminants and remaining adaptors (<https://ftp.ncbi.nlm.nih.gov/pub/UniVec/08/17/20>). The quality of the reads was monitored before and after this trimming
272 process with FastQC v.0.11.5
273 (<https://www.bioinformatics.babraham.ac.uk/projects/fastqc/>). The *C. gigas* reference
274 genome (Peñaloza et al., 2021) was downloaded from NCBI (GCF_902806645.1) and
275 indexed with Gmap v2020.06.01. Filtered reads were mapped against the reference
276 genome using GSNAP v2020-06-30 keeping default parameters but allowing a
277 minimum mismatch value of 2 and a minimum read coverage of 90%. Finally, the
278 gene expression levels were assessed using HTSEQ v0. 6.1. The DESeq2 v1.30.0 R
279 package was used to process the expression with a first step of normalization using the
280 variance-stabilizing transformation implemented in the 'vst' function. The vst matrix
281 was used to build a signed weighted co-expression network analysis implemented in
282 the WGCNA v1.69 R package. First, genes with low overall variance (< 5%) were
283 removed for the analysis as recommended (Langfelder & Horvath, 2008). We fixed
284 the “soft” threshold powers of 13 the scale-free topology criterion to reach a model fit
285 ($|R|$) of 0.90. Clusters were defined using the “*cutreeDynamic*” function (minimum of
286 50 genes by cluster and default cutting height of 0.99) based on the topological overlap

288 matrix, and an automatic merging step with the threshold fixed at 0.25 (default)
289 allowed merging correlated clusters. For each cluster, we defined the cluster
290 membership (kME; Eigengene-based connectivity) and only clusters showing
291 significant correlation ($p < 0.01$) to pH were kept for downstream functional analysis.

388 **Statistical analysis**

389 All statistical analyses were performed using the R software v4.0.3 and the
390 threshold of statistical significance was fixed at 0.05 unless specifically stated.
391 Relationships between dependent variables and average pH recorded during the
392 exposure period (or the incubation period for net calcification and respiration rates)
393 were computed using regression models. Dependent variables were biometrics (shell
394 length, total body weight, and growth), physiological rates (ingestion, net calcification
395 and respiration), biochemistry (lipid reserves, carbohydrates) and gene expression.
396 Each gene included in the WGCNA clusters were individually tested against pH. Fatty
397 acids were summarized using principal component analysis and separated into two
398 groups according to their correlation with first principal component (positive or
399 negative). Each group was then summed and tested against pH. Piecewise, linear and
400 log-linear regression models were tested and compared for each individual variable
401 (or set of variables). In each case, the model that had the highest R^2 , the lowest Akaike
402 and Bayesian information criteria (AIC, BIC) and the lowest residual sum of squares
403 was selected. For each piecewise regression model, we estimated the tipping point,
404 defined as the values of the pH where the dependent variables tip, by implementing
405 the bootstrap restarting algorithm (Wood, 2001). For physiological rates, we also

406 determined the critical-point defined as the pH at which the dependent variable was
407 equal to zero. Normality of residual distribution was tested using Shapiro-Wilk test
408 and homogeneity of variances was graphically checked. Significance of each slope was
409 tested according to Student's *t* test. Piecewise regression models were built using the
410 segmented v1.3-4 R package.

411 For transcriptomic analysis, only genes that are significantly correlated to pH were tested
412 among the retained clusters (Pearson correlation). The frequency distribution of pH
413 tipping-point values was plotted for each cluster of genes. Groups of genes which exhibit
414 neighboring tipping points with distribution frequencies > 5%, were grouped together and
415 used for GO enrichment analysis using GOA-tools v0.7.11 (Klopfenstein et al., 2018),
416 implemented in the Github repository '*go_enrichment*'
417 (https://github.com/enormandeu/go_enrichment) and the go-basic.obo database
418 (release 2019-03-19) with Fisher's exact tests. Only significant GO terms that
419 included a minimum of three genes and with Bonferroni adjusted $P < 0.01$ were kept.
420 For complementarity with previous studies, we also specifically examined the genes
421 that are commonly reported as involved in the calcification process and in the
422 formation of the organic matrix of the shell and periostracum (Supplementary File 1).

423 **Results**

424 **Acclimation of oysters to 15 different pH conditions**

425 During the experiment, pH levels in the oyster tanks were stable and reached the
426 targeted values, except for the lowest pH condition that was 6.5 ± 0.3 instead of 6.4
427 (Supplementary Note 1, Supplementary Table 2, Supplementary Figure 2). The effects of
428 acidification were clearly visible at the end of the experiment on the color and the

429 size of the shells, as shown in Figure 1. Shell pigmentation apparently decreased with
430 decreasing pH. Total body weight and shell length of oysters ranged from 0.4 ± 0.1 to
431 2.0 ± 0.8 g and from 12.9 ± 2.1 to 25.4 ± 4.5 mm respectively (mean \pm SD; Figure 2A,
432 Supplementary Figure 3).

433 **Most macro-physiological traits tip at low pH values between 7.1-6.9**

434 We measured biometric parameters like the length, thickness, and weight of the
435 shell and the total body weight and the dry flesh weight at the end of the 23-day exposure
436 to the 15 different pH conditions. We calculated growth rates for shell length and total
437 body weight, and we measured physiological rates like calcification, ingestion and
438 respiration rates. From these data, we identified an overall tipping point for macro-
439 physiological traits at pH \sim 7.1-6.9 below which they declined sharply (Figures 2A-H).
440 Calcification rate and growth rates exhibited critical points at pH 6.8 and 6.6, respectively,
441 below which they became negative and turned to net dissolution of the shell and weight
442 and length losses (Figures 2B-D). Concomitantly, respiration rate was arrested at pH 6.7
443 and ingestion rate was near-zero at pH 6.5 (Figure 2E-F).

444 **Shell parameters and respiration rate are impacted above tipping point**

445 Although macro-physiological traits were generally unaffected by reductions in
446 pH above tipping points, this was not the case for shell length, shell weight and
447 respiration rate. Both shell parameters indeed decreased with decreasing pH while the
448 respiration rate increased before reaching the tipping point (Figures 2A, 2E and 2G).
449 In addition, the shell thickness was the only parameter that decreased linearly over
450 the entire pH range without demonstrating a measurable tipping point (Figure 2I).

451 **A major remodeling of membrane lipids occurs at pH 6.9**

452 To provide an in-depth characterization of the reaction norms at the whole
453 organism level, we aimed to link the oyster reaction norm established for the macro-
454 physiological traits described previously to the molecular responses of oysters. We first
455 analyzed the fatty acid composition of membrane lipids that play an important role in
456 exchanges between intracellular and extracellular compartments. Principal component
457 analysis of all fatty acids showed that the first axis (PC1) alone explained 66% of the total
458 variance in relation to pH (Figure 3A). The set of fatty acids was reduced to two terms
459 defined by the sums of fatty acids that correlated with PC1 either positively or negatively,
460 and each term was plotted against pH (Figure 3B-C). Positively correlated fatty acids
461 mainly consisted of docosahexaenoic acid (DHA, 22:6n-3) and palmitic acid (PA, 16:0)
462 contributing 43% and 14%, respectively, to PC1 (Supplementary Table 3). This group of
463 fatty acids exhibited a tipping point at pH 6.9, below which their contribution to
464 membranes decreased markedly (Figure 3B). In contrast, the contribution to membrane
465 of the fatty acids that were negatively correlated with PC1 increased markedly below pH
466 6.9. These negatively correlated fatty acids consisted of arachidonic acid (ARA, 20:4n-
467 6), eicosapentaenoic acid (EPA, 20:5n-3) and non-methylene interrupted fatty acids
468 (22:2NMI_{i,j}), which contributed 12%, 6% and 6%, respectively, to PC1 (Figure 3C)
469 (Supplementary Table 3).

470 **Expression of most genes shows tipping points at pH 7.3-6.9**

471 To further assess the molecular effects of pH change, we compared the
472 transcriptome responses of oysters exposed to the 15 pH conditions for 23 days using
473 RNA-seq. To do this, we first clustered the differentially expressed genes that co-vary
474 together using WGCNA analysis and retained the clusters that were correlated with pH
475 (Supplementary Table 4). Then, we plotted the frequency distribution of pH tipping-point

476 for each cluster of genes (Figure 4). Owing to this original method, we found that 1054
477 genes, distributed in three clusters, showed linear (or loglinear) or piecewise
478 regression with pH (Supplementary Table 4). Among them, 49% showed tipping-points
479 at pH 7.3-6.9 (Figure 4A-C). Expression level of most genes were unchanged between
480 pH conditions down to the pH tipping point, below which it increased for genes in clusters
481 1 and 2 (Figure 4A-B), or decreased for genes in cluster 3 (Figure 4C). Some genes
482 linearly increased for clusters 1 and 2, or decreased for cluster 3 with decreasing pH.

483 Gene ontology analysis (GO) showed that most of the genes from cluster 1 (42%)
484 exhibited tipping-points at pH 7.3-6.9 (Figure 4A) and were associated with GO terms
485 corresponding to the regulation of RNA-transcription, cellular metabolism,
486 macromolecule biosynthesis and negative regulation of cell-cell adhesion (Table 1). The
487 expression of another group of genes from cluster 1 (14%) increased linearly (or
488 loglinearly) with decreasing pH and was associated with GO terms corresponding to
489 GTP-binding, GTPase activity and ribonucleotide metabolism (Table 1). The expression
490 of most of the genes from cluster 2 (44%) exhibited tipping-points at pH 7.3- 7.0, whereas
491 another large group of genes (18%) increased linearly (or loglinearly) with decreasing pH
492 (Figure 4B). These genes were associated with GO terms corresponding to ribosome
493 synthesis, RNA-binding, translation and protein/amino acid synthesis (Table 1). The
494 expression of 62% of the genes from cluster 3 exhibited tipping-points at pH 7.2-6.9 and
495 decreased thereafter (Figure 4C). These genes were associated with GO terms
496 corresponding to ion transport and more specifically to transmembrane cation transport
497 (Table 1).

498 **Expression of genes related to biomineralization shows tipping point at pH 7.1-6.9**

499 We specifically examined the genes that are commonly reported in the
500 scientific literature as being involved in the calcification process and in the formation
501 of the organic matrix of the shell and periostracum. We found that the expression of
502 60% of the 38 genes involved in the calcification process that were retained by our
503 models showed pH tipping points between 6.9 and 7.1 (Table 2). These genes encode for
504 calcium-binding proteins, Ca²⁺ signaling pathway, amorphous calcium carbonate-binding
505 proteins and ion transmembrane transporters. Most of these genes decreased below the
506 tipping-point (n = 14) while others increased (n = 8). The expression of genes associated
507 with the regulation of the synthesis of the shell organic matrix and the periostracum (n =
508 11) generally increased with decreasing pH (Table 2). The relationships were loglinear (n
509 = 3) or piecewise (n = 8).

510 Among these 38 genes, the family of genes that are the most represented are
511 coding for acetylcholine receptors, monocarboxylate transporters and tyrosinase
512 synthesis (Table 2). The expression of four genes coding for acetylcholine receptors
513 decreased below tipping points at pH 6.9-7.0. The expression of five genes coding for
514 monocarboxylate transporters increased with decreasing pH, and four of them showed pH
515 tipping points between 7.3 and 6.6. The expression of four genes associated to tyrosinase
516 synthesis early increased with decreasing pH and three of them showed tipping points
517 between pH 7.4 and 7.1.

518 **Discussion**

519 Here we provide the first reaction norm of juvenile oyster *C. gigas* assessed by
520 combining macro-physiological traits and micro-molecular characteristics. This novel
521 approach applied to juvenile oysters exposed to a wide range of pH conditions revealed

522 that macro-physiological parameters such as growth, calcification, food intake, and
523 respiration exhibited pH tipping points that coincide with a major reshuffling in
524 membrane lipids and transcriptome that was previously unappreciated, but others like
525 shell parameters seemed uncoupled from global effects (Figure 5). This comprehensive
526 view of the oyster response to pH sheds new light on adaptation capacity of this species
527 to OA. We indeed identify low tipping points for most physiological traits that suggest
528 the species is robust to OA, but reveal sensitivity of shell parameters above the tipping
529 points that potentially impact animal fitness. We therefore determine the true sensitivity
530 of oyster to pH and identify the most relevant and sensitive response variables.

531 We first identify a global tolerance threshold for juvenile *C. gigas* at pH 6.9-7.3,
532 corresponding to the tipping points identified for the majority of the examined
533 parameters. In line with this, several studies based on IPCC scenario assumed the
534 existence of tipping points below pH 7.5-7.4 for growth, calcification, acid-base
535 equilibrium, and reproduction in oysters and mussels (Boulais et al., 2017; Fitzer et al.,
536 2014; Lannig et al., 2010). Our results are also in agreement with previous studies
537 showing that there are no significant changes in growth, respiration, mortality, metabolic
538 rate, ion regulation, energy reserves, gene expression and fatty acid profile in juveniles
539 and adults of *C. gigas* for pH values above 7.3. (Clark et al., 2013; Lannig et al., 2010;
540 Lemasson et al., 2018; Timmins-Schiffman et al., 2014; Wang et al., 2020). Below tipping
541 points, growth, calcification, respiration and feeding rate decreased markedly, likely
542 reflecting increasing maintenance cost up until reaching critical points that are
543 representative of metabolic depression (Michaelidis et al., 2005; Sokolova, 2021). It is
544 noteworthy that longer exposure time might have revealed an impact of the pH on survival
545 or reproduction, two important parameters for fitness. Survival should be compromised

546 below the tipping point as the animal shift to metabolic depression, i.e., a short-term
547 survival strategy (Michaelidis et al., 2005).

548 The tipping points we determined at pH 7.3-6.9 ($p\text{CO}_2 \sim 2600\text{-}8200 \mu\text{atm}$) are well
549 below IPCC projections for 2100 in open ocean waters (pH=7.8 according to scenario
550 RCP 8.5 IPCC, 2019). However, acidification events with pH values as low as 7.4-7.0
551 ($p\text{CO}_2 > 3000 \mu\text{atm}$) currently occur transiently in estuarine ecosystems in relation to
552 eutrophication and hypoxia (Frankignoulle et al., 1996; Melzner et al., 2013; Proum et
553 al., 2017; Wallace et al., 2014) and may explain why the physiological tipping point of
554 oysters is so low. These acidification events are expected to become increasingly frequent
555 and intense in the future (IPCC, 2019), such that the physiological tipping points defined
556 here for juvenile oysters may be reached.

557 This point out the importance of tipping point for coastal management and
558 conservation in a changing world. Tipping-point is valid for a whole population
559 regardless of habitat. Here we used juveniles that originate from a large genetic pool and
560 *C. gigas* is a weakly genetically-structured species (Meistertzheim et al., 2013). However,
561 it was recently shown that some wild and domesticated oysters populations vary in their
562 adaptive response to OA (Durland et al., 2021). We therefore need to verify that pH
563 tipping points defined in our study are valid in genetically differentiated populations
564 before integrating them in biogeographic models of species distribution. Finally, tipping
565 point is a single value that reflects susceptibility to stressors that is easily communicable
566 to end-users and society (Bednaršek et al., 2019, 2021).

567 We show here that shell parameters, i.e. thickness, weight and length, were altered
568 as soon as pH decreased from ambient levels, as already reported for many shellfish
569 species (Byrne & Fitzer, 2019). Shell thickness is generally related to shell strength and
570 therefore with protection against predation and resistance to mechanical stress related to

571 wave exposure and aquaculture processes. Thus, moderate acidification increases
572 predation risk of young *C. gigas* through reduction of shell strength (Wright et al., 2018).
573 We also find that respiration rate first increased when pH decreased, suggesting that
574 metabolism was readily impacted. However, body condition (dry flesh weight) and
575 energy reserves (TAG-ST and carbohydrate, Supplementary Figure 4) were not affected
576 by pH, likely because oysters were fed *ad libitum* (Leung et al., 2019; Thomsen et al.,
577 2013). Finally, we report here a linear increase in the expression level of genes related to
578 GTPase activity and GTP binding, which are characteristics of stress response in
579 *Crassostrea* spp. (Yan et al., 2018). Overall, these changes suggest that longer exposure
580 to moderate acidification (above tipping point) could impair overall oyster fitness.

581 We further show that this reduction in shell parameters was not related to
582 metabolic depression or to changes in net calcification or global gene expression. In
583 contrast, a recent meta-analysis on *C. gigas* suggests that OA induces a reduction in shell
584 thickness that is related to an overall transcriptional change inducing metabolic
585 depression and alteration of calcification rate (Ducker & Falkenberg, 2020). Here we
586 revisit these assumptions and find in agreement with other prior studies that no metabolic
587 disruptions occurred while shell strength and thickness decreased at pH 7.3-7.7
588 (Timmins-Schiffman et al., 2014; Wright et al., 2018).

589 Concomitantly, a delamination of the periostracum, the organic coat covering the
590 shell, may have occurred at pH levels above the tipping point, probably altering shell
591 protection. This was supported by an increase in shell bleaching (not measured) and
592 expression of four genes coding for tyrosinase-like proteins. Tyrosinases are involved in
593 periostracum synthesis and the increase in expression of their related genes is often
594 considered as a mechanism to limit the damage to the periostracum and the corrosion of
595 the shell in reaction to OA (Hüning et al., 2013). Delamination of the periostracum due

596 to moderate OA was frequently associated with alteration of shell properties such as
597 weakening and thinning (Alma et al., 2020; Auzoux-Bordenave et al., 2019; Bressan et
598 al., 2014; Coleman et al., 2014; Peck et al., 2016, 2018; Zhao et al., 2020). Our results
599 agree with the idea that OA is more a dissolution problem than a biomineralization
600 problem (Rajan et al., 2021).

601 This investigation of tipping points at the micro-scale also provides new insights
602 on the physiological response of oysters to OA. For the first time, we find a major
603 remodeling of membrane lipids in response to OA and observed a tipping point at pH 6.9.
604 This remodeling consisted of decreasing the long chain PUFA DHA (22:6n-3) that is
605 essential for growth and survival (Knauer & Southgate, 1999; Langdon & Waldock,
606 1981), at the benefit of eicosanoid precursors (ARA, 20:4n-6 and EPA, 20:5n-3) involved
607 in the stress response (Delaporte et al., 2003). Since membrane fatty acid composition
608 influences the activity of transmembrane proteins involved in ion transport (Hazel &
609 Williams, 1990; Hochachka & Somero, 2002), it could also have been related to
610 regulation of acid-base homeostasis and perhaps calcification under OA.

611 In line with this, we find an overall decrease in expression of genes related to
612 cation transmembrane transport below tipping points at pH 6.9-7.2 that can be related to
613 alteration of calcification and acid-base homeostasis (Zhao et al., 2020). Concomitantly,
614 we observe an overall decrease in the expression of genes coding for proteins involved
615 in the regulation of calcification through calcium signaling pathway, calcium homeostasis,
616 calmodulin signaling pathway and regulation of calcium carbonate crystal growth (Feng
617 et al., 2017; Wang et al., 2017; Zhao et al., 2020).

618 In our analysis, we also identify families of genes that must play an important role
619 in oyster response to OA. Among these genes, we identify four genes coding for
620 acetylcholine receptors that are known for regulating and ordering the formation of the

621 shell micro-structure (Feng et al., 2017). We also find five monocarboxylate transporters
622 coding genes, members of a family of proteins that act as co-transporters of protons H⁺,
623 that may be involved in the regulation of acid-base homeostasis and calcification process
624 (Tresguerres et al., 2020; Wang et al., 2020). These proteins also co-transport
625 monocarboxylates such as lactate or pyruvate and were reported to be involved in the
626 stress response of oysters through induction of anaerobiosis under metabolic depression
627 (Ertl et al., 2019).

628 In conclusion, we show that juvenile *C. gigas* have a broad tolerance to ocean
629 acidification, exhibiting tipping points around pH 7.3-6.9 for most parameters (Figure 5).
630 Nonetheless, we observe that shell parameters change as soon as pH drops, well before
631 tipping points are reached, suggesting animal fitness is likely to be affected. This thus
632 raises concerns about the future of natural and farmed oyster populations in a high-CO₂
633 world. This new framework for identification of tolerance threshold in organisms
634 represents a breakthrough in the field of global change research. It was made possible by
635 (1) combining reaction norm assessment and thorough molecular and biochemical
636 analyses of animal responses, and (2) developing a procedure to analyze and synthesize
637 omics data measured over an environmental range.

638 We believe that such an integrative and holistic approach could now be applied to other
639 organisms and integrate intra-specific variation, life-stages, generations, and other
640 stressors such as temperature, nutrition, pollutants or oxygen levels. Although this
641 approach requires significant financial resources, it allows to determine the true
642 sensitivity of a species to a stressor and to identify the most relevant and sensitive
643 response variables to study in the future.

644

645 **Acknowledgments**

646 We are grateful for K. Lague, J. Veillet, C. Quéré, V. Le Roy and I. Queau for their
647 participation to data recording and the Ifremer staff for their involvement in oyster and
648 algae production. We thank J. Thebault and E. Dabass for their advices in shell analysis.
649 We are also grateful for G. Le Moullac for project conception and funding. This work
650 was funded by the Ocean Acidification Program of the French Foundation for Research
651 on Biodiversity (FRB - www.fondationbiodiversite.fr) and the French Ministère de la
652 transition écologique.

653 **Author contributions**

654 ML, CDP, and FP designed and conducted the experiment. All authors analyzed the data.
655 ML performed statistics. ML and FP wrote the first draft of the document and all authors
656 contributed and accepted it. FP and JL obtained the funding. This work is part of the PhD
657 thesis of ML.

658 **Data availability**

659 RNA-seq data have been made available through the SRA database (BioProject accession
660 number PRJNA735889). Other data analyzed during this study are included in this
661 published article and its supplementary information files or available through the
662 SEANOE database (<https://doi.org/10.17882/83294>). Complementary information is
663 available from the corresponding authors on reasonable request.

965 **Figure captions**

966 **Figure 1.** Oysters exposed to 15 pH conditions for 23 d. Five oysters were selected from
967 each condition, and sorted from the smallest to the biggest. Corresponding pH (total scale)
968 and saturation states of seawater with respect to calcite (Ω_{CA}) are shown.

969 **Figure 2.** Biometry and physiological rates of oysters as a function of pH (total scale).
970 (a) shell length, (b) net calcification, (c) growth rate in shell length, (d) growth rate in
971 total body weight (TW), (e) respiration rate, (f) ingestion rate, (g) shell weight, (h) dry
972 flesh weight and (i) minimal shell thickness. Data are means \pm SD when available.
973 Tipping points and critical points and their 95% confidence intervals are shown in grey
974 and red, respectively. The significance levels of the slopes are presented using symbols
975 ($P < 0.001$ ***, < 0.01 **, < 0.05 *, < 0.1 ·).

976 **Figure 3.** Membrane fatty acid (FA) composition of oysters as a function of pH (total
977 scale). (a) Principal component analysis of polar fatty acid classes for oysters ($n = 15$
978 pools of five oysters) exposed to 15 pH levels. Arrows represent fatty acids contributing
979 to more than 5% of the first principal component (PC1). Individuals are colored according
980 to the average pH. Contribution to membrane of the sum of fatty acids that are (b)
981 positively or (c) negatively correlated to PC1 as a function of pH. Tipping points and
982 their 95% confidence intervals are shown in grey. The significance levels of the slopes
983 are presented using symbols ($P < 0.001$ ***, < 0.01 **, < 0.05 *, < 0.1 ·).

984 **Figure 4.** Tipping points of oyster transcriptome. (a-c) Frequency distribution of tipping-
985 point for piecewise linear relationships (left side). Linear and loglinear models (no
986 tipping-point) are under “Lin” name. Genes are grouped into three clusters of genes that
987 co-vary together. The grey line indicates the distribution frequency of all genes
988 irrespective of clusters. Groups of genes which exhibit neighboring tipping points with
989 distribution frequencies $> 5\%$ (shown as a dotted line), were grouped together. The

990 segments above the bars indicate the groups of genes on which GO analyses were
991 conducted. In each case, the gene that best represents the cluster according to module
992 membership, gene significance for pH and R^2 is presented as a function of pH as an
993 example (right side). Tipping points and their 95% confidence intervals are shown in
994 grey. The significance levels of the slopes are presented using stars (P <0.001 ***, p<0.01
995 **, p<0.05 *). Gene names are: LOC117690205: monocarboxylate transporter 12-like,
996 LOC105317113: 60S ribosomal protein L10a, LOC105331560: protocadherin Fat 4

1051

1052

1053 **Supplementary Note 1.**

1054 Temperature, salinity and O₂ saturation levels were stable across the experimental period
1055 and similar among pH conditions (Supplementary Table 1). Seawater was undersaturated
1056 with respect to calcite and aragonite when pH was below 7.3 and 7.6, respectively
1057 (Supplementary Table 1). However, parameters of carbonate chemistry were sometimes
1058 similar for different pH conditions. This reflects the difference in the frequency of
1059 measurements between the parameters (twice daily for pH and weekly for TA). Also, TA
1060 decreased slightly but linearly with increasing pH ($R^2 = 0.82$, slope = -0.08, $P < 0.001$)
1061 suggesting that seawater renewal was likely not sufficient to counteract both the uptake
1062 and the release of carbonate ions from net calcification at high pH and net dissolution at
1063 low pH, respectively (Supplementary Figure 2).

1064

Supplementary Figure 1. Experimental design for the determination of oyster's reaction norms to pH. Each batch of oysters was exposed 23 d to one nominal pH condition after 7 d of gradual pH decrease at a rate of 0.2 unit d⁻¹. There were 15 nominal pH conditions. The aspect of 5 oysters is shown for each pH conditions at the end of the exposure period (23th day) in the lower panel.

1066

1067 **Supplementary Figure 2.** Total alkalinity as a function of pH (total scale). Data are

1068 means \pm SD values recorded during the 23 d of exposure. The significance level of the

1069 slope is presented using stars (P <0.001 ***, <0.01 **, <0.05 *, <0.1 .).

1070

1071

1072 **Supplementary Figure 3.** Total body weight of oysters as a function of pH (pH on the
 1073 total scale). Data are means \pm SD. Tipping-point and its confidence intervals is shown in
 1074 grey. The significance levels of the slopes are presented using stars ($P < 0.001$ ***, < 0.01
 1075 **, < 0.05 *, < 0.1 ·).

1076

1077 **Supplementary Figure 4.** Energy reserves of oysters as a function of pH (total scale).

1078 (A) total carbohydrates and (B) triacylglycerol/sterol ratio (TAG-ST). Relationships were

1079 not significant ($P > 0.05$).

1080 **Supplementary Table 1** Seawater parameters during the incubations. pH on the total
 1081 scale (pH_T), calcite saturation state (Ω_{CA}), total alkalinity (TA), oxygen saturation (O₂),
 1082 salinity (S) and temperature (T). *Average* represents the mean values between the onset
 1083 and the end of the incubations. Δ represents the difference between the end and the onset
 1084 of the incubations. Values are mean \pm SD.

1099 **Supplementary Table 4** Number of genes modelled against pH. Each step of filtering
1100 and the corresponding number of selected genes are specified.

	WGCNA cluster of gene	correlated with pH	modelled & slope $\neq 0$	model	
1	3380	1691	664	piecewise	567
				linear	97
2	723	343	148	piecewise	130
				linear	18
3	2073	623	242	piecewise	221
				linear	21
