11 **Abstract**

12 Submerged fault ruptures generate earthquake-triggered mass flow deposits, which are
13 extensively used as a tool in subaqueous paleoseismology. In tectonically active deep
14 sedimentary basins, such as the Sea of Marmara (SoM), these mass flow deposits are defined
15 as turbidite-homogenite units (THUs), consisting essentially of a coarse basal part and an
16 overlying homogeneous mud (homogenite). Detailed characterization of THUs is crucial in
17 order to establish meaningful criteria to link these units with earthquakes events and to identify
18 their transport routes and depositional mechanisms. Here, we combine μ -X-ray Fluorescence
19 (μ -XRF), Anisotropy of Magnetic Susceptibility (AMS) and additional rock magnetism
20 analyses of a 21-m long piston core from the Kumburgaz Basin of SoM to define the upper
21 stratigraphic boundary of THUs with hemipelagic sediments and investigate the controls of
22 hydrological changes on turbidite frequency and thickness over the last 15 kyrs BP. The
23 sedimentary succession of this period includes a lower lacustrine and an upper marine unit with
24 two Holocene sapropel intervals. The sequence is interrupted by a total of 70 THUs,
25 characterized by a significant magnetic foliation related to the depositional setting rather than

26 the magnetic signature. Magnetic mineralogy of the coarse basal parts of THUs have more
27 ferromagnetic particles than the overlying homogenites and background sediments. While the
28 homogenite parts have a more constant mineralogy than the basal parts, they do not differ the
29 background sediments.

30 Based on an event-free chronostratigraphic model derived from radiocarbon ages and the
31 published age of lacustrine-marine (L-M) transition, the average THU occurrence intervals in
32 the lacustrine (14.8-12.6 kyrs BP), lower sapropel (11.2-5.7 kyrs BP), upper sapropel (5.4-2.7
33 kyrs BP) and non-sapropelic part of the marine unit (2.7 kyrs BP-present) are 235 yrs, 287 yrs,
34 114 yrs and 160 yrs respectively. The average thickness of the THUs in the same units are 20.8
35 cm, 15.7 cm, 6.1 cm and 6.1 cm. The variability of average THU occurrence intervals and THU
36 thicknesses are controlled by the sea level rise and salinity increase following the full marine
37 connection of the SoM at 12.6 kyrs BP, which caused changes in slope stability, sediment
38 composition and sediment deposition in different parts of the basin. Geomechanical properties
39 of the lower sapropel appears to have been important in resulting long THU recurrence intervals
40 and relatively high THU thicknesses.

43

44 **1. Introduction**

45 Many years after rock magnetic studies led on marine sediments (Harrison & Funnell, 1964;
46 Opdyke et al., 1966), similar approaches were done in subaqueous environments dealing with
47 a broad spectrum of problems related to (a) instantaneous sedimentary processes (Hiscott et al.,
48 1997; Ge et al., 2012; Campos et al., 2013; Stachowska et al., 2020), (b) major past-climatic
49 events (Kruiver et al., 1999; Demory et al., 2005a; Drab et al., 2015a), and (c) environmental
50 changes (and resilience of sedimentary environments) (Pozza et al., 2004; Franke et al., 2009;
51 Akinyemi et al., 2013; Nizou et al., 2016). Instantaneous sedimentary processes include
52 subaqueous landslides and mass-flows that result in deposition of debris flows, mudflows and
53 turbidites. They can be triggered by earthquakes (Shiki et al., 2000; Nakajima and Kanai, 2000;
54 Goldfinger et al., 2003, 2017; Beck et al., 2007), storm waves (Prior et al., 1989), hyperpycnal
55 flows (Mulder and Syvitski, 1995), gas hydrate dissociations (Bourry et al., 2009), sediment
56 overloading (Nemec, 1990; Chapron et al., 1999), volcanic eruptions (Cita and Aloisi, 2000)
57 and floods (Beck et al., 1996). In tectonically active sedimentary basins, turbidite units are
58 common and occur interbedded with hemipelagic or pelagic sedimentary sequences. The most
59 common triggering mechanism of turbidites in such basins is the seismic activity of submerged
60 fault systems (Goldfinger et al., 2011; Çağatay et al., 2012; McHugh et al., 2014; Avşar et al.,
61 2015; Yakupoğlu et al., 2019; Gastineau et al., 2021). Hence, turbidites have been widely used
62 as a tool in subaqueous paleoseismology in different settings, including in the Sea of Marmara
63 (SoM) (Adams, 1990; Nakajima and Kanai, 2000; Shiki et al., 2000; Gorsline et al., 2000;
64 Goldfinger et al., 2003, 2007, 2008, 2017; Sarı and Çağatay, 2006; Beck et al., 2007;
65 Goldfinger, 2011; Çağatay et al., 2012; Drab et al., 2012, 2015; Eriş et al., 2012; Poudoux et
66 al., 2012a, 2012b; Gutiérrez-Pastor et al., 2013; Barnes et al., 2013; Polonia et al., 2013, 2017;
67 McHugh et al., 2014; Moernaut et al., 2014, 2017; Patton et al., 2015; Avşar et al., 2015; Van

68 [Daele et al., 2017](#); [Yakupoğlu et al., 2019](#); [Ikehara et al., 2020](#); [Wils et al., 2020](#); [Gastineau et](#)
69 [al., 2021](#)).

70 Seismically triggered turbidites commonly consist of a coarse basal part (T: Turbidite
71 Body) and an overlying homogenous silt-clay size cap (H: Homogenite, muddy turbidite or
72 turbidite tail), and commonly termed as turbidite-homogenite units (THU). The term
73 homogenite broadly represents the “Bouma E” sublayer that contains homogenous mud
74 deposited from the suspension cloud of a turbidity current. Thick (>1 m) homogenite layers can
75 be imaged as seismically transparent facies in high-resolution seismic reflection profiles
76 ([Kastens and Cita, 1981](#); [Cita and Rimoldi, 1997](#); [Beck et al., 2007](#); [McHugh et al., 2011](#); [Eriş](#)
77 [et al., 2012](#)). However, homogenites are hardly distinguished from the overlying hemipelagic
78 sediments using the usual physical and sedimentological properties such as gamma density and
79 grainsize parameters ([Çağatay et al., 2012](#); [Eriş et al., 2012](#); [Barnes et al., 2013](#); [McHugh et al.,](#)
80 [2014](#); [Goldfinger et al., 2017](#); [Yakupoğlu et al., 2019](#)). These deposits have been recently best
81 distinguished from the background hemipelagic sediments using the magnetic foliation
82 determined from Anisotropy of Magnetic Susceptibility (AMS) measurements ([Ge et al., 2012](#);
83 [Campos et al., 2013](#); [Petersen et al., 2014](#); [Tamaki et al., 2015](#); [Rapuc et al., 2018](#); [Stachowska](#)
84 [et al., 2020](#)). A clear demarcation of these boundaries is important for construction of a robust
85 age-depth model based on an event-free stratigraphy, which can then be used dating THUs and
86 establishing long-term paleoseismological records ([Beck et al., 2009](#); [Goldfinger, 2011](#); [Barnes](#)
87 [et al., 2013](#); [Yakupoğlu et al., 2019](#)),

88 The SoM, being located along the North Anatolian Fault (NAF), is an important location
89 for subaqueous paleoseismological studies (e.g. [Çağatay et al., 2012](#); [Eriş et al., 2012](#); [Drab et](#)
90 [al., 2012](#); [McHugh et al., 2014](#); [Drab et al., 2015b](#); [Yakupoğlu et al., 2019](#)). Moreover, because
91 of its interesting oceanographic setting between the Aegean (Mediterranean) Sea and Black
92 Sea, its environment alternated between lacustrine and marine, with latest marine connection

93 taking place ~12.6 cal yrs BP and ensued sapropel formations during c.12.3 - 5.7 cal kyrs and
94 5.4 and 2.7 cal kyrs BP (Çağatay et al., 2015).

95 In this study, we integrate micro-X-Ray Fluorescence (μ -XRF) elemental geochemistry,
96 AMS and other rock magnetism analyses of a Calypso core (MRS CS-14) from the Kumburgaz
97 Basin of SoM with two main objectives: (1) to distinguish the boundary between the
98 homogenite layers of the THUs and overlying background hemipelagic sediments, and (2) to
99 understand how sea level and salinity rise control turbidite thickness and frequency during
100 different phases of the lacustrine and marine periods in the last 15 kyrs, based on a robust,
101 event-free age-depth model. Our findings from this integrated approach contribute to the
102 understanding of hydrological and seismotectonic controls on turbidite generation in a
103 tectonically active restricted basin, where tsunami generation (including reflection and seiche
104 effect) would be also expected (e.g. Beck et al., 2007; Çağatay et al., 2012; Ashi et al., 2014).

105 **2. Tectonic and oceanographic setting**

106 SoM is located in the NW part of Turkey and the western termination of the 1600-km
107 long NAF Zone. The deformation zone includes three main branches where northern and middle
108 branches of NAF are submerged faults systems within the SoM (Fig. 1). Based on GPS rates,
109 75 percent of the plate motion is transferred on the northern branch of NAF (NNAF) (~18-20
110 mm/yr) with the remainder being accommodated on the southern branches (Reilinger et al.,
111 1997; Straub et al., 1997; McClusky et al., 2000; Le Pichon et al., 2001; Armijo et al., 2002;
112 Provost et al., 2003; Flerit et al., 2003; Şengör et al., 2005; Reilinger et al., 2006). NNAF passes
113 through three fault-controlled basins, which from west to east are Tekirdağ (-1133 m), Central
114 (-1268 m), and Çınarcık (-1276 m) basins, that are separated by the Western and Central highs
115 (Fig. 1).

116 The SoM is connected to the Black Sea and Aegean Sea via the Bosphorus and
117 Dardanelles straits, respectively (Fig. 1). This connection allows exchange of two water masses

118 of different salinities; Mediterranean water (~38.5 psu) and Black Sea water (~18 psu) results
119 in a two-way water current system with a permanent pycnocline at -25 m in the SoM (Ünlüata
120 et al., 1990; Beşiktepe et al., 1994; Chiggiato et al., 2012; Aydoğdu et al., 2018). Renewal time
121 of the upper and lower water masses of the SoM is 5-6 months and 6-7 years, respectively
122 (Beşiktepe et al., 1994). The fluvial water and sediment input to the SoM is mainly from its
123 southern catchment region by Kocasu, Gönen and Biga rivers (2.2×10^6 t/yr suspended material)
124 (EIE, 1993; Kazancı et al., 2004).

125 During the Late Quaternary glacial-interglacial cycles, the environmental conditions in
126 SoM alternated between lacustrine and marine, being controlled by the sills depths in the
127 Dardanelles and Bosphorus, currently at -65 mbsl and -35 mbsl, respectively (e.g. Çağatay et
128 al., 2000, 2015, 2019; Eriş et al., 2007). The last reconnection of the SoM with the Aegean Sea
129 is dated between 14.7 kyr (initial connection, Vidal et al., 2010) and 12.6 kyr BP (full
130 connection, Çağatay et al., 2015) and with the Black sea at c. 9 kyr BP (Major et al., 2006;
131 Ryan, 2007). After the last marine reconnection, two sapropels were deposited in the SoM:
132 Lower Sapropel (12.3-5.7 kyr BP, Çağatay et al., 1999, 2003, 2015; Vidal et al., 2010) and the
133 Upper Sapropel (5.4-2.7 kyr BP, Çağatay et al., 1999; Tolun et al., 2002).

134 Kumburgaz Basin, where the studied core is located, is a depression located on the
135 Central High with maximum depth of 880 m. It is a 35 km long, 11 km wide, ENE-trending
136 depression, covering an area of 160 km² and bounded by NNAF to its north (Fig. 1; Çağatay
137 and Uçarkuş, 2019). Continental slope to the north is marked by two amphitheater-like canyons.
138 The eastern canyon is located off Büyük Çekmece Lagoon. The rocks exposed in the catchment
139 area of the Kumburgaz Basin include Paleozoic schists and meta-granites and the overlying
140 Eocene reefal limestones and Oligocene-Miocene sandstones and mudstones (Alp, 2014;
141 Dalgiç, 2004). The basin has a sedimentation rate (2 to 2.5 mm/yr) for Holocene period but two
142 to three times higher rates for the lacustrine late glacial period (~5.4 mm/yr) (Beck et al., 2007).

143 3. Material and methods

144 3.1 Cores and multi-parameter analyses

145 Two ~21-m-long calypso cores CS-01 (28.50362/40.87140; 834 mbsl) (Yakupoglu et
146 al., 2019 and see figures therein) and CS-14 (28.47740/40.85860; 820 mbsl) were recovered
147 from Kumburgaz Basin during the 2014 EC FP7 MARsite project cruise by RV “*Pourquoi*
148 *pas?*” (Figs. 1B, 2). The core CS-14 was split into 1-m-long sections (21 sections), and core
149 sections were split into two halves. One half was photographed, visually logged sampled for
150 rock magnetism analyses Istanbul Technical University (ITU) Eastern Mediterranean Centre
151 for Oceanography and Limnology (EMCOL). Core sections were split into two halves. Another
152 half is used for Non-destructive analyses at the ITU-EMCOL core analysis laboratory, using
153 Itrax μ -XRF core scanner and Geotek Multi Sensor Core Logger (MSCL). The core scanner
154 was used for elemental composition (Fe, K, Ca, Sr, Mn) and digital X-ray radiography, and
155 operated at 1 mm resolution and 20 s measurement time, using a Mo X-ray tube powered at of
156 30 kV and 50 mA. The MSCL was used for gamma density (GD) measurements at 10 mm
157 resolution (Figs. 4-6). Total Organic Carbon (TOC) (difference between total carbon and total
158 inorganic carbon (TIC)) analyses were performed using a Shimadzu TOC/TIC analyzer at ITU-
159 EMCOL. Before the analysis, samples were dried in a freeze-dryer and processed on an augite
160 mortar. Thus, total carbon content was measured by burning the sample at 900°C in a catalytic
161 combustion furnace. For total inorganic carbon content, samples were treated with 85%
162 phosphoric acid under 200°C, and the evolved carbon dioxide was measured by the detector.
163 TOC concentration is calculated as the difference between total carbon and total inorganic
164 carbon content. The precision for TOC and TIC analyses were 2% at 95% confidence level.
165 (Fig. 3).

166 3.2 Anisotropy of magnetic susceptibility and rock magnetism analyses

167 All magnetic measurements were conducted in the Rock Magnetic Laboratory of the
168 CEREGE (Aix-Marseille University). A total of 879 samples were collected using 8 cm³ plastic
169 boxes directly pushed into the sediment. For those samples, AMS was measured using AGICO
170 MFK1-FA Kappabridge. The magnetic susceptibility tensors deduced from AMS
171 measurements are characterized by three principal components (χ_{\max} , χ_{int} and χ_{\min}) and angles
172 (declination and inclination) defining their orientation in the split-core reference frame (Jelinek,
173 1981; Hrouda, 1982; Tarling & Hrouda, 1993). Additionally, magnetic lineation ($\chi_{\max}/\chi_{\text{int}}$),
174 magnetic foliation ($\chi_{\text{int}}/\chi_{\min}$) and mean tensorial magnetic susceptibility ($\chi_m=(\chi_{\max}+\chi_{\text{int}}+\chi_{\min})/3$)
175 were calculated for each specimen.

176 In order to characterize magnetic mineralogy, two types of laboratory remanent
177 magnetizations were artificially imparted on 98 samples through the core: Anhyseretic
178 Remanent Magnetization (ARM) and Isothermal Remanent Magnetization (IRM). ARM was
179 produced in-line and measured with the SRM760R using a 100 mT alternating field with a bias
180 field of 50 μ T. The ARM was also measured after a demagnetization step of 30 mT (ARM₃₀).
181 The ratio ARM₃₀/ARM deduced from ARM measurements is a magnetic grain size indicator
182 valid for constant low-coercive magnetic fraction (Johnson et al., 1975; Rochette et al., 1992;
183 Tarling & Hrouda, 1993; Stoner & St Onge, 2007; Campos et al., 2013; Nizou et al., 2016).
184 Isothermal Remanent Magnetization (IRM) was acquired at 3 T, measured and then at 0.3 T in
185 the opposite direction using a pulse magnetizer MMPM9 from Magnetic Measurements Ltd.
186 From these measurements, S-ratio was calculated by using formula $(1 - \text{IRM}_{-0.3\text{T}} / \text{SIRM}_{3\text{T}})/2$.
187 S-ratio is a parameter of the relative abundance of high coercivity minerals with values close to
188 1 for magnetite and decreasing with increased proportion of high coercivity minerals
189 (Bloemendal et al., 1992; Demory et al., 2005b).

190 3.3 Chronology and age-depth model

191 Accelerator Mass Spectrometry ^{14}C analyses of four samples were carried out at the
192 TÜBİTAK-MAM (İzmit-Turkey) Radiocarbon Laboratory. Hemipelagic sediment samples
193 from beneath the mass-flow units were wet-sieved, and $>63\ \mu\text{m}$ fractions were used to hand-
194 pick carbonate shell material under binocular microscope. Dated materials were epifaunal
195 benthic foraminifera, echinoderm spicules and occasionally bivalve shells, in addition to the
196 planktonic foraminifera. Care was taken to sample whole shells without evidence of reworking
197 and diagenesis. All samples were washed in distilled water and dried (at $40\ ^\circ\text{C}$) before the
198 analysis. Results were calibrated using Calib v7.0 software with Marine13 ^{14}C calibration curve
199 (Reimer et al., 2013) and a reservoir age correction of 390 ± 85 for marine (Siani et al., 2000)
200 and 900 ± 100 for lacustrine samples (Çağatay et al., 2015) (Table 1). Inclusion of benthic and
201 pelagic shells in the same sample would not affect the reservoir age because of the negligible
202 difference (6–7 years) between the residence time of upper and lower water masses in the SoM
203 (Beşiktepe et al., 1994). In addition to the calibrated ages, we used the previously dated
204 lacustrine-marine (L-M) transition as dating point for the age-depth modelling (Table 1). The
205 two sapropel layers in the core were defined in 2.3-5.9 mbsf and 6.3-15.4 mbsf intervals, using
206 mainly by TOC analysis, as well as lithological and physical properties (Fig. 4), and were
207 previously dated by several authors in the SoM (Çağatay et al., 1999, 2003, 2015; 2019; Tolun
208 et al., 2002; Vidal et al., 2010; Filikçi et al., 2017). L-M transition in the SoM was previously
209 dated to be between 14.7 cal kyrs BP (for the initial connection) and 12.6 cal kyrs BP (full
210 connection) (Çağatay et al., 2015; Vidal et al., 2010). The L-M transition is marked by a 30 cm-
211 thick coarse shelly sand layer between 17.18-17.48 mbsf in core CS-14, which is characterized
212 by high χ_m ($450\ 10^{-6}$ SI) values and a positive Mn excursion (>800 cps) (Fig. 3; Section 4.1).

213 For the age-depth modelling of core CS-14, all THUs thicknesses were discarded to
214 obtain an event-free composite depth, and all calibrated ages were processed with R-studio

215 using the script “CLAM” non-Bayesian method (Blaauw, 2010). The script created age-depth
216 model, calculating the 95% Gaussian confidence interval around the best model (Fig. 4).

217 **4. Results**

218 **4.1 Core lithology and geochemistry**

219 The 21 m-thick sedimentary sequence in core CS-14 consists of a lower lacustrine unit
220 and an upper marine unit on the bases of lithology, color, physical properties and fossil content
221 (Figs. 2-4; Table 1). The boundary between the two units is located at c. 17.18 mbsf and the
222 entire core sequence includes 70 THUs.

223 The marine unit is characterized by grey-green clayey-silty mud containing marine
224 euryhaline molluscs, and benthic and planktonic foraminifera (Fig. 3). The uppermost ~2.3
225 mbsf of the marine unit contains homogenous fine silty clay showing a gradual downward
226 change in color from brownish (oxidized mud) to light olive gray mud intercalated with twelve
227 thin (average of 6.1 cm) THUs (Fig. 3; Table 2). The background sediments in this topmost unit
228 are deposited at a rate of 0.79 m/kyr, and characterized by high χ_m values ($\sim 200 \cdot 10^{-6}$ S.I) and
229 low TOC (<1%) (Fig. 4; Table 2). The marine interval between 2.3-5.9 meters contains an olive
230 gray homogenous silty clay with an oily luster, having ~1-1.5 % TOC and relatively low χ_m
231 ($\sim 20 \cdot 10^{-6}$ S.I) values (Fig. 4; Table 2). According to its TOC content, the interval between 2.3-
232 5.9 mbsf corresponds to the upper sapropel in the SoM (Çağatay et al., 1999, 2015; Tolun et
233 al., 2002). This sapropel contains 21 silty TH units within the range of 2.4-14.5 cm (Figs. 3-5;
234 Table 2). Event-free part of the sapropel is deposited 0.68 m/kyr. Below the upper sapropel, the
235 marine unit between 5.9-6.3 mbsf is green grey mud intercalated with two THUs with average
236 of 5.1 cm in thickness thus, having 1.2-1.8% TOC concentration and sedimentation rate of 0.95
237 m/kyr (Fig. 4; Table 2).

238 The underlying interval between 6.3-15.4 mbsf is relatively dark green grey, laminated
239 mud with an oily luster. It contains abundant Fe-monosulphide nodules and patches and high
240 TOC contents of up to 3 % (Figs. 3,4; Table 2). Considering its lithological properties, the 6.3-
241 15.4 mbsf interval is correlated with the lower sapropel which was previously identified in the
242 SoM by different workers (e.g., Çağatay et al., 2000; Tolun et al., 2002; Vidal et al., 2010). The
243 event-free sapropel unit was deposited at a rate of 1.12 m/kyr (Fig. 4;). This interval contains
244 21 THUs in range of 3.5 to 59 cm (Table 2).

245 The marine interval between 15.4-17.2 mbsf a homogenous green gray clayey-silty
246 marine mud with scarce Fe-sulfide nodules and benthic foraminifera and without oily luster and
247 laminations (Figs. 3,4). This unit contains up to 2.5 % TOC in the lower part, which is mainly
248 of terrestrial origin according to C/N and C-isotope analysis (Tolun et al., 2002). Event-free
249 (background part) of the unit is deposited at a rate of 0.96 m/kyr. In this interval, four THUs
250 composed of silty-clayey fractions are observed with average of 11.1 cm in thickness. (Table
251 2). The underlying interval between 17.18 - 17.48 mbsf is a brownish grey, coarse sand layer
252 that separates the overlying marine sequence from the underlying lacustrine sequence (i.e. L-
253 M transition) (Figs. 3). It contains large marine and lacustrine bivalve shell fragments, abundant
254 black Fe-monosulfides spots, mm-size pyrite concretions and secondary gypsum crystals, and
255 is characterized by a high (c. 700 cps) Mn pulse and up to c. 500 10^{-6} SI χ_m values (Figs. 3-5).
256 The lacustrine unit below 17.48 mbsf in the core consists of brownish light gray clayey-silty,
257 massive mud, including fresh-brackish bivalves (*Dreissena* sp.) intercalated with 10 THUs. The
258 unit have up to 51 cm thick THUs (average of 20.8 cm), with its event-free background
259 sediments deposited at a rate of 0.8 m/kyr (Figs. 3,4; Table 2).

260 **4.2 Sedimentology and geochemistry of turbidite-homogenite units**

261 A total of 70 THUs consisting of a basal coarse part and an overlying turbiditic mud
262 (homogenite) were identified based on lithological, physical and geochemical properties (Figs.

263 3-6). The lower boundaries of the coarse basal part of the turbidites with the underlying
264 hemipelagic sediments are commonly sharp showing no scour and fill structures indicating non-
265 erosional base (Fig. 6) except some sandy thicker THUs in lower sapropel and lacustrine phase
266 (Fig. 6). The abrupt lithological change between the lower coarse basal parts and the upper
267 homogeneous parts is detected in GD (gamma density), χ_m , Ca, Sr, Fe profiles and digital X-
268 ray radiography images (Figs, 3, 6). Starting from middle of the lower sapropel frequent,
269 positive Mn excursions occurs in the top 11 m part of the sequence and at the L-M transition
270 (Figs. 4, 6). The upper boundary of homogenites of most THUs with the overlying background
271 sediments are not clearly discernable visually and in the μ -XRF elemental profiles while some
272 THUs show decrease in Fe and Ca at the boundary (Fig. 6). In contrast, homogenite lower
273 boundaries are commonly marked by a sharp change from parallel, silty laminae of the coarse
274 basal parts to massive mud of the homogenites. Some THUs' basal parts in the core sequence
275 are stacked without the homogenite part or hemipelagic sediments in between (Fig. 3). The
276 homogenites consist mainly of massive, fine silty clay, and have lower GD values than the
277 coarse basal parts but slightly higher GD values than the hemipelagic sediments (Figs. 3, 6).
278 However, transition from the homogenites into the overlying background sediments are not
279 clearly visible in the digital radiographic images (Figs. 3,6). Details about the thicknesses of
280 the THUs and their coarse basal and homogenite parts in the different chronostratigraphic units
281 are described in Section 4.4.

282 **4.3 Magnetic properties of turbidite-homogenite units**

283 In order to better characterize the boundaries between the THUs and overlying
284 background hemipelagic sediments, and the magnetic signature of the different
285 chronostratigraphic units, we derived magnetic foliation, lineation and mean susceptibility
286 precursors from the AMS (Figs. 5, 6). First 10 mbsf show magnetic foliation values of ~1.03-
287 1.04, interrupted by positive spikes of the THUs (Fig. 5). The sequence between 10 to 17 mbsf

288 contains high background foliation values (up to 1.06), regardless of the THU positive spikes,
289 compared to the lacustrine background sediments (17.4-21 mbsl; foliation: 1.02-1.03). (Fig. 5).
290 We observe a stable background foliation trend throughout the core, which reveals the magnetic
291 characteristics of the THUs with positive excursions. Regardless of the TH lithology, AMS
292 displays positive anomalies both on the coarse basal and homogenite parts of the sequence, with
293 similar foliation values of 1.04-1.10 and 1.04-1.06, respectively (Figs. 5, 6). The boundary
294 between homogenite and overlying background sediment shows a sharp drop on magnetic
295 foliation on most of the THUs (Figs. 3, 6). Magnetic lineation has very low values throughout
296 the core (1-1.03) (Figs. 5,6). Only some THUs have relatively high lineation (>1.007) having a
297 positive pulse in coarse basal parts (Figs. 3, 5, 6).

298 Analysis of 98 samples from the core provided S-ratio, SIRM, ARM₃₀/ARM ratios in
299 order to determine the magnetic characteristics of the lithological facies (Fig. 5). Accordingly,
300 three lithologically different sections are identified corresponding to the coarse basal parts (18
301 samples), homogenites (7 samples) and background sediments (13 samples). S-ratio of these
302 samples provided a scarce distribution (0.93-0.99). First 7 m of the core have the lowest values
303 (0.93-0.96) (Fig. 5). Rest of the core have high S-ratios (0.96-0.99). ARM₃₀/ARM profile shows
304 a narrow distribution in the core (0.2-0.6; have 0.43 average) (Fig. 5). In 9-14 mbsf interval,
305 ARM₃₀/ARM has the lowest values (down to 0.2). The SIRM is rather constant along the core
306 with values of 1-2 mA m⁻¹ (Fig. 5). Still, several positive increments are observed in first 2 m
307 and 18-21 m interval (Fig. 5).

308 Three selected THUs (THUs, A, B, C) were studied in detail to display the magnetic
309 characteristics of THUs and background sediments in the main lithological units (i.e. marine,
310 sapropel and lacustrine) (Figs. 3, 5, 6). In THU-A, ARM₃₀/ARM values oscillate between 0.40-
311 0.45 and S-ratio is between 0.95-0.98. Foliation, lineation and χ_m of the coarse basal part show

312 positive pulses (up to 1.06, 1.01 and up to 2.5×10^{-6} SI, respectively). Homogenite part of THU-
313 A is characterized by a decreasing foliation trend (down to 1.02) (Fig. 6).

314 THU-B is an amalgamated turbidite containing an Fe-depleted coarse base, which is
315 overlain by a Ca-rich coarse sediment. In this interval, S-ratio has a decreasing trend (down to
316 0.96), whereas ARM_{30}/ARM shows increasing trend with values up to 0.3 (Fig. 6). In the
317 homogenite part of THU-B, the ratio shows an increasing trend from 40% to %80. Foliation
318 profile has a positive pulse at the top of the coarse basal part and a high stable value over the
319 homogenite (1.03-1.05), whereas lineation only has a positive pulse at the coarse basal part of
320 the unit (up to 1.01). In THU-B, χ_m have higher values than the overlying background sediments
321 (up to $60-80 \times 10^{-6}$ SI) (Fig. 6).

322 In both coarse basal and homogenite parts of THU-C, ARM_{30}/ARM values range
323 between 0.35-0.65 and S-ratio shows a fluctuating trend between 0.97 and 0.99 (Fig. 6).
324 Foliation and lineation profiles give positive pulses in the coarse basal part of this THU, with
325 up to 1.1 and 1.03, respectively. In the homogenite part, foliation values range between 1.04
326 and 1.05), which are higher than those in the overlying background sediments (1.03-1.04) (Fig.
327 6). χ_m profile has a peak in the coarse basal part of THU-C (up to 250×10^{-6} SI) but low values
328 in the homogenite part ($\sim 50 \times 10^{-6}$ SI) (Fig. 6).

329 **4.4 Average occurrence interval and thickness variation of turbidite-homogenite units in** 330 **different chronostratigraphic units**

331 The age-depth model of core CS-14, based on four Accelerated Mass Spectrometry ^{14}C
332 ages and one chronostratigraphic horizon (i.e. L-M transition) (Table 2), is presented in Fig. 4.
333 “Clam” cubic spline script of this model allows us to determine the individual ages of 70 THUs
334 in the core and their average occurrence interval (or event frequency) in the different
335 chronostratigraphic units, including the lacustrine and marine units and the two sapropel layers

336 (Table 2, Supplementary Table). According to the model, the sedimentary sequence of core CS-
337 14 extends back to c.15 cal kyrs BP and hence, the lacustrine unit was deposited between 14.8
338 and 12.6 cal kyrs BP (Fig. 4). The model also provides ages for the lower and upper sapropels
339 within intervals of 11.2-5.7 kyrs BP and 5.4-2.7 kyrs BP, respectively (Fig. 4).

340 Using the age model, we determined the average occurrence interval of the THUs in
341 different chronostratigraphic units of the core CS-14, which were defined based on visual
342 observations, μ -XRF elemental and AMS profiles (Table 2; Supplementary Table). The
343 lacustrine unit deposited during a ~2.4 kyr interval in the core includes 10 THUs, with an
344 average occurrence interval of 235 yrs (Figs. 3, 4; Table 2; Supplementary Table). During the
345 5.5 kyr long lower sapropel interval, 21 THUs were deposited with an average occurrence
346 interval of 287 yrs. The Upper sapropel with a depositional period of 2.7 kyrs has 21 THUs
347 deposited with 114 yrs of average THU occurrence interval. The recent marine interval above
348 the upper sapropel contains 12 THUs with an average occurrence interval of 160 yrs (Table 2).
349 The average THU thicknesses and their percentages in the same units, from bottom to top, are
350 20.8, 15.7, 6.2 and 6.1 cm, and 30, 38, 35, and 53 %, respectively. The coarse basal part-to-
351 homogenite part (TB-TT) thickness ratio range from an average of 0.3 (range: 0.1-0.5,
352 neglecting on outlier value of 0.9) in the lacustrine unit to 0.9 (0.5-1.2) in the non-sapropelic
353 marine unit below the lower sapropel (Supplementary Table 1). A gradual increase is observed
354 in the average TB-TT thickness ratio from the lower sapropel (average. 0.6; range: 0.3-1.2)
355 through upper sapropel (0.7; 0.2-1.1) to the upper non-sapropelic marine unit (0.8; 0.3-2).

356 **5. Discussion**

357 **5.1 Factors controlling the magnetic properties of lacustrine and marine units and** 358 **sapropels**

359 Chronostratigraphic units of core CS-14 sequence show significant variations in all
360 magnetic parameters. The core spans to the last ~15 kyrs BP with the earliest ~2.4 kyrs
361 representing the lacustrine unit (Figs. 3,4). It has higher SIRM values than marine and
362 sapropelic sediments, which are possibly related to higher content in ferromagnetic minerals
363 inferred by higher mean susceptibility and relatively higher foliation (Fig. 5). The shelly sand
364 layer with positive magnetic susceptibility and foliation pulses marking the L-M transition is
365 interpreted to be a debrite (Figs. 3-5). Such unusual layers at the transition were previously
366 reported in sediment cores from elsewhere in the SoM, and interpreted to be due to carbonate
367 shell accumulation, inorganic carbonate precipitation and microbial reactions induced by
368 mixing of lacustrine and marine waters (Çağatay et al., 2009, 2015, 2019; Eriş et al., 2011,
369 2019; Filikçi et al., 2017).

370 Despite the presence of the two sapropelic layers, the marine facies are characterized by
371 relatively low χ_m ($<50 \times 10^{-6}$ SI) similar to the cores from the Çınarcık, Tekirdağ and Central
372 basins (Beck et al 2007; Drab et al., 2012; 2015a). The exception to this is the high χ_m values
373 ($>120 \times 10^{-6}$ SI) for the upper 2.2 m of the core, which represents the active diagenetic (redox)
374 zone including the oxidized layers (Figs. 4, 5). This oxidized layer is accompanied also with
375 low S-ratio and high SIRM, suggesting hematite enrichment.

376 Lower sapropelic sediments have significantly lower ARM_{30}/ARM in comparison to the
377 rest of the marine sediments, indicating larger magnetite grain size. Indeed, the high S-ratio and
378 low ARM_{30}/ARM suggest accumulation of magnetite (Fig. 5). The upper sapropelic layer
379 possess low TOC values (1 – 1.5%) compared to the lower sapropel (Fig. 4). This layer is
380 characterized by low χ_m despite the increment of hematite contribution to the magnetic signal
381 (lower S-ratio and higher SIRM) (Fig. 5). Relatively low TOC enrichment in the upper
382 sapropelic layer explains the low degree of sulfurization of the iron oxides including hematite.
383 Background foliation profile has low values in the lower sapropel supported by relatively low

384 χ_m (Fig. 5). Even though S-ratio indicates that upper sapropel layer contains a portion of
385 hematite, this could indicate that the magnetic signature is carried by both magnetite and
386 hematite in this interval (Fig. 5) (Drab et al., 2015a).

387 **5.2. Sedimentological, geochemical and magnetic properties of turbidite-homogenite** 388 **units: Demarcation between homogenite and background hemipelagic sediments**

389 Sedimentological, geochemical and physical (gamma density and lithology) properties
390 of the THUs in Kumburgaz Basin core CS-14 are quite similar with those documented from the
391 other basins in the SoM (McHugh et al., 2006, 2014; Beck et al., 2007; Çağatay et al., 2012;
392 Eriş et al., 2012; Drab et al., 2015b; Yakupoğlu et al., 2019). Overall background sediments
393 display more variability depending on facies than THU sediments.

394 The coarse basal part of THUs (Fig. 6A) in the marine unit is represented by parallel
395 lamination and a sharp basal contact with the underlying background sediments. The basal parts
396 have a higher magnetic susceptibility and higher content in ferromagnetic grains. In the marine
397 THU example (Fig. 6A), coarse basal part has stronger foliation and lineation than both the
398 homogenites and background sediment. All THU units in the non-sapropelic facies except some
399 thinner examples have higher foliation than the overlying background sediments (Figs. 3, 6).
400 However, the transition upward is often progressive, and may be difficult to pinpoint based on
401 AMS data alone. This is especially true for the thinner events as the maximum resolution of
402 AMS data is 2 cm. Therefore, we have also taken into account the radiographic images (pattern
403 changes light to dark) and geochemical elemental distribution of THUs (especially trends of Fe,
404 Ca and Sr) to define the upper boundaries more precisely. The positive magnetic foliation
405 anomaly is not entirely correlated to the variations of other magnetic properties (see Fig. 6;
406 ARM_{30}/ARM and S-ratio profiles). In average, the turbidite layers appear to have a slight (but
407 statistically significant) increase of ARM_{30}/ARM compared with both homogenites and

408 background sediments.. The distinction of homogenite-coarse basal unit is rather visible in the
409 core photographs and radiography (Figs. 3, 6) due to different depositional mechanisms (Beck
410 et al., 2007). In Gulf of Corinth, combination magnetic foliation and the rock magnetic
411 measurements shows the boundaries between homogenites and overlying background
412 sediments on selected examples (Campos et al., 2013). Coarse basal units represent deposition
413 of clastic sediments that are transported by the head and body of a turbidity current. These
414 sediments are detritus, containing high amount of Fe-bearing minerals and reworked Ca- and
415 Sr-bearing fossil fragments (Fig. 6). In particular, the transition between coarse basal and
416 homogenite parts of the THUs are commonly enriched in Ca and Sr, indicating the presence of
417 biogenic carbonate material remobilized from the shelf and upper slope of the Kumburgaz
418 Basin (Figs. 1,2,6) (Eriş et al., 2012).

419 Coarse sandy basal parts of THUs in the sapropels have thick laminations and
420 commonly show undulated base contact indicating erosional contact with underlying
421 background sediments (Fig. 6B). In lower sapropelic unit, marine sediments possess lower
422 ARM_{30}/ARM , which are likely related to magnetic grain size variation and/or occurrence of
423 greigite,. THU units have comparatively higher ARM_{30}/ARM In the lower sapropel, the average
424 foliation of the background sediment is not systematically lower, and even sometime higher,
425 than that of the homogenites, but the higher variability of the foliation parameter in the
426 laminated sediment at the 2 cm sampling scale still allows making a distinction (Figs. 3,
427 5). Homogenites in the sapropels are rather thick (up to 80 cm) (Figs. 3,6; Table 2), and show
428 darker shade than the background sediments in most radiographic images and photography
429 (Figs. 3, 6B). Moreover, the χ_m is an additional proxy to mark the upper boundary in sapropelic
430 THUs (Figs. 3,6) with both χ_m and foliation, showing a sharp decrease at the boundary between
431 these units, as previously documented by Campos et al. (2013).

432 Basal parts of THUs in the lacustrine unit are commonly thicker and coarser than those
433 of THUs in the sapropels and the upper marine unit (Fig. 6C). As in the THUs in the upper
434 marine and sapropel units, these coarse basal parts are represented by high Sr counts generated
435 by platy biogenic carbonate material (Fig. 6). ARM₃₀/ARM, SIRM and χ_m values in the
436 lacustrine interval are in average larger than in the other facies (Fig. 3), but also display a high
437 variability, while values in the homogenite remain homogeneous (Fig. 6). The lacustrine facies
438 presents the sharpest foliation contrast at the top of homogenites, typically 1.06 to 1.02 across
439 the boundary between the homogenite and the background sediment.

440 In summary, coarse basal parts of the THUs have more ferromagnetic particles than the
441 homogenites and background sediments (Fig 6), suggesting that the magnetic signature is
442 mainly controlled by the depositional environments (Fig. 5). The homogenite tends to be
443 relatively homogenous in magnetic properties as in chemistry. However, the diagenesis plays
444 an important role on magnetic grain size, as exposed by the variability of ARM₃₀/ARM values
445 of the THUs (see sapropelic and lacustrine THU example in Figs. 6). The variability as a
446 function of facies is higher for the background sediment than for the homogenites. As a result
447 the ARM₃₀/ARM is lower in the background sediment than in the homogenites within the lower
448 (laminated) sapropel facies, while the opposite is observed in the lacustrine facies (Figs. 3-6).
449 SIRM and χ_m are also higher in the lacustrine background sediment indicating a higher content
450 in ferromagnetic minerals. The sharpest contrast in magnetic properties and fabric between
451 homogenites and background sediment is observed within the lacustrine interval. Similarly,
452 distinct boundary between THUs and the background sedimentation are observed on Alpine
453 lakes (Crouzet et a., 2019). On the other hand, contrast is minimal, or reversed, within the
454 laminated sapropel interval. These observations suggest that magnetic mineralogy and/or grain
455 size is one of the factors influencing the magnetic fabric. Yet, in Sea of Marmara, variations in
456 magnetic foliation in THUs are related to the deposition from turbulent flows rather than the

457 magnetic mineralogy of the sediments (Campos et al., 2013). Homogenite units are deposited
458 from suspension clouds following the deposition of the coarse basal layers from a body of
459 turbulent flow, and differ from the overlying background sediment by having more
460 homogeneous and compact textures and higher density (Shiki et al., 2000; Beck et al., 2007;
461 Eriş et al., 2012; Polonia et al., 2013, 2017; Drab et al., 2015b; Van Daele et al., 2017;
462 Yakupoğlu et al., 2019). Absence of bioturbation may also be a factor as the laminated sapropel
463 appear to have relatively high (and highly heterogeneous) average magnetic foliation. Similarly,
464 thick homogenites in lacustrine and marine non-sapropel facies should be less affected by
465 bioturbation than background sediments and this could, regardless of mineralogy and
466 depositional processes, favor a contrast in magnetic fabric.

467 **5.3. Climatic and Hydrological Controls on Turbidite-Homogenite Frequency and** 468 **Thickness**

469 In general, the occurrence interval (or event frequency) and thickness of THUs in
470 different chronostratigraphic units are highly variable (Fig. 3; Table 2; Supplementary Table
471 1). The occurrence interval ranges from an average of 114 yrs in the upper sapropel to 235 yrs
472 in the lacustrine unit. Since we discarded the muddy hyperpycnal turbidites that may have been
473 triggered by floods and storm waves, the remaining THU units, with a coarse and laminated
474 basal part and a homogenous muddy upper part (homogenite), could be triggered by earthquake
475 shaking in the tectonically active SoM basins (Fig. 3) (e.g. see Çağatay et al., 2012; McHugh
476 et al., 2014; Drab et al., 2015b; Yakupoğlu et al., 2019).

477 Comparison of two piston cores (CS-01 and CS-14), which are ~ 2.5 km apart in the
478 Kumburgaz Basin, show that THUs in Late Holocene period are rather similar in terms of THU
479 event frequency, thickness and grain-size. However, the numbers of THUs deposited in the last
480 6 kyrs in the two cores are different; CS-01 and CS-14 contain 28 and 34 THUs respectively,
481 which correspond to average recurrence intervals of 220 and 150 years, respectively (Fig. 2).

482 Moreover, different units in core CS-14 has widely variable THU occurrence intervals, with the
483 individual event intervals ranging from 37 to 1200 years (Supplementary Table 1). If it is
484 presumed that these units are triggered with earthquakes, this high variability is inconsistent
485 with the 200-250 yrs recurrence interval of historical $M_w > 7$ earthquakes in the Marmara region
486 (e.g., Ambraseys and Finkel, 1995; Parsons, 2004). THUs also show different thicknesses in
487 different units of core CS-14 succession. These observations suggest that factors other than
488 earthquake magnitude need to be considered in order to explain the temporal and spatial
489 variability of THU occurrence and thickness in a given basin (e.g. Wilhelm et al., 2016; Ikehara
490 et al., 2016, 2017, 2020). These include core location in relation to the basin morphology,
491 sedimentation rate, sediment sensitivity to earthquake shaking, and sea level change and related
492 paleoenvironmental changes.

493 The basin depo-centers are assumed to be the best locations for a complete THU record,
494 potentially comprising the highest THUs thicknesses of gravity-driven sedimentary deposits
495 (McHugh et al., 2006, 2014; Goldfinger, 2011; Patton et al., 2015). However, the difference in
496 the number of THU units and average THU occurrence intervals between cores CS-01 and CS-
497 14 in the Kumburgaz Basin can be explained by their accessibility to the sediment transport
498 routes rather than the water depth (Figs. 1, 2). Core CS-01 is recovered at -834 m near the toe
499 of the north eastern canyon (Fig. 1), whereas core CS-14 is recovered at -820 m near the basin
500 center on a structural high between two depo-centers. Its central position in the basin, together
501 with its accessibility to sediment input from both the northeastern and northern canyons and
502 possibly the northwestern canyon, makes the location of core CS-14 ideal for recording the
503 maximum number of turbidites (Figs. 1, 2). The common presence of several amalgamated
504 turbidites in core CS-14 supports sediment transport and deposition by turbidity currents
505 arriving from the two or three canyons (Supplementary Table 1).

506 Other factors, such as intensity of earthquake shaking, sedimentation rate, sensitivity of
507 the sediments to remobilization, and environmental factors (e.g. climate, sea/lake level, salinity
508 changes), appear to be important in THU frequency and thickness variations. In particular,
509 earthquake epicenter and magnitude, and the distribution of strong-motion parameters (e.g. the
510 peak ground acceleration: PGA) are believed to be important for generating turbidity flows (e.g.
511 [Howarth et al. 2021 and references therein](#)). Short average event intervals (e.g. average: 114
512 yrs in upper sapropel of core CS14) suggest that the earthquake magnitude threshold for
513 triggering turbidity currents may not be only limited to large events if there are efficient
514 sediment transport routes such as the steep northern slope (with up to 20-degree slope angles)
515 and canyon systems in the Kumburgaz Basin ([Fig 1](#)). This assertion is supported by the
516 occurrence of the turbidity currents triggered by the Mw 5.8 earthquake of Sept 26, 2019 in the
517 NE corner of the Central Basin ([Henry et al., 2022](#)). This raises the question if a remote but
518 strong earthquake, not necessarily in submerged context, may also trigger turbidites and
519 recorded in the sedimentary sequence. However, subaqueous paleoseismological data from the
520 Sea of Marmara (SoM) (e.g., [Çağatay et al., 2012](#); [Drab et al., 2012, 2015b](#); [McHugh et al.,](#)
521 [2015](#)) and historical earthquake data (e.g., [Ambraseys, N.N., Finkel, C.F., 1995](#)) suggests that
522 ground acceleration generated by onshore M=6-7.4 earthquakes east and south of the SoM with
523 epicenters more than ca. 50 km of the basins did not trigger turbidites. For example, some
524 earthquakes (e.g. 25 May 1719 earthquake with Ms=7.4 and 1754 earthquake with Ms=6.8 with
525 epicenters east of the İzmit Gulf) were not recorded in the sediments of the Karamürsel Basin
526 in the İzmit Gulf ([Çağatay et al., 2012, p.356 and references therein](#)).

527 The THU occurrence interval and thickness distribution in core CS-14 also indicates the
528 importance of environmental and hydrological factors such as sea level, sedimentation rate and
529 salinity changes. The lacustrine unit contains the thickest and coarsest (coarse sand in basal
530 parts) THUs in the core lithology with an average thickness of 20.8 cm and an event frequency

531 of 4.255 kyrs⁻¹ (i.e. average event interval: 241 yrs) (Table 2). It is also characterized by the
532 highest total sedimentation rate (1.98 mm/yr) and lowest TB-TT thickness ratio of 0.3, with
533 THUs forming 53% of the unit's thickness (Table 2; Supplementary Table 1). THU thickness
534 in the unit, calculated as five-point moving average, decreases from 38 cm from 14.6 kyrs BP
535 to 8.5 cm before the sapropel deposition at 11.2 krs BP (Fig. 7A). A parallel change occurs in
536 THU fraction, calculated as five-point moving average of each THU thickness divided by total
537 sediment thickness between two events, as well as in the event interval (Fig 7B, C); the THU
538 fraction ranges up to 73 % in the lower part of the lacustrine unit, but decreases to 35 % in the
539 upper part of the lacustrine unit and in the marine unit below the lower sapropel and the five-
540 point moving average event interval changes from ~250 yrs to 95 years (Fig. 7C). The high
541 sediment input in the Kumburgaz basin during the Late Glacial period can be explained by the
542 fact that, water level of the Marmara "lake" was below the Dardanelles Strait's sill depth, but
543 gradually increase to -85 m just before the marine reconnection at ~12.6 kyrs BP (Figs. 1,3,4)
544 (Çağatay et al., 2003; 2015; Eriş et al., 2011). Hence, the shelf was largely exposed during the
545 deposition of the lacustrine unit until ~13.5 kyrs and fluvial sediment input from the Büyük
546 Çekmece drainage network was directly delivered to the shelf edge and slope en route to the
547 deep basin by gravity flow deposits. However, a decrease in the sediment input occurred during
548 the 13.5-12.6 ka BP, which is likely to be due to a lake level increase.

549 Slope instability may have been another likely factor for THU events during the
550 lacustrine period. Based on Cl⁻, O and H isotope analyses of pore waters and a transport model,
551 Aloisi et al. (2015) estimated the salinity of ~4 psu for the Marmara "lake" waters before the
552 marine reconnection. Under such lacustrine fresh-brackish conditions together with low sea
553 level provides hydrostatic pressure change on sediments, which deposited along the canyon and
554 basin slopes would have been relatively unstable and may have further contributed to the thick
555 THU deposition and low TB-TT thickness ratio in the Kumburgaz Basin.

556 After the full marine connection at 12.6 kyrs BP, the salinification of the SoM deep
557 water was rapid, reaching the present levels within 1-2 kyrs of the connection (Çağatay et al.,
558 2009; Aloisi et al., 2015), which possibly contributed to the stability of the slopes and reducing
559 the canyon activity. The lower sapropel was deposited during 11.2-5.7 kyrs interval. The sea
560 level rose from -85 m at 12.6 kyrs BP to the present sea level ~6 kyrs BP, before the end of the
561 lower sapropel deposition (Grant et al., 2012). The total sedimentation rate was relatively high
562 (1.68 mm/yr) with the THUs forming 35% of the sapropel thickness. High sedimentation rate
563 for this period could have resulted from: (1) a wet and warm climatic condition with a high
564 fluvial input (Caner and Algan, 2002; Mudie et al., 2002; Valsecchi et al., 2012), and (2)
565 salinity-derived flocculation of clay-size fluvial material (Gibb, 1983; Wilkinson et al., 1997).
566 However, this process is expected to enhance clay settling near river-marine water mixing
567 zones, but with the relatively lower sea level, the mixing zone close to the shelf edge and a
568 larger flux of hemipelagic sediment was settling out of suspension in the basin.

569 The lower sapropel includes relatively thick THUs with an average thickness of 15.7
570 cm and average TB-TT thickness ratio of 0.6 (Supplementary Table 1). THUs in this unit were
571 deposited with the lowest frequency of 3.484 events kyrs⁻¹ (i.e. longest average event interval
572 of 287 yrs) in the sequence (Table 2; Supplementary Table 1). Five-event moving average THU
573 thickness in this unit ranges between ~40 cm and 6 cm, while average fractional thickness varies
574 between 20 % and 40 %, with a decrease in both parameters towards the top of the unit (Fig.
575 7A, B). The THU event interval is ~700 years for the main part of the unit but decreases to
576 ~150 years in the upper quarter part (Fig. 7C). Hence, the THU fraction in the lower sapropel
577 is much lower and the THU event interval is considerably longer than those in the lacustrine
578 unit. Moreover, the basal parts of THUs within the lower sapropel are finer in grain size and
579 TB-TT thickness ratio is higher than that of THUs of the lacustrine unit.

580 The main control on the long event interval and grain size of THUs in most part of the
581 lower sapropel appears to be the cohesive and relatively high shear strength of sapropels, which
582 result from particle bonding between the organic matter and in situ organic and clay fabrics that
583 develop by deposition from anoxic water column (Kopf et al., 1998; Obuka et al., 2015). Such
584 geomechanical properties would require a relatively large earthquake shaking (strong-ground
585 motion) to trigger turbidity currents from the basin slopes. Long intervals between the turbidite
586 events in turn allowed thick sediment accumulation (sediment loading) on the slope and shelf
587 edge, which was consequently remobilized by earthquake shaking, resulting in the relatively
588 thicker THUs, with relatively higher TB-TT thickness ratios in the sapropel unit. This
589 conclusion is supported by similar trends of the THU thickness and event interval profiles for
590 almost the entire core section (Fig 3; Table 2).

591 The rising sea level was stabilized towards the end of the lower sapropel deposition, and
592 the sedimentation rate, THU thickness, and event recurrence interval decreased, and the TB-TT
593 thickness ratio increased towards end of the upper sapropel deposition and during the ensuing
594 marine (5.7-5.4 kyrs BP), upper sapropel (5.4-2.7 kyrs BP) and recent marine (2.7 kyrs BP to
595 present) depositional intervals (Fig. 7A, C; Table 2; Supplementary Table 1). The transition to
596 low sedimentation rates and gradual increase in the TB-TT thickness ratio starting from ~7 kyrs
597 BP was mainly due to rise in sea level (Fig. 4), which caused most fluvial sediments to be
598 trapped in the Büyük Çekmece Lagoon and near coastal areas, rather than reaching to the shelf
599 edge, slope and basinal areas. Only small amounts of fine sediments would have been
600 transported by currents to accumulate on the slopes, and subsequently mobilized en route to the
601 basin to be deposited as thin (6-7 cm-thick) and largely muddy THUs at high frequency in the
602 upper sapropel and latest marine units, as indicated also by the relatively low TB-TT thickness
603 ratio (Fig 3, Table 2; Supplementary Table 1). Indeed, the frequency of THU occurrence in the
604 two units, and in particular in the upper sapropel, is higher than the underlying lower sapropel

605 and lacustrine units. This is mainly due to the sensitivity of these marine sediments to
606 earthquake shaking because of their lower TOC content, compared to that of the lower sapropel,
607 and to their deposition under high sea level, compared to the lake level during the deposition of
608 the lacustrine unit.

609 The upper sapropel and the recent marine unit show some fluctuations in the turbidite
610 thickness, turbidite fraction and event interval (Fig. 7), which are likely due to artefacts in the
611 age model (e.g. two radiocarbon ages in a short interval). However, some differences may be
612 related to environmental conditions; upper sapropel was deposited with slightly higher organic
613 productivity and under relatively lower bottom-water oxygen conditions than the recent marine
614 unit, as indicated by the TOC and Mn profiles (Fig. 4). These differences are reflected in the
615 relatively higher total and background sedimentation rates, lower TB-TT thickness ratio and
616 shorter average event interval of the upper sapropel unit than those of the recent marine unit
617 (Table 2).

618 **6. Conclusions**

619 Geochemical and rock magnetic parameters of core CS-14 from Kumburgaz basin enable us to
620 provide a more accurate determination of the THU boundaries within the last 15 kyrs BP. THUs
621 deposited in marine (including Holocene sapropels) and lacustrine facies of the core show
622 different characteristics in terms of thickness, grain size, geochemical and magnetic aspects.
623 These differences are mainly related to the sensitivity of sediments to remobilization, core
624 location and hydrological conditions related to both the sea level and salinity rise subsequent to
625 the full marine connection of the SoM. In 15 kyrs-long sedimentary record includes different
626 lacustrine and marine, including Holocene sapropels, are characterized by lithological and
627 geochemical precursors (TOC, μ -XRF). A robust event-free age-depth model was constructed
628 to date the units and determine the frequency (event interval) of THUs.

629 Boundaries between homogenites and overlying background sediments are well-defined by
630 *AMS* (magnetic foliation). The magnetic foliation shows strong positive pulses in THUs in
631 every facies indicating that its trend is related to the changes in depositional setting and to the
632 rising sea level rather than the magnetic signature of THUs and hemipelagites. Based on the
633 age-depth model of the core, average THU occurrence intervals in marine (2.7 kyrs BP-present),
634 upper sapropel (5.4-2.7 kyrs BP), lower sapropel (11.2-5.7 kyrs BP), marine (12.6-11.2 kyrs
635 BP) and lacustrine units (15-12.6 kyrs BP) are ~160 yrs, ~114 yrs, ~287 yrs, 246 yrs and ~235
636 yrs, respectively.

637 Results of this study enhance our understanding of turbidite generation and its use in
638 subaqueous paleoseismology. Short THU intervals of upper sapropel and the most recent
639 marine sequence suggest the possibility of turbidity current triggering and THU deposition by
640 moderate magnitude earthquakes (5-6.5 Ms). Several environmental factors (climatic and
641 hydrological), together with seismic activity, affect the deposition of THUs, and should be
642 considered in subaqueous paleoseismological studies. In particular, sensitivity of sediments to
643 remobilization during earthquake shaking, together with hydrological (sea level and salinity),
644 changes are considered to be of critical importance in understanding the conditions of turbidite
645 generation, and therefore, in paleoseismological studies in the Sea of Marmara and similar
646 marine/lacustrine settings.

1025 **Figure Captions**

1026

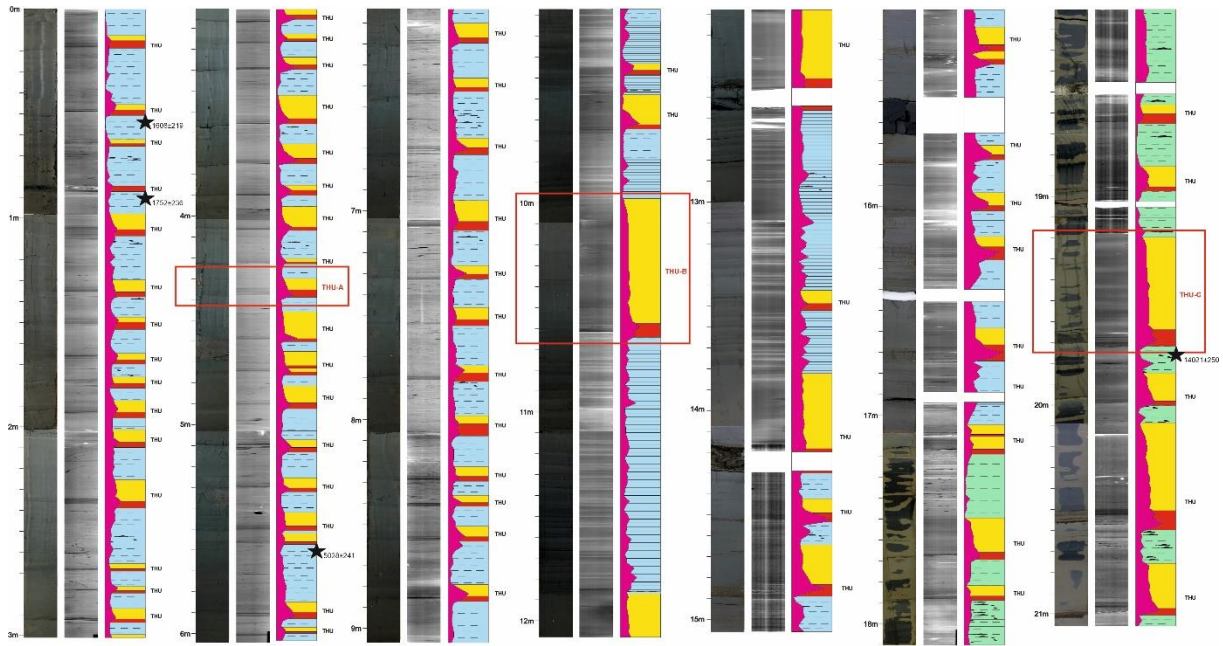

1027 **Fig. 1.** A) High resolution multi-beam bathymetry map of the Sea of Marmara (west to east;
 1028 TB: Tekirdağ Basin, WH: Western High, CB: Central Basin, KB: Kumburgaz Basin, CH:
 1029 Central High, CiB; Çınarcık Basin, GI: Gulf of İzmit) (Revised from Uçarkuş, 2010). Black
 1030 lines represent the active faults. White box indicates the location of the Kumburgaz Basin and
 1031 the inset map. B) Close up of bathymetry map of Kumburgaz Basin. Black lines indicate the
 1032 active faults. Thick black line and yellow dots represents the CHIRP profile (P02) and core
 1033 locations of CS-01 (Yakupoğlu et al., 2019) and CS-14 (this study) respectively. Note that

1034 northern canyons are indicated as following: NEC: North Eastern Canyon, NE: Northern
1035 Canyon, NWC: North Western Canyon.

1036

1037 **Fig. 2.** CHIRP profile (P02) from the Kumburgaz Basin, showing the main depositional units
1038 along the basin floor. Lacustrine-Marine transition (12.6 kyrs BP; Çağatay et al., 2015) is shown
1039 in blue line. Core CS-01 is located at depocenter covering the last 6 kyrs BP sedimentary records
1040 (Yakupoğlu et al., 2019) and Core CS-14 penetrates through lacustrine units of SoM up to 15
1041 cal kyrs BP (Figs. 3, 4).

1042

1043

Fig. 3. Generalized lithological log of the core CS-14, showing the main lithostratigraphy

1044

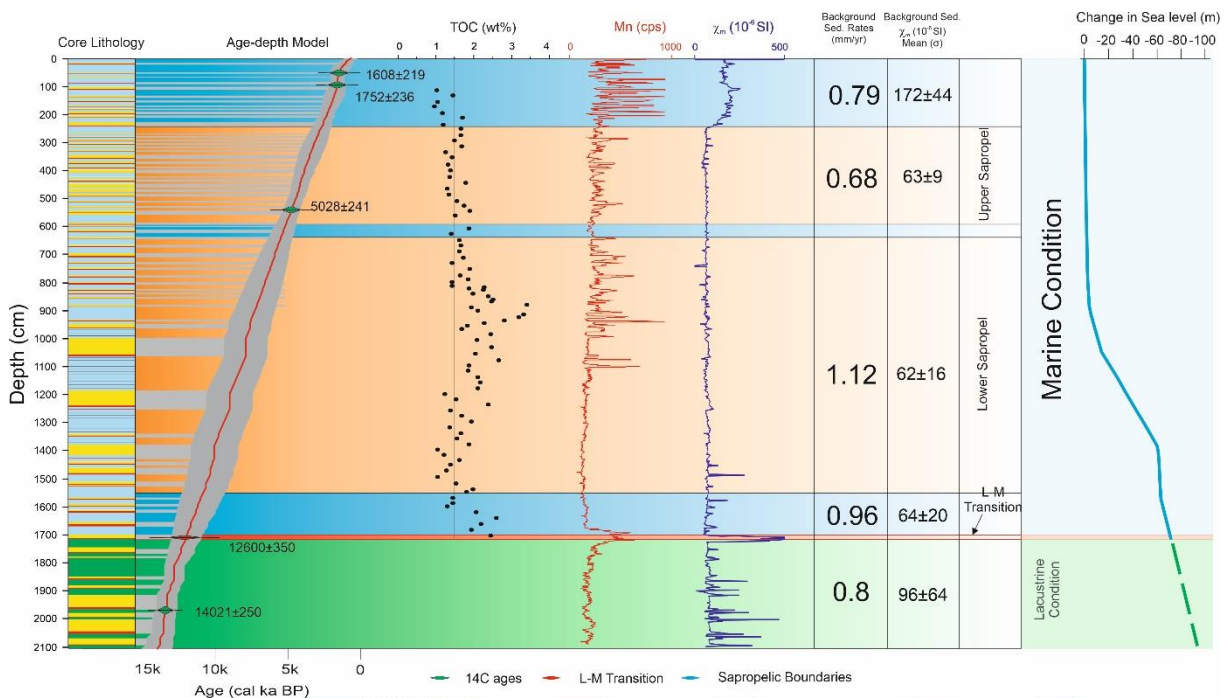

photography and radiography of the marine and lacustrine units deposited during the last ~15

1045

cal ka BP (Fig. 4). 70 turbidite layers are differentiated based on sedimentological, geochemical

1046

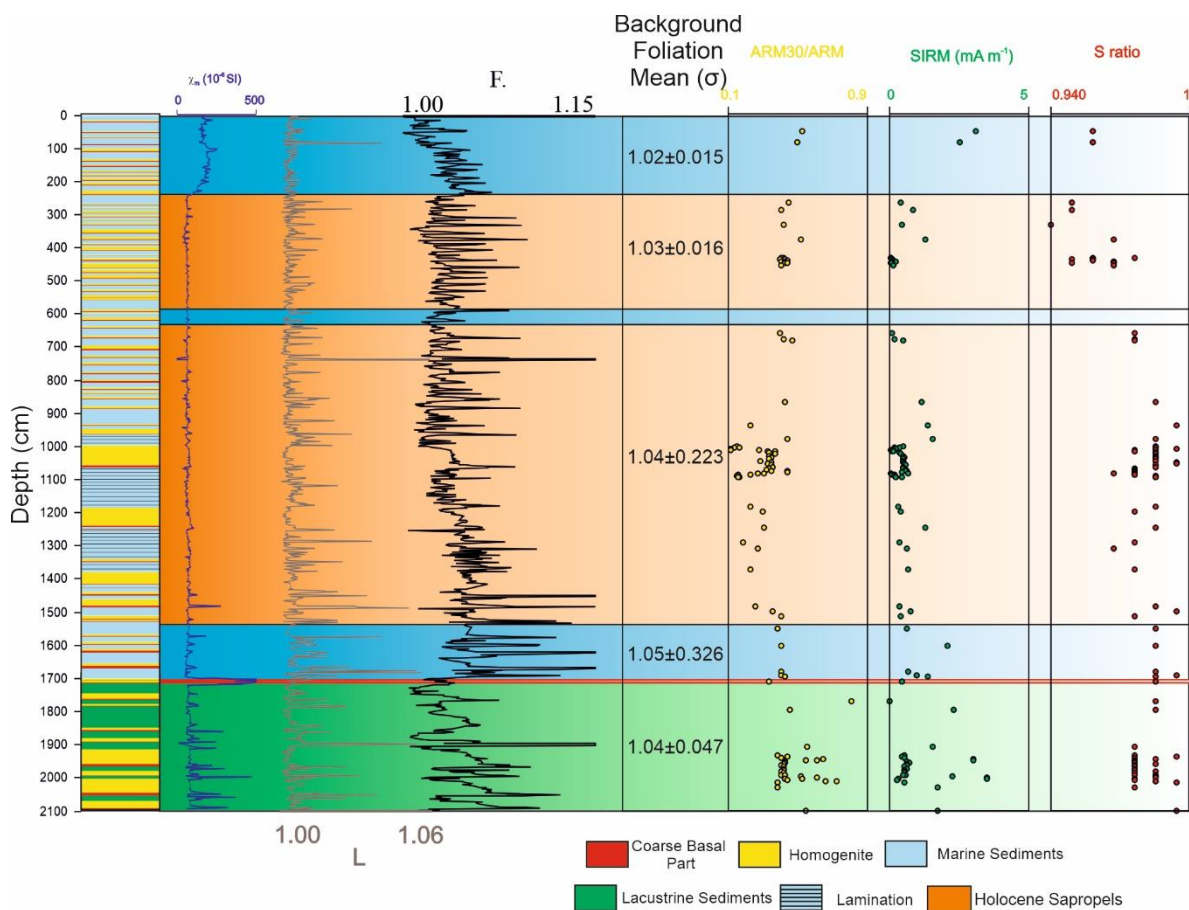

and magnetic precursors. Legend below shows different lithological units and symbols.

1047

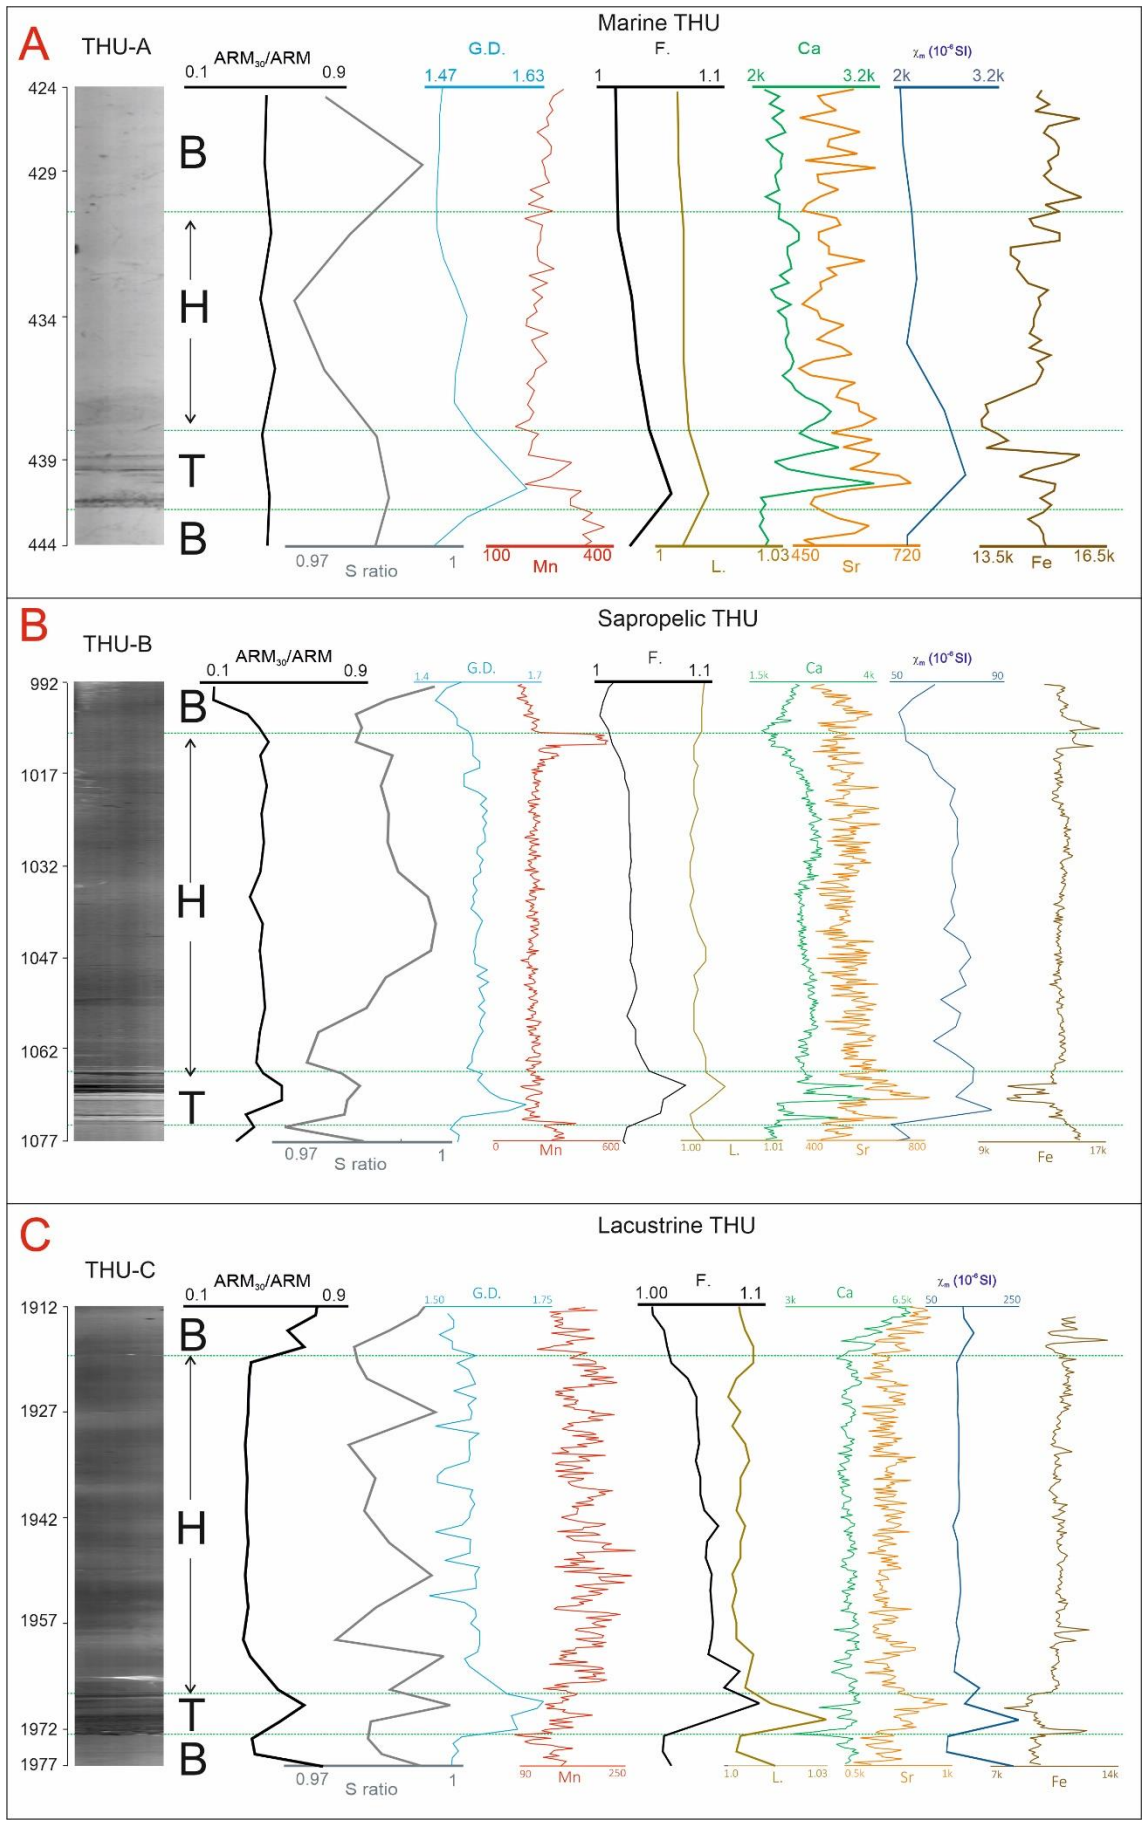

1048 **Fig. 4.** Age-depth model of the core CS-14. Summarized sedimentary log shows the main
 1049 lithostratigraphy of the marine and lacustrine units and TOC concentrations of the first 18 m.
 1050 Age-depth model of the background sediments of the core CS-14 are reconstructed based on
 1051 four ^{14}C ages and the age of a major lithological change (L-M transition) by using Clam.r Script
 1052 (Blauuw, 2010). Red line represents the mean age of the iterations. Green, blue and red dots are
 1053 the levels of the ^{14}C samples, L-M transition respectively. Gray overlay indicates the probability
 1054 distribution. Mn profile and χ_m profiles are marked in red and blue color respectively.
 1055 Background sedimentation rates are indicated according to each facies. The rightmost column
 1056 indicates the climatic phases and global sea level curve of the last 12 kyrs BP (Grant et al.,
 1057 2012).

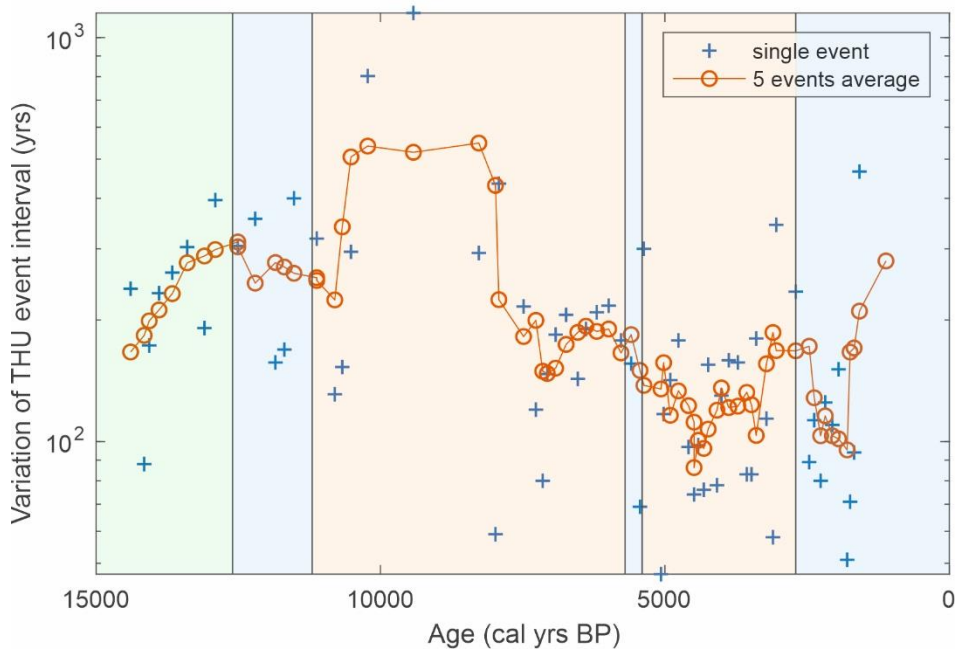

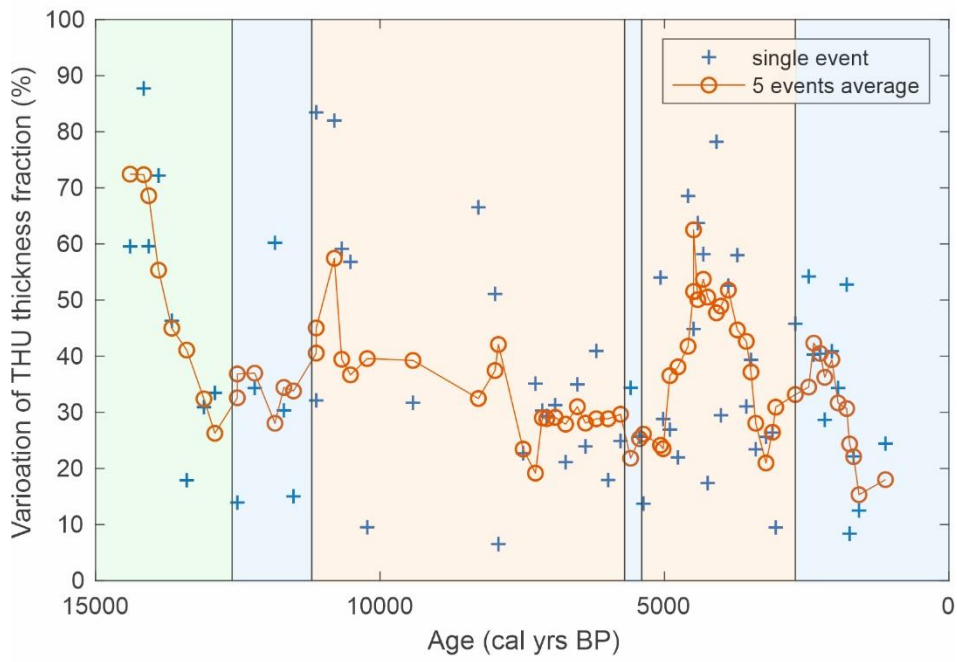

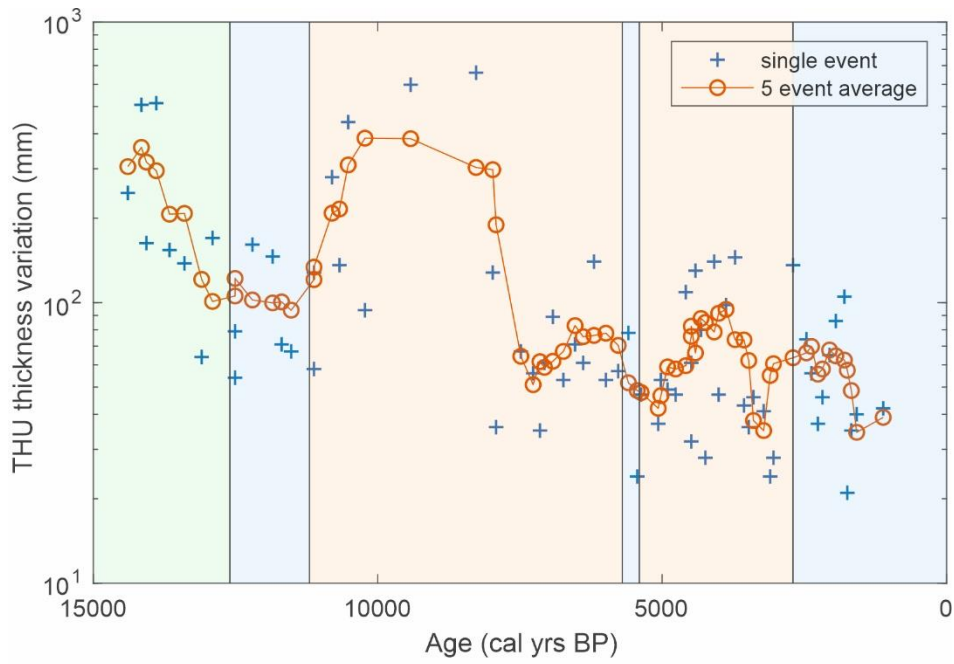

1058

1059 **Fig. 5.** Summarized sedimentary log of the core accompanied with magnetic foliation, magnetic
1060 lineation, S ratio, SIRM, ARM₃₀/ARM profiles of 98 samples showing the rock magnetism
1061 proxies.

1062

1063 **Fig. 6.** Radiography and multi-parameter analyses (left to right; ARM_{30}/ARM , S ratio, gamma
1064 density, Mn, magnetic foliation and lineation, Ca, Sr, χ_m , Fe) of the selected THUs (THU-A,
1065 B, C) (see their positions on Fig 3). Green lines represent the boundary of THU units with
1066 background sediments.

1068 **Fig. 7.** (A) THU thickness variation, (B) Variation of THU thickness fraction, calculated as
 1069 each THU thickness divided by total sediment thickness between two events, (C) Variation of
 1070 THU event interval.

1071 **Table Captions**

1072 **Table 1.** Summary of Accelerated Mass Spectrometry ¹⁴C ages obtained from core CS-14 and
 1073 the referenced age of full L-M transition (Çağatay et al., 2015). Reservoir correction for
 1074 Accelerated Mass Spectrometry dates applied as $\sim 390 \pm 85$ yrs for marine according to Siani et
 1075 al. (2000) and $\sim 900 \pm 100$ yrs for lacustrine (Çağatay et al., 2015).

Sample ID	Depth (cm)	Uncalibrated Age (BP)	Calibrated Ages (BP)	Material
TÜBİTAK-675	52	2552±53	1608±219	benthic & planktonic foraminifera, echinoderm spicules
TÜBİTAK-676	92	2432±32	1752±236	benthic & planktonic foraminifera, echinoderm spicules
TÜBİTAK-678	554	5115±40	5028±241	benthic & planktonic foraminifera, echinoderm spicules
TÜBİTAK-794	1984	12538±51	14021±250	Bivalves
Lacustrine-Marine Transition	1740		12600±350 (Çağatay et al., 2015)	

1076

1077 **Table 2.** THU intervals, frequencies and thicknesses over the lithological facies. Extended list
 1078 of each unit is displayed on [Supplementary Table 1](#). Note that, standard deviation of THU
 1079 intervals and thicknesses are indicated in parenthesis.

Unit/Facies	THU interval (yrs)	THU frequency (kyrs-1)	Background Sedimentation Rate (mm/yr)	Total Sedimentation Rate (mm/yr)	THU thickness (cm)	Percentage of THU (%)	TB/T ratio
-------------	--------------------	------------------------	---------------------------------------	----------------------------------	--------------------	-----------------------	------------

Non-sapropelic Marine	174 (112)	5.747	0.61	0.77	7 (3.9)	30	0.8
Upper Sapropel	114(62)	8.621	0.68	1.29	6.1 (3.6)	38	0.7
Lower Sapropel	287 (254)	3.484	1.12	1.68	15.7 (17.8)	35	0.6
Lacustrine	235(85)	4.255	0.8	1.9	20.8 (16)	53	0.3

1080

1081

1082 **Supplementary Table 1.** Summary of THU list obtained from the core CS-14. Their depths,

1083 facies, thickness, mean ages are listed according to the stratigraphy. Average thicknesses and

1084 average recurrence intervals of THUs for each facies, turbidite-homogenite ratios and the

1085 background sedimentation rates are listed at the rightmost columns.

1086
