#### Abstract

In order to better document food practices of past societies, we butchered a female adult American bison (Bison bison) using replicas of Middle Palaeolithic stone tools. This experiment, carried out as part of the collective research project "Des Traces et des Hommes", was designed to test whether specific stone tools or raw materials were more efficient for certain activities, build a new dataset for activity specific use-wear patterns, and identify cut-marks characteristic (i.e. location and orientation) of each stage of the butchery process. The carcass was skinned, defleshed, and disarticulated, with the tendons also removed. Each butchery stage left cut-marks on the bison bones. Comparisons with available data for medium-sized ungulates shows comparable patterns in the interpretation of cut-marks, although some differences were observed, suggesting caution when interpreting cut-mark data on larger species such as bison. Moreover, our experiment revealed certain tools to be more efficient than others for butchery, and that the choice of tool type and/or raw material can influence the generation of cut-marks.

Keywords experimentation; butchery; Middle Palaeolithic stone tools; bison; cut-marks

## 1. Introduction

Cut-marks on bones and use-wear on stone tools are amongst the most reliable means for identifying carcass processing by past societies. Combined with our current understanding of taphonomic processes, several different forms of experimental and ethnographic evidence are available to reconstruct past butchery practices. There is now sufficient comparative data linking patterns in cut-mark distribution and frequency with butchery activities to allow these processes to be identified on various species, including reindeer, deer, African bovids, birds or rabbits (e.g. Binford 1981; Bez 1995; Nilssen 2000; Laroulandie 2001; Lloveras et al. 2009; Val and Mallye 2011; Soulier and Costamagno 2017; Costamagno et al. 2019; Soulier 2021). In order to add another reference collection to this growing body of evidence, we butchered an adult female American bison (Bison bison) using replicas of Middle Palaeolithic stone tools. This experiment was carried out as part of the collective research project "Des Traces et des Hommes' (coord. C. Thiébaut: Thiébaut et al. 2019). Our goal was to test potential correlations between stone tool types or particular raw materials and specific activities, characterize use-wear generated on stone tools for each activity, and build an interpretative framework for cut-marks that allow traces on large ungulate bones to be linked to a specific stage of the butchery process. This is of particular importance for bison, as this species is frequently encountered on archaeological sites (e.g. Speth 1983; Todd and Frison 1992; Farizy et al. 1994; Gaudzinski 1996; Frison 2004; Johnson and Bement 2009; Rodríguez-Hidalgo et al. 2017) and no reference collection is currently available for this large ungulate. Here we present the results of our butchery experiment, paying particular attention to the cut-mark data, and explore whether the coding system for medium-sized ungulates is equally applicable to bison. To this end, we mobilized data from butchery experiments involving red deer carried out within the framework of the same collective research project (Soulier and Costamagno 2017; Costamagno et al. 2019).

## 2. Material and methods

The bison (Bison bison) carcass was butchered in April 2011, 48h after its death. This 300 kg , twenty-year old adult female was raised at the 'Randals Bison' park (Lanuéjols, France) and transported in a refrigerated truck. In order to reliably recognize and interpret traces left on both stone tools and bones, the experiment was designed to avoid as much as possible carrying out more than one activity on the same area of a bone, and only one tool was used in a given activity. For example, the circular incision in the skin was made at mid-diaphysis on the metacarpals such that the tendons could be cut at the proximal and the distal end of the bone. This ensured that cutmarks potentially generated by these activities, could be reliably recorded. As control, the entire experiment was videotaped ${ }^{1}$, photos were taken, and all contacts between the tool and bone as

[^0]well as tool motions were recorded for each activity on a dedicated data sheet. The butchery experiment involved several types of stone tools, including hafted examples, made of various raw materials (Table 1). All butchery activities were carried out by several archaeologists familiar with bison anatomy and experimental carcass processing, with two professional butchers present to provide advice on how to best process the carcass.

A total of 35 stone tools were used during the butchery experiments. Surgical plasticine molds were made of the edges of the stone tools before and after butchery in order to identify macro- and micro-traces. Related lithic use-wear data have already been partially published (Claud and Thiébaut 2011; Claud et al. 2015, 2019). The leg bones were soaked in water with enzymes and the axial skeleton buried for a year in order to be cleaned and prepared for the cut-mark analysis. Bones were observed by two zooarchaeologists (M.-C. S and S. C) under low-angled light using a 30x magnifying hand-lens. All cut-marks were recorded on Adobe Illustrator® bone templates and, for ease of presentation, cut-mark distributions on left and right bone elements and each group of vertebrae and ribs were combined on the same anatomical drawing. The action that created them was then deduced from the contact sheets filled out during the butchery experiment. Cut-mark orientations on the meat-bearing long bones were assessed and quantified using QGIS (version 3.4.11 Madeira). In order to better visualize the data, a 6-part division is shown on figures depicting cut-marks on meat-bearing long bones ( 1 proximal and 6 distal portions).

## 3. Carcass Processing Protocol

The carcass was entirely processed on the ground. For health reasons, the bison was already eviscerated via an opening cut in the abdomen. The first stage of the butchery process, skinning (blue and gray areas in Fig. 1), was begun from this incision, with a cut made along the throat and a circular incision around the neck. Circular incisions were then made mid-diaphysis on both metacarpals of the front legs. For the right front leg, a longitudinal incision was made on the inner side, along the limb to the ventral incision for evisceration. For the left leg, this longitudinal incision started on the inner side from the metacarpal to the radio-ulna, and continued on the anterior face on the humerus. As the proximal diaphyses of the metatarsals had been broken at the slaughterhouse, a circular incision was unnecessary on the hind legs. On both sides on the hind legs, this longitudinal incision was made on the inner face of the legs from the metatarsals up to the ventral cut made for evisceration. For the axial skeleton, the skin was removed longitudinally, pulled from the ventral incision to the spine. The skin was subsequently removed from the lower legs, starting from the circular incision on the metacarpals and the broken area of the metatarsals.

[^1]A longitudinal incision was then made on the inner face of both rear legs, on the anterior face of the right hind-leg and on the lateral face on the left one. The remnant skin was removed via a circular incision made as close as possible to the hooves, which on a bison is at the level of the second phalanx. For the head, the skin was first removed from the mandible, beginning with an incision along the lower teeth, and then removing the skin from the body of the mandible with a motion from the teeth to the ventral face of the mandible. The skull was skinned by first making an incision along the teeth, and then moving upward.

As much meat as possible (cf infra) was recovered from all anatomical elements, including the head. The carcass was disarticulated (red area in Fig. 1) after defleshing in a manner consistent with the storage of bones for later use. The head was removed with three direct blows with a hafted quartzite cleaver at the junction with the atlas vertebra. Once defleshed, the mandible was detached by cutting and twisting. The sternum was separated from the ribs using hafted quartzite cleavers, with the surface scraped beforehand to facilitate breakage. The right side ribs were separated from the vertebrae, with ribs 2,3 and 4 forcibly detached once the sternum was opened, while ribs 5 to 13 were broken using a cleaver at the proximal end of the rib. The pelvis was separated from the trunk by percussion at the $4-5^{\text {th }}$ lumbar vertebrae junction. The limb bones were disarticulated using cutting motions involving different tools and raw material according to the leg (see Table 1). Extensor and flexor tendons were removed from the lower legs, and we attempted to extract the horny outer covering of the hooves.

## 4. Results

A total of 2203 cut-marks were recorded on the butchered bones (Table 2). Despite paying particular attention to avoid performing multiple activities at a same location, this was not always possible. For example, tool/bone contacts on the pelvis were signaled by the experimenter during both disarticulation and defleshing; however, due to the mass of flesh, it was difficult to precisely identify the location of these contacts. Consequently, reliably interpreting cut-marks in certain areas of the carcass is complicated. Moreover, cut-marks were identified in certain areas despite no contact being reported during butchery, making it difficult to assign them to a particular activity. Cutmarks impossible to reliably assign to a specific butchery activity are shown in gray in the figures.

### 4.1 Skinning

Removing the skin from the bison's head produced cut-marks on the maxilla, just above the cheek teeth, as well as on the vestibular surface of the teeth, around the orbital zone, and on the nasal and frontal bones (Fig 2a). The circular incision around the nose left multiple transverse cut-marks both on the nasal bones and premaxilla. Cut-marks on the tympanic bulla are connected to the removal of the ears during the skinning process. Skinning the jaw (Fig. 2b) generated cut-
marks on teeth, both on cheek teeth and the third incisor, at the periphery of the mental foramen and the corpus of the mandible up to the mandibular angle. Transverse cut-marks were recorded on the palmar edge of the mandible, slightly extending to the lingual side.

On the legs, the circular incisions made at mid-diaphysis on the metacarpals are clearly visible, with transverse and clustered cut-marks evident on the medial face of both metacarpals (Fig. 3a). No circular incision was made on the metatarsals (see above). The second circular incision made as close as possible to the hooves generated transverse and clustered cut-marks on the mesial phalanges of the rear legs (Fig 3e). Scattered, oblique or sub-transverse cut-marks were left on the metacarpals and the metatarsals as well as the phalanges when stone tools were used in an oblique motion to detach the skin. Whether on the metacarpals, the metatarsals or the associated short bones, no longitudinal cut-marks were produced by the longitudinal incision in the skin, even when made on the lateral or medial faces where the skin is in direct contact with the bone.

### 4.2 Defleshing

The carcass was nearly completely defleshed, with very little meat remaining on the bones after the experiment (Fig. 4). Just over 140kg of meat was recovered, with the axial skeleton producing 53 kg and the two femurs an identical amount. Considering the mass of meat recovered, the front legs appear to be substantially less interesting. The proportions of meat recovered from the legs are very similar to what was observed by Emerson (1990:432) for a 16-year-old female Bison bison, where the femur accounted for $58 \%$ of the meat retrieved from the appendicular skeleton.

All the meaty long bones bear cut-marks produced during defleshing, comprising $87 \%$ ( $\mathrm{N}=741$ ) of all cut-marks observed on the long bones. Cut-marks are evident across the entire diaphysis (Fig. 5). Cut-marks linked to defleshing are also present on or around several articular extremities, such as the tibia plateau. Defleshing cut-marks are mostly transverse or oblique, and longitudinal cut-marks produced by defleshing represent less than $3 \%$ of all marks on long bones (Table 3).

Significant numbers of cut-marks connected to defleshing were also recorded on the scapular and pelvic girdles (cf Fig. 2c\&d), most of which are longitudinal and elongated. On the axial skeleton, most cut-marks are also longitudinal (i.e. aligned with the cranio-caudal axis). Defleshing related cut-marks on vertebrae (Fig. 6) primarily occur on the spinous process (axis; thoracic 1 to 5 and 7 to 10 ; lumbar 3 to 5 ) and on the transverse processes (cervical 5 and 6 ; thoracic 1,4 to $11,13,14$; lumbar 1,3 to 5 ). Cut-marks are less frequently positioned close to the cranial or caudal articular process (axis, cervical 4 and lumbar 2), near the fovea costalis inferior
(thoracic 3) or near the inferior articular process (cervical 4 and thoracic 4). On the axis, defleshing cut-marks are also evident on the vertebral body as well as on the lamina and on both the ventral and dorsal faces of the atlas.

Cutmarks are mostly located at the neck and on the head of the ribs and occur both on the ventral and the dorsal faces (Fig. 7). They occur less frequently on the shaft and the sternal extremity, and only one is evident on the articular facets.

Flesh was also removed from the head, especially the cheeks, leaving cut-marks on the maxilla and the ascending ramus when the masseter muscle was removed (Fig. 2a). The removal of the tongue (Fig. 2b) produced oblique cut-marks on the lingual side of the mandible, with more transverse examples occurring just below the jugal teeth on the lingual face. Long longitudinal cutmarks are also present near the symphysis (lingual side).

### 4.3 Disarticulation

After being defleshed, the entire carcass was disarticulated. The head was removed by percussion with a hafted cleaver, splitting one of the occipital condyles (Fig. 8a). Some tearing is observable on the atlas vertebrae (Fig. 8b), probably resulting from the twisting of the head, and is associated with cut-marks on the cranial articulation (Fig. 2). The separation of the skull from the jaw left cutmarks on the zygomatic, the ascending ramus and on the distal face of the upper third molar. The rib cage was dislocated by percussion with a hafted flake cleaver, producing several fractures. The right transverse process is entirely or partially broken on 6 of the final thoracic vertebrae (thoracic 9 to 11 and thoracic 13 to 15 ), as well as the caudal articular facet of the $14^{\text {th }}$ thoracic vertebrae. Tearing is evident on the fovea costalis of the second thoracic, linked to the removal of the $3^{\text {rd }}$ rib by flexion. All but the first and last right ribs were broken when removed from the spinal column (Fig. 8e). Although the left ribs were left attached to the vertebrae, three (rib 3, 8, 13) were nevertheless fractured by a blow brought to the other side of the rib cage. The opening of the sternum by percussion did not leave any marks on the ribs. The anterior and posterior portions of the carcass were separated by percussion at the $4-5^{\text {th }}$ lumbar junction, which broke the $4^{\text {th }}$ lumbar in 3 pieces. The mamillary process of the $5^{\text {th }}$ lumbar was broken and chopmarks are evident on the body of this vertebra and on the spinous process of the sacrum (Fig. 8c).

Of the 850 cut-marks identified on the long bones, only $11 \%$ ( $\mathrm{n}=94$ ) were produced during disarticulation (Table 4). Interestingly, $30 \%$ of these marks are orientated longitudinally. The detachment of the entire leg from the body and the disarticulation of the humerus produced no cutmarks on the scapula. No cut-marks were produced on the humerus when it was separated from the scapula. The disarticulation of the humerus and radio-ulna (Fig. 5), on the other hand,
generated several cut-marks on the distal part of the humerus of both legs as well as on the olecranon, close to the trochlear incision of the radius. A small crushed area can be observed on the anconeal process (Fig. 8d), probably resulting from twisting during disarticulation. The disarticulation of the forelimb was followed by separating the radius from the first row of carpals. Cut-marks are observable on the right pyramidal and on both legs on and around the ulnar styloid process as well as on the semi-lunars and the scaphoids.

Due to the very large muscle mass around the pelvic girdle, which requires both defleshing and disarticulation at the exact same place, only cut-marks located on the femoral head (Fig. 5c) can be confidently attributed to disarticulation, as their location and orientation match those reported by the butcher. Separating the femur from the tibia generated cut-marks on both of the femoral medial condyles as well as on the tibial plateau (Fig. 5). Numerous cut-marks were produced when disarticulating the tibia and tarsal bones, especially on the medial face of the talus, but also on the calcaneum and the cuboid (Fig. 3). Several cut-marks are also observable on the distal part of the tibia and on the malleolus. The dislocation of the metacarpophalangeal joint left cut-marks on the distal condyles of the metacarpal, close to the proximal articulation of the first phalanges and on the sesamoids. Cut-marks on the hind legs are uniquely observable near the proximal articulation of the second phalanx. Finally, cut-marks are evident on the abaxial side of a second phalanx, produced when the axial and abaxial phalanges were separated from each other.

### 4.4 Tendon removal

Cutting the flexor and extensor tendons (Fig. 3) on the front leg with an upward motion left cutmarks on the distal half of the pyramidal, the upper part of the hamate bone and on the capitatetrapezoid, and on the upper portion of the posterior face of the first phalanges. On the hind leg, this cutting motion created cut-marks on the proximal portion of the anterior face, the condyles of the metatarsal, and on the first phalanx. Oblique and longitudinal cut-marks were also produced on the diaphyses of the metapodials, on the sesamoids and phalanges when tools were used in a longitudinal motion between the bone and the tendon.

## 5. Discussion

Butchery experiments are a necessary first step towards a better understanding of cut-marks on bison as well as large ungulates in general. Although the cut-mark dataset produced during our experiment is relatively limited due to the processing of a unique carcass, several interesting patterns can nevertheless be observed

## Correspondence with cut-mark patterns on medium-sized ungulates

The cut-mark data presented here are almost entirely in agreement with previously published data for medium-sized artiodactyles (Soulier and Costamagno 2017; Costamagno et al. 2019). Of the 135 cut-mark codes documented here ${ }^{2}, 127$ perfectly match the medium-sized artiodactyls dataset (detailed table available here: https://figshare.com/s/336e50835696f3d0aff8). Some discrepancies are however evident with cut-marks produced by activities differing from those previously documented for medium-sized ungulates. The least consistent codes come mostly from the vertebrae (4 of the 8 non-concordant codes), where several cut-marks that would normally be interpreted as linked to disarticulation based on medium-sized ungulates data (Nilssen 2000; Costamagno et al. 2019) were produced by defleshing.

Our data further highlights the need for caution when interpreting cut-marks near articular extremities, as $63 \%$ of the cut-marks located in these areas (portions $1 \& 6$ ) in our experiment result from defleshing instead of dismemberment.

No codes existed for several locations and/or orientations, meaning that new ones were created for the butchery of the bison ( $\mathrm{N}=83$; Fig. 9). As was done for red deer (Soulier and Costamagno 2017), these codes incorporate data collected by Nilssen (2000) for the butchery of large ungulates in South Africa ${ }^{3}$.

## Cut-mark incidence: the influence of stone tools, raw material, experimenter and carcass size

Cut-mark orientations are roughly similar to those documented for red deer as part of the same collective research project and hence butchered by same people. Upon closer examination, several differences are however evident (Table 5). Fewer longitudinal cut-marks were generated on the bison bones during defleshing ( $5.7 \%$ on the red deer vs $2.8 \%$ on the bison), while more longitudinal cut-marks were produced during disarticulation on the bison (31\%) compared to the red deer (11\%). However, this does not necessarily demonstrate the disarticulation of a bison to produce more longitudinal cut-marks compared to medium-sized ungulates as 1) longitudinal cutmarks produced during disarticulation mostly occur on the right femoral head and right humeral trochlea (although different butchers were involved) and no cut-marks were produced in these areas for the left limbs, and 2) longitudinal disarticulation marks were also generated in these areas during the disarticulation of the red deer (see fig 5 in Soulier and Costamagno 2017).

The participation of multiple experimenters, raw materials and tools makes it difficult to explain these differences. The two participants (Butcher V. \& Butcher M.) who butchered the red deer with a quartzite cleaver produced cut-marks distributed in comparable proportions in terms of

[^2]orientation (Table 6). In contrast, Butcher M. produced significantly different proportions of cut-mark orientations on the bison, notably transverse cut-marks. Carcass size therefore might influence the orientation of cut-marks produced during defleshing, perhaps connected to the likelihood that a heavier and therefore less manageable carcass constrains butchering movements. More focused experiments are necessary to shed additional light on the relationship between cut-mark orientation and carcass size.

Carcass size has been suggested to influence, positively or negatively, the frequency of cut-marks produced on bones (Egeland 2003; Dominguez-Rodrigo and Barba 2005; Pobiner and Braun 2005). Our dataset shows that despite using the same type of tool/raw material (i.e. a quartzite cleaver), a greater number of cut-marks were produced on the bison compared to the red deer (Table 6). However, this difference is based on the total number of cut-marks counted on complete bones. In archaeological assemblages bones are fragmented, and it is often the percentage of fragments bearing at least one cut-mark that is used for analysis. How differences in the total number of cut-marks (as observed in our experiments) are related to cut-mark percentages (as reported in most zooarchaeological studies) is still poorly understood and requires further research.

## Cutmarks and cleaning treatment

Several of the cut-marks observed on the bison bones are superficial and may not be preserved on archaeological material as a result of post-depositional alterations. These superficial traces were primarily observed on the leg bones compared to the axial skeleton and, interestingly, these two sections were cleaned in different ways. Prolonged immersion in water with enzymes appears to slightly attack the bone surface and is therefore an unsuitable cleaning process for experiments focused on the analysis of cut-marks.

## Tool efficiency

In addition to exploring cut-mark distribution and frequency, our bison butchery experiment equally aimed to investigate the function and efficiency of different typical Middle Palaeolithic tools. As detailed use-wear data for these tools has been published elsewhere (Claud and Thiébaut 2011; Claud et al. 2015, 2019), here we focus uniquely on tool efficiency. During our experiments, quartzite tools proved more difficult to handle during butchery, as the grease quickly settled in the pores of the quartzite, making it necessary to constantly clean them. On the other hand, the quartzite cleavers proved to be extremely efficient for disarticulating the bison carcass by percussion. Moreover, hafting the cleavers both increased the force of the blow and avoided fatiguing the user by absorbing part of the shock. The hafting of two small quartzite pseudoLevallois points equally increased their ease of use, as these pieces were very uncomfortable to
use when held in the bare hands. Moreover, the thin handles on to which the points were fixed did not hinder the tool penetrating the flesh and were very quick to fashion (partially split wooden stick).

## 6. Conclusion

Several reference collections resulting from controlled butchery experiments are currently available for the interpretation of cut-marks on small and medium-sized species. The analysis of cut-marks sheds light on the activity that produced them, which, in turn, permits a more accurate reconstruction and understanding of the butchery chaîne opératoire of past human groups. In particular, experiments butchering red deer have linked cut-mark orientation and distribution with specific butchering activities (Soulier and Costamagno 2017; Costamagno et al. 2019). The applicability of this approach to larger mammals has, however, remained difficult to assess. Our experiment further strengthens the interpretive potential of this analytical tool, providing a new dataset for large bovids, a family that was frequently exploited throughout the Palaeolithic and into later periods. Our results confirm the applicability of the red deer butchery data for the interpretation of cut-marks on large ungulates, such as bison albeit with some adjustments to the analysis, especially elements of the spinal column. Differences observed in cut-mark orientations on the bison long bones compared to what was documented for medium-sized ungulates needs to be explored more thoroughly, including additional experiments and a better appreciation of the impact of tools and butchers.

## Acknowledgments

Our warmest thanks go to the Regional Archaeology Service of the Midi-Pyrénées region for financial assistance to this multi-year collective project. This project has been very stimulating in terms of research questions and has deeply enriched our capacity to visualize the lifeways of prehistoric societies. We are very grateful to our colleagues who participated in the experiment, especially Michel Brenet, Stéphane Brenet, Aude Coudenneau, David Colonge, Marie-Pierre Coumont, Jean-George Ferrié, Jessica Lacarrière, Vincent Mourre, Célimène Mussini, and Aurore Val. A special mention goes to Céline Thiébaut, who coordinated the collective research project over the last 10 years. We would also like to acknowledge the French National Institute of Rescue Archaeology (INRAP) for allowing several of its members to participate in this project. Thanks also go to the Natural History Museum of Toulouse for cleaning the limb bones. Finally, we would like to thank Emmanuel Discamps for his comments on the manuscript, Brad Gravina for the language editing, and the SMP3C research team of the CNRS-UMR5608 for their continued support and financing of the language editing.

## Captions

Fig 1 Schematic depiction of the butchery activities carried out during the bison experiment. The locations of the circular incisions in the skin are indicated in blue (in grey: incisions made at the slaughterhouse) and the disarticulation spots are in red (lines = cutting motions; circles = disarticulation by percussion).

Fig 2 Cut-marks produced on the (a) skull, (b) mandible, (c) scapula, and (d) pelvis by activity: black $=$ defleshing; green $=$ dismemberment; blue $=$ skinning. In grey, cut-marks impossible to link to a specific activity.

Fig 3 Cut-marks produced on the (a) metacarpal, (b) metatarsal, (c) sesamoids, (d) malleolus, (e) phalanges, (f) carpals, (g) tarsals per activity: green = dismemberment; red = tendon removal; blue = skinning. In grey, cut-marks impossible to link to a specific activity. * abaxial side of the medial phalanx.

Fig 4 Meat remaining on a defleshed bison limb and weight of meat ( kg ) recovered per skeletal element. Photo © "Des Traces et des Hommes".

Fig 5 Cut-marks on the (a) humerus, (b) radio-ulna, (c) femur, and (d) tibia per activity: black = defleshing; green = dismemberment. In grey, cut-marks impossible to link to a specific activity.

Fig 6 Cut-marks on the a) atlas, b) axis, c) cervical, d) thoracic, e) lumbar and f) sacrum vertebrae per activity: black = defleshing; green = dismemberment (atlas); purple lines = chopmarks. Grey cut-marks on the sacrum cannot be linked to a specific activity.

Fig 7 Cut-marks (in black) produced on the ribs during defleshing.

Fig 8 Splitting of a) the occipital condyles, b) the atlas, c) chopmarks on the sacrum, d) crushing on the anconeal process of the ulna and e) breakage on the ribs (in red) produced during disarticulation.

Fig. 9 New coded areas for undocumented elements (a) skull, e) ribs, j) pelvis), and new areas created on previously coded elements (b) mandible lingual side, c) sacrum, d) atlas, f) radius distal, g) metatarsal distal, h) lunate, i) calcaneum, k) first phalanx and I) second phalanx. Bluish tints are for defleshing, reddish for disarticulation, greenish for skinning and yellowish for tendon extraction. See https://figshare.com/s/336e50835696f3d0aff8 for a descriptive table.

Table 1 Tools and raw materials ( $F=$ flint; Qzte=quartzite) used by activity.

Table 2 Total number of cut-marks produced on the bison by skeletal part.

Table 3 Orientation of the defleshing cut-marks on the meaty long bones. $\mathrm{R}=$ Right; $\mathrm{L}=\mathrm{Left}$

Table 4 Orientation of cut-marks produced by disarticulation. $\mathrm{R}=$ Right; $\mathrm{L}=$ Left

Table 5 Comparison of cut-mark orientation between bison and red deer. Red deer data derived from drawings in Soulier and Costamagno 2017.

Table 6 Comparison of cut-marks made with the same tool/raw material (quartzite cleaver) on a red deer and bison by two different experimenters.
