This work investigates a 2D vector field behavioral model to describe the anisotropic magnetic permeability and losses in Grain Oriented Electrical Steels (GOES) within quasi-static and magneto-harmonic working conditions. The model includes the an-hysteretic magnetic field driven by the total anisotropy, the coercive force responsible for the quasi-static hysteresis losses and the dynamic damping eddy field responsible for the extra losses. Each field contribution requires the definition of a tensor property whose diagonal and non diagonal coupling components are experimentally identified as a function of the flux density magnitude B and its angle θ with the Rolling direction (RD). The static behavior is identified at low frequency and the dynamic one takes the frequency dependent field diffusion into account. Diagonalization tools reveal main characteristic magnetic axis for the separate properties with deflections at the macroscale.

Index Terms — grain oriented electrical steels, losses, magnetic structure, permeability, tensor properties, 2D vector magnetic field.

I. INTRODUCTION – CONTEXT AND STATE OF THE ART

Iron loss and dynamic hysteresis models either 1-D scalar [1, 4] or 2-D vectorial [6] are based on a separation principle between the classical losses and the microscopic ones due to reversal mechanisms. Combining the local behavior to the field diffusion equations has been proposed up to now for scalar models [7]. Developing both vector hysteresis models [8] and loss models [9] in 2D is still a subject of research to compute a magnetic flux that makes an angle with RD in electrical steels used for transformers, inductors and machines (Fig. 1).

Fig. 1: Application of proposed methodology (transformers, chokes, machines).

II. THE VECTOR MODEL - TENSOR MAGNETIC PROPERTIES

A. General behavioral model

Inspiring from [1, 4, 6] and following the reference [8], we work with a complex magneto-harmonic behavior between the magnetic field \mathbf{H} and the flux density \mathbf{B} , resulting from the minimization of the total energy state including the losses as a function of \mathbf{B} , involving three contributions (1): the static an-hysteretic magnetic field \mathbf{H}_M at equilibrium, the quasi static coercive field \mathbf{H}_h responsible for the quasi-static hysteresis losses and the dynamic damping magnetic field \mathbf{H}_d due to microscopic eddy currents (see Fig. 2).

$$\mathbf{H}(\mathbf{B}, \omega) = \mathbf{H}_M(\mathbf{B}) + \mathbf{H}_h(\mathbf{B}) + \mathbf{H}_d(\mathbf{B}, \omega) \quad (1)$$

This quasi-linear law within time harmonics at frequency f and angle velocity $\omega = 2\pi f$ is only able to relate the magnetic field and the flux density but not yet the hysteresis loops. Therefore, it is mainly used to estimate the magnitude permeability and losses given by each cycle slope and area.

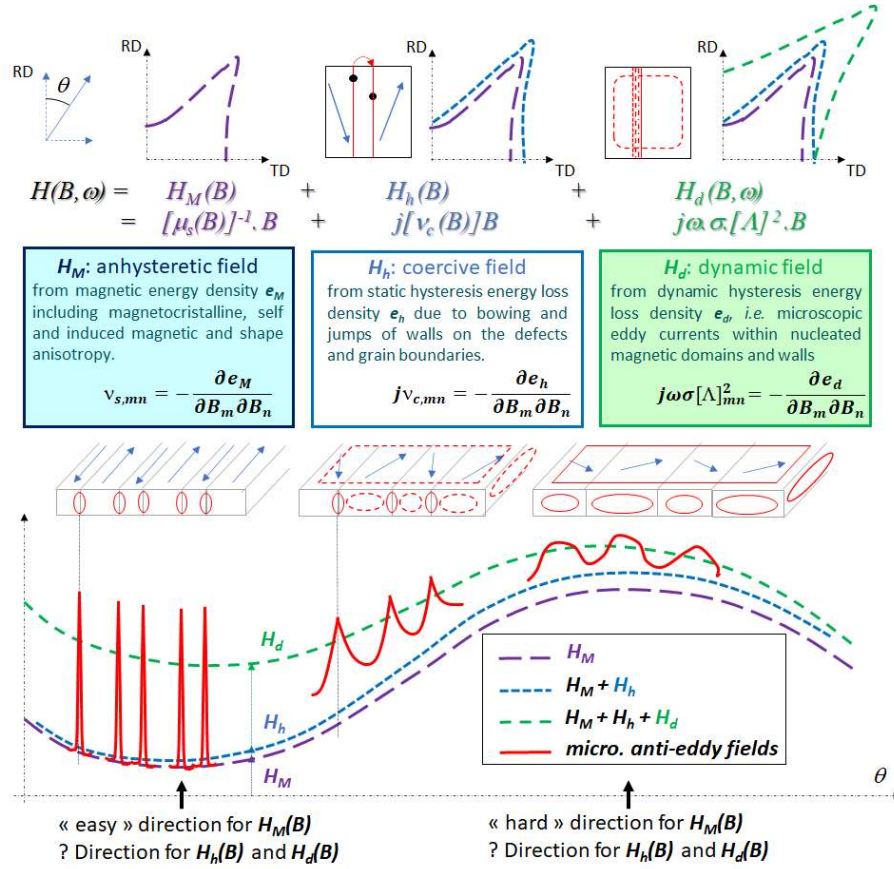

Fig. 2: Physical principles of the 2D vector field model for magnetic materials.

1) The static an-hysteretic field

This static an-hysteretic field contribution H_M is non dissipative and closely related to the magnetic anisotropy of the material (magneto-crystalline anisotropy, metallographic shape anisotropy, stress induced anisotropy). $[\nu_s] = [\mu_s]^{-1}$ is defined as the static internal magnetic reluctivity and it is a tensor derived from the non-dissipative magnetic energy density e_M , responsible for the major part of reactive power (3).

$$H_M(\mathbf{B}) = [\nu_s(\mathbf{B})]\mathbf{B} = [\mu_s(\mathbf{B})]^{-1}\mathbf{B} \quad (2)$$

$$\nu_{s,mn} = -\frac{\partial e_M}{\partial B_m \partial B_n} \quad (3)$$

2) The quasi-static coercive field

The quasi-static coercive field H_h is dissipative and corresponds to microscopic anti-eddy fields mainly due to jumps of walls at defects and grains boundaries. The tensor $[\nu_c] = [\mu_c]^{-1}$ is defined as the coercive reluctivity, closely linked to non reversibility of magnetization at very low frequency [3] (4) ($j = \exp(i\pi/2)$). $[\nu_c]$ is derived from the static hysteresis energy loss density e_h (5) responsible for the static hysteresis active power loss density $p_{nv} = \text{real}(\frac{1}{2}j\omega e_h)$:

$$H_h(\mathbf{B}) = j[\nu_c(\mathbf{B})]\mathbf{B} \quad (4)$$

$$j\nu_{c,mn} = -\frac{\partial e_h}{\partial B_m \partial B_n} \quad (5)$$

3) The dynamic damping eddy field

At the mesoscopic scale, the magnetization reversal processes induce microscopic eddy currents that generate the extra damping magnetic field H_d . It can be expressed as a function of the electrical conductivity σ , the angle velocity ω and a structural dynamic magnetization property called $[\Lambda]$ (6). $[\Lambda]$ represents and lumps the magnetic domains and walls properties [8] averaged among various orientations $\vec{\theta}_w$ with the help of the product tensor $[\varpi(\theta_w)] = \vec{\theta}_w \otimes \vec{\theta}_w = \vec{\theta}_w \cdot \vec{\theta}_w^t$ (8). The generalization proposal consists in deriving the excess energy loss density e_d (7) due to microscopic eddy currents within nucleated magnetic domains and walls and responsible for the dynamic hysteresis active power loss density [8].

$$H_d(\mathbf{B}) = j\omega\sigma[\Lambda(\mathbf{B}, \omega)]^2\mathbf{B} \quad (6)$$

$$j\omega\sigma[A]^2_{mn} = - - \frac{\partial e_d}{\partial B_m \partial B_n} \quad (7)$$

$$[A(\mathbf{B}, \omega)]^2 = \left\langle \frac{1}{2\sigma J_s n_w \eta_w S_w} [\varpi(\theta_w)] + S_{DMR,w} ([1] - [\varpi(\theta_w)]) \right\rangle_{\bar{\theta}_w} \quad (8)$$

S_w is the walls surface, η_w the walls mobility and n_w the walls density [2] stand for the **Domain Walls Displacement (DWD)**. $S_{DMR,w}$ is the domains surface polarizability [5] and stands for the **Domain Magnetization Rotation (DMR)** mechanism.

B. Tensor magnetic properties

Fig. 3. Description of (x,y) and (TD, RD) reference frames. Definition of angle θ between the flux direction y and the rolling direction RD .

The most natural reference frame called (TD, RD) for GOES contains the two perpendicular directions known as the Transverse Direction (TD) and the Rolling direction (RD).

Given a magnetic flux density B oriented in the direction y , forming an angle θ with the rolling direction RD , the TD and RD components of B can be deduced as follows (Fig. 3):

$$B_{TD} = B \sin \theta \text{ and } B_{RD} = B \cos \theta \quad (9a)$$

$$B = \sqrt{B_{TD}^2 + B_{RD}^2} \quad (9b)$$

$$[T]_{(TD, RD)-(x, y)} = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \quad (9c)$$

The (x,y) reference frame being the frame related to the magnetic measurements, the normalized change of frame transfer matrix from (x,y) to (TD, RD) is given by (9c). It will be shown in the following that tensor properties are not necessarily diagonal in the (TD, RD) reference frame, meaning that \mathbf{H}_{TD} does not depend only on \mathbf{B}_{TD} but $\mathbf{H}_{TD}(\mathbf{B}_{TD}, \mathbf{B}_{RD})$. \mathbf{H}_{RD} does not depend only on \mathbf{B}_{RD} but $\mathbf{H}_{RD}(\mathbf{B}_{TD}, \mathbf{B}_{RD})$. The important issue addressed in this work consists in finding the (XH, YH) main reference frame in which tensor properties will be diagonal (see Fig. 4). These magnetic axis may be different for $[\mu_s]$, $[\nu_c]$ and $[A]$ respectively. This goal requires to identify first the non-diagonal coupling TD - RD components.

Φ	Direction of magnetic flux
XH_M	YH_M eigenvectors for quasi-static anhysteretic field H_M
XH_h	YH_h eigenvectors for static hysteretic coercive field H_h
XH_d	YH_d eigenvectors for dynamic magnetization field H_d

Fig. 4: Definition of reference frames for matrix diagonalization.

1) An-hysteretic quasi-static internal permeability

The an-hysteretic field \mathbf{H}_M involves the static internal magnetic permeability $[\mu_s] = [\nu_s]^{-1} = \mu_0[\mu_{sr}]$, a symmetrical tensor. We consider the non-linear diagonal components $\mu_{sr,TD} = \mu_{sr,TD-TD}$ and $\mu_{sr,RD} = \mu_{sr,RD-RD}$ of $[\mu_{sr}]$ as a function of B_{TD} and B_{RD} respectively. Any cross dependence between TD and RD are included in the non-diagonal $\mu_{sr,TRD} = \mu_{sr,TD-RD}$ components. The vector field dependences of the latter must be identified to find the eigenvectors \mathbf{XH}_M and \mathbf{YH}_M depending on B and angle θ . It gives information on the total anisotropy energy density $e_M(\theta)$ and its main macroscopic magnetic axis.

$$[\mu_s] = \mu_0 \begin{bmatrix} \mu_{sr,TD}(B_{TD}) & \mu_{sr,TRD}(B, \theta) \\ \mu_{sr,TRD}(B, \theta) & \mu_{sr,RD}(B_{RD}) \end{bmatrix}_{(TD,RD)} \quad (10)$$

2) Static coercive reluctivity and static hysteresis losses

The static coercive field \mathbf{H}_h involves the coercive magnetic permeability $[\mu_c]$ or its inverse, the reluctivity $[\nu_c] = [\mu_c]^{-1}$,

$$[\mu_c] = \mu_0 \begin{bmatrix} \mu_{cr,TD}(B_{TD}) & \mu_{cr,TRD}(B, \theta) \\ \mu_{cr,TRD}^*(B, \theta) & \mu_{cr,RD}(B_{RD}) \end{bmatrix}_{(TD,RD)} \quad (11a)$$

$$p_{hm} = \frac{p_{hv}}{\gamma} = \text{real}\left(\frac{1}{2\gamma} \mathbf{H}_h \cdot (j\omega \mathbf{B})^*\right) = \frac{1}{2\gamma} [\nu_c] \omega \mathbf{B} \cdot \mathbf{B}^* \quad (11b)$$

This field is responsible for the static hysteresis losses given by equation (11b) (γ being the mass density). The diagonal RD component of $[\nu_c]$ is related to the hysteresis loss coefficient K_h of Bertotti [1, 4] in case of 1-directional flux ($\pi \nu_{c,RD} = K_h$).

We consider the non-linear diagonal components $\mu_{cr,TD} = \mu_{cr,TD-TD}$ and $\mu_{cr,RD} = \mu_{cr,RD-RD}$ of $[\mu_{cr}]$ as a function of the induction components B_{TD} and B_{RD} respectively. Any cross dependence between TD and RD are included in the non-diagonal $\mu_{cr,TRD} = \mu_{cr,TD-RD}$ components. The vector field dependences of the latter must be identified to find the eigenvectors \mathbf{XH}_h and \mathbf{YH}_h depending on B and angle θ . It gives information on the static hysteresis energy loss density $e_h(\theta)$, linked to grains shape and boundaries or dislocations directions.

3) Dynamic and structural magnetization property

The dynamic field \mathbf{H}_d involves the magnetic structure represented by $[A]$, an Hermitian tensor whose components A_{ij} are equivalent to a local excess loss coefficient relative to $j\omega B_i$ and $j\omega B_j$. In order to fit the measurements, the diagonal components $A_{TD} = A_{TD-TD}$ and $A_{RD} = A_{RD-RD}$ of $[A]$ must be considered non-linear and dependent on both components (B_{TD}, B_{RD}) and the frequency f . The vector field dependences of non-diagonal $A_{TRD} = A_{TD-RD}$ can also be identified to find the eigenvectors \mathbf{XH}_d and \mathbf{YH}_d depending on B and angle θ (12). It gives information on the excess energy loss density $e_d(\theta)$ linked to activated magnetic domains phases, the vector microscopic magnetization mechanisms, including the domain walls motion and domains magnetization rotation.

$$[A] = \begin{bmatrix} A_{TD}(B_{TD}, B_{RD}, f) & A_{TRD}(B, \theta, f) \\ A_{TRD}^*(B, \theta, f) & A_{RD}(B_{TD}, B_{RD}, f) \end{bmatrix}_{(TD,RD)} \quad (12a)$$

$$A_{TRD}(B, \theta, f) = A'_{TRD}(B, \theta, f) + jA''_{TRD}(B, \theta, f) \quad (12b)$$

Both the electrical conductivity and the magnetic structure represented by $[A]$ are responsible for microscopic and macroscopic eddy currents and finally for the eddy current losses (classical and excess ones). The complete dynamic losses within time harmonics can be deduced from the magnetic field diffusion principles as explained in the following.

C. Magnetic field diffusion

1) Diffusion-like equation

Combining the Maxwell-Ampere and the Maxwell-Faraday equations and the behavioral model (1) in the (TD, RD) reference frame, one has to solve equation (13) by using the tensor $[\tau] = \sigma[A]^2[\mu_s]$, and by separating the static hysteresis contribution which does not involve any space variations related to the field diffusion effect.

$$-\frac{\partial^2}{\partial z^2}((1 + j\omega[\tau])\mathbf{H}_M) + j\omega\sigma[\mu_s]\mathbf{H}_M = 0 \quad (13a)$$

The solution of (13a) can be written in (13b) such that it provides the average flux density \mathbf{B} as a function of the real $H'_{M,TD/RD}$ and imaginary $H''_{M,TD/RD}$ parts of the components TD/RD of vector \mathbf{H}_M averaged through the sheet cross section:

$$\mathbf{B} = [\mu_s]\langle\mathbf{H}_M\rangle = \mu_0[\mu_{sr}] \begin{pmatrix} H'_{M,TD} + jH''_{M,TD} \\ H'_{M,RD} + jH''_{M,RD} \end{pmatrix} \frac{\sinh(jk\zeta/2)}{jk\zeta/2} \quad (13b)$$

ζ is the sheet thickness and k is the wave vector obeying (13c)

$$\det \begin{bmatrix} k^2(1 + j\omega\tau_{TD}) + j\omega\sigma\mu_{s,TD} & k^2j\omega\tau_{TD-RD} + j\omega\sigma\mu_{s,TRD} \\ k^2j\omega\tau_{RD-TD} + j\omega\sigma\mu_{s,TRD} & k^2(1 + j\omega\tau_{RD}) + j\omega\sigma\mu_{s,RD} \end{bmatrix} = 0 \quad (13c)$$

Then, the vector field $\langle\mathbf{H}_M\rangle$ with complex components in (TD, RD) can be calculated by solving the system given by (13d) with $(\alpha + j\beta) = (\sinh(jk\zeta/2))/(jk\zeta/2)$, first with the flux density component B_{TD} ($B_{RD} = 0$) and then B_{RD} ($B_{TD} = 0$).

$$\begin{pmatrix} H'_{M,TD} \\ H''_{M,TD} \\ H'_{M,RD} \\ H''_{M,RD} \end{pmatrix} = \begin{bmatrix} +\alpha\mu_{s,TD} & -\beta\mu_{s,TD} & +\alpha\mu_{s,TRD} & -\beta\mu_{s,TRD} \\ -\beta\mu_{s,TD} & -\alpha\mu_{s,TD} & -\beta\mu_{s,TRD} & -\alpha\mu_{s,TRD} \\ +\alpha\mu_{s,TRD} & -\beta\mu_{s,TRD} & +\alpha\mu_{s,RD} & -\beta\mu_{s,RD} \\ -\beta\mu_{s,TRD} & -\alpha\mu_{s,TRD} & -\beta\mu_{s,RD} & -\alpha\mu_{s,RD} \end{bmatrix}^{-1} \begin{pmatrix} B_{TD} \\ 0 \\ B_{RD} \\ 0 \end{pmatrix} \quad (13d)$$

The magnetic field applied at the sheet surface in both (TD, RD) and (x, y) frames can then be calculated from (13e) and (13f)

$$\mathbf{H}_{a,(TD,RD)} = (1 + j\omega[\tau]) \begin{pmatrix} H'_{M,TD} + jH''_{M,TD} \\ H'_{M,RD} + jH''_{M,RD} \end{pmatrix} \cosh\left(\frac{jk\zeta}{2}\right) \quad (13e)$$

$$\mathbf{H}_{(x,y)} = [T]^{-1}\mathbf{H}_{(TD,RD)} \quad \text{and} \quad \mathbf{B}_{(x,y)} = [T]^{-1}\mathbf{B}_{(TD,RD)} \quad (13f)$$

2) Apparent magnitude permeability

The apparent magnitude permeability, linked to each loop slope, defined as the ratio between the peak induction and the corresponding magnetic field on the loop, is given by (14a).

3) Iron losses

The dynamic iron losses, closely linked to each hysteresis loop area, is then given by the equation (14b).

$$\mu_{app,x/y}(B, \theta, f) = \frac{|B_{x/y}|}{|H_{x/y}||B_{x/y}|} = \frac{\text{module}\left(\frac{B_x \text{ or } y}{H_x \text{ or } y}\right)}{\left|\cos\left(\text{angle}\left(\frac{B_x \text{ or } y}{H_x \text{ or } y}\right)\right)\right|} \quad (14a)$$

$$p_{dm}(B, f) = p_{fm}(B, f) - p_{hm} \frac{f}{5} = \text{real}\left(\frac{H_a(j\omega B)^*}{2\gamma}\right) \quad (14b)$$

D. Unknowns, working conditions – Identification strategy

The two tensors $[\mu_{sr}]$ and $[\mu_{cr}]$ lead to 6 unknown components (3 each). The tensor $[A]$ contains 4 unknown components. The strategy proposed to identify the 10 unknowns in total.

1) Quasi-static working conditions

The identification procedure starts at low frequency to identify separately the components of static tensors: $[\mu_{sr}]$ and $[\mu_{cr}]$.

a) Rolling and transverse directions

Measurement of the permeability in both RD ($\mu_{app,x \text{ or } y}(B, \theta = 90^\circ \text{ or } 0^\circ, f = 5\text{Hz})$) and TD ($\mu_{app,x \text{ or } y}(B, \theta = 0^\circ \text{ or } 90^\circ, f = 5\text{Hz})$) for samples 0 and 90 (see Fig. 5 and TABLE 1) allows to identify the two diagonal components $\mu_{sr,TD}(B_{TD})$ and $\mu_{sr,RD}(B_{RD})$. Measurement of static hysteresis losses in the same directions ($P_{fh,x \text{ or } y}(B, \theta = 90^\circ \text{ or } 0^\circ)$) in RD and

$p_{hm,x \text{ or } y}(B, \theta = 0^\circ \text{ or } 90^\circ)$ in TD) for the same samples, allows to identify the diagonal components $\mu_{cr,TD}(B_{TD})$ and $\mu_{cr,RD}(B_{RD})$.

b) *Misoriented flux with an angle θ*

For misoriented fluxes forming an angle θ with RD , it can be shown that neither the magnitude permeability nor the static hysteresis losses in y or x directions can be accurately reproduced by using a simple combination of diagonal TD and RD properties and cosines and sines functions of θ . Thus, it is necessary to consider non diagonal properties inside any tensor $[\mu]$ and to use the frame change transfer rules as follows (15):

$$[\mu]_{(x,y)} = [T]_{(TD,RD)-(x,y)}^{-1} [\mu]_{(TD,RD)} [T]_{(TD,RD)-(x,y)} \quad (15)$$

Measurement of the permeability in any direction x or y ($\mu_{app,x \text{ or } y}(B, \theta, 5\text{Hz})$) for samples 15 to 75 (see Fig. 5 and TABLE 1) leads to the non-diagonal component $\mu_{sr,TRD}(B, \theta)$ of $[\mu_{sr}]$ as a function of B and θ . Measurement of static hysteresis losses in the same directions ($p_{hm,x \text{ or } y}(B, \theta, 5\text{Hz})$) for the same samples, allows to identify the non-diagonal component $\mu_{cr,TRD}(B, \theta)$ of $[\mu_{cr}]$ as a function of B and θ .

2) *Dynamic working conditions*

The next identification step include measurements at variable frequencies to identify separately the components of $[A]$.

a) *Rolling and transverse directions*

Simultaneous measurement of the dynamic permeability and losses in both the transverse direction ($\mu_{app,x \text{ or } y}(B, \theta = 0^\circ \text{ or } 90^\circ, f)$ and $p_{dm}(B, \theta = 0^\circ \text{ or } 90^\circ, f)$) and the rolling direction ($\mu_{app,x \text{ or } y}(B, \theta = 90^\circ \text{ or } 0^\circ, f)$ and $p_{dm}(B, \theta = 90^\circ \text{ or } 0^\circ, f)$) for samples numbered 0 and 90 (see Fig. 5 and TABLE 1) allows to identify the two diagonal components $\Lambda_{TD}(B_{TD}, B_{RD} = 0)$ and $\Lambda_{RD}(B_{TD}, B_{RD} = 0)$ of $[\mu_{sr}]$ first; then $\Lambda_{TD}(B_{TD} = 0, B_{RD})$ and $\Lambda_{RD}(B_{TD} = 0, B_{RD})$.

b) *Misoriented flux with an angle θ*

Simultaneous measurement of the angle and frequency dependent permeability and losses in both x and y directions ($\mu_{app,x \text{ and } y}(B, \theta, f)$ and $p_{dm}(B, \theta, f)$) for samples numbered from 15 to 75 (Fig. 5, TABLE 1) gives the real $\Lambda'_{TRD}(B, \theta, f)$ and imaginary $\Lambda''_{TRD}(B, \theta, f)$ parts of non-diagonal component $\Lambda_{TRD}(B, \theta, f)$ of $[A]$ as a function of B , θ and f .

E. *Diagonalization conditions of Tensor properties*

In case of diagonal tensors, the identification should lead to non diagonal components negligible compared to diagonal ones. The results in Fig. 9, Fig. 11, Fig. 17 and Fig. 18 reveal significant couplings between the RD and TD directions that appear for misoriented fluxes. The measurement data shows that the eigenvectors of the reference frame (XH, YH) able to diagonalize the tensor properties must be adapted to the variations of induction B and angle θ . The corresponding equivalent ‘‘hard’’ and ‘‘easy’’ magnetic axis for each property can thus be revealed and valued by determining the eigenvectors and eigenvalues of $[\nu_s]$ and $[\nu_c]$.

III. EXPERIMENTS – PERMEABILITY AND LOSS MEASUREMENTS WITH MISORIENTED FLUX

A. *The experimental set-up*

Magnetic measurements have been carried out with a Single Sheet Tester (SST150) adapted to $150 \times 150 \text{ mm}^2$ specimens. Error is always under 5%: about 5% for $B \approx 0.1 \text{ T}$ and $f \approx 5 \text{ Hz}$, less than 1 % for $B \geq 1 \text{ T}$ and $f \geq 50 \text{ Hz}$. Error bars are not plotted on the upcoming figures for better legibility. Meanwhile, the SST magnetic circuit is closed and any demagnetizing effect due to the cutting angle should have a coefficient for such large samples below 1% of magnetization.

B. *Material and samples*

In order to characterize the 2D behavior with misoriented but 1-directional fields, seven GOES samples have been prepared with specific cutting angles (see Fig. 5 and TABLE 1).

Fig. 5: Definition of cutting angles and flux density directions of specimens.

TABLE 1: LIST AND DESCRIPTION OF SAMPLES WITH CUTTING ANGLES

sample	Angle(y, RD) / Angle(\mathbf{B}, RD)	Direction of flux \mathbf{B} measured and components in (TD, RD) frame
0	$\theta=0^\circ/0^\circ$	y ($B_{RD}=B_y, B_{TD}=B_x=0$)
0	$\theta=0^\circ/90^\circ$	x ($B_{RD}=B_x=0, B_{TD}=B_y$)
15	$\theta=15^\circ/15^\circ$	y ($B_{RD}=B_x \cos 15, B_{TD}=B_x \sin 15$)
15	$\theta=15^\circ/75^\circ$	x ($B_{RD}=B_x \cos 75, B_{TD}=B_x \sin 75$)
30	$\theta=30^\circ/30^\circ$	y ($B_{RD}=B_x \cos 30, B_{TD}=B_x \sin 30$)
30	$\theta=30^\circ/60^\circ$	x ($B_{RD}=B_x \cos 60, B_{TD}=B_x \sin 60$)
45	$\theta=45^\circ/45^\circ$	y ($B_{RD}=B_x \cos 45, B_{TD}=B_x \sin 45$)
45	$\theta=45^\circ/45^\circ$	x ($B_{RD}=B_x \cos 45, B_{TD}=B_x \sin 45$)
60	$\theta=60^\circ/60^\circ$	y ($B_{RD}=B_x \cos 60, B_{TD}=B_x \sin 60$)
60	$\theta=60^\circ/30^\circ$	x ($B_{RD}=B_x \cos 30, B_{TD}=B_x \sin 30$)
75	$\theta=75^\circ/75^\circ$	y ($B_{RD}=B_x \cos 75, B_{TD}=B_x \sin 75$)
75	$\theta=75^\circ/15^\circ$	x ($B_{RD}=B_x \cos 15, B_{TD}=B_x \sin 15$)
90	$\theta=90^\circ/90^\circ$	y ($B_{RD}=B_x \cos 90=0, B_{TD}=B_x \sin 90=B_x$)
90	$\theta=90^\circ/0^\circ$	x ($B_{RD}=B_x \cos 0=B_x, B_{TD}=B_x \sin 0=0$)

C. Quasi-static Measurements ($f = 5\text{Hz}$)

1) The $B(H)$ curves and quasi-static permeability

Fig. 6 shows the results on the apparent static magnetic permeability measured linking the magnitudes of H_y and B_y for the whole samples. As expected for GOES, the permeability for y parallel to RD is much higher than the permeability when y forms an angle θ with RD . Usually, the permeability is reduced when θ increases, however some marginal effects appear for weak and strong angles ($\theta < 15^\circ$ and $\theta > 45^\circ$) (§ IV.A).

1) The quasi-static hysteresis losses and coercive field

Fig. 7 shows the results on the quasi-static hysteresis losses measured for the whole samples. As expected, the losses for y parallel to RD is much lower than the losses when y forms an angle θ with RD . $[\mu_c(B, \theta)]$ variations are discussed in § IV.B.

Fig. 6. $B(H)$ curves measured on the seven samples at low frequency ($f=5\text{Hz}$) and as a function of the magnitude value of flux density B and its angle θ .

Fig. 7. Hysteresis losses $P_{hm}(B, \theta)$ measured on the 7 samples at low frequency ($f=5\text{Hz}$) as a function of the magnitude value of flux density B and its angle θ .

Fig. 8. Total losses $P_{fm}(B, \theta)$ measured on the 7 samples at frequency $f = 50$ Hz as a function of the magnitude value of flux density B and its angle θ .

D. Dynamic measurements (variable frequency, $f = 50$ Hz)

1) The Apparent Permeability $\mu_{app}(B, \theta, f)$

Dynamic $\mu_{app}(B, \theta, f)$ can be deduced from (14a) by using results similar to that of Fig. 6 with damping effects.

2) The dynamic losses $P_f(B, f)$

Fig. 8 shows the results on the total iron losses measured for the whole samples. As expected, the losses for $f \gg 5$ Hz are mainly driven by the dynamic contributions. For y parallel to RD it is still much lower than the losses when y forms an angle θ with RD . $[A(B, \theta, f)]$ variations are discussed in § IV.A.

IV. IDENTIFICATIONS – TENSOR MAGNETIC PROPERTIES

A. Static internal permeability $[\mu_s(B, \theta)]$ - discussions

The identification procedure for each component of $[\mu_s(B, \theta)]$ is summed up with the equations (16) below:

$$\mu_{s,TD}(B_{TD}) = \mu_{app,y}(B, 90^\circ, 5\text{Hz}) \quad (16a)$$

$$\mu_{s,RD}(B_{RD}) = \mu_{app,y}(B, 0^\circ, 5\text{Hz}) \quad (16b)$$

$$\mu_{sr,TRD}(B, \theta) = \frac{\mu_{sr,TD}(B_{TD}) \sin^2 \theta + \mu_{sr,RD}(B_{RD}) \cos^2 \theta}{2 \cos \theta \sin \theta} - \mu_{app,y}(B, \theta, 5\text{Hz}) \quad (16c)$$

Fig. 9 and Fig. 10 show the identifications of $[\mu_{sr}]$. At small angle θ , and for low or intermediate flux densities ($B < 0.8T$), $\mu_{sr,TRD}$ can be negative even if lower than $\mu_{sr,RD}$, with beneficial impact on the $B(H)$ curves corresponding to $\theta < 15^\circ$. The misoriented flux seems to activate a coupling between TD polarizations of domains with moving walls and RD components of main 180° domains. When θ is increased ($\theta \geq 30^\circ$, $B < 0.8T$), $\mu_{sr,TRD}$ becomes positive with a negative impact on the $B(H)$ curves with lower slopes. The higher the flux density ($B > 0.8T$), the stronger the coupling term $\mu_{sr,TRD}$, comparable to $\mu_{sr,RD}$ or $\mu_{sr,TD}$. The maximum of $\mu_{sr,TRD}$ apparently always occur at the magnetization knee. For higher angles ($\theta \geq 30^\circ$, $B > 0.8T$), $\mu_{sr,TRD}$ is decreasing with θ , however, for angles $\theta \geq 45^\circ$, $\mu_{sr,TRD}$ can still have a value bigger than $\mu_{sr,TD}$, such that the $B(H)$ curves show a slope lower than in TD .

Fig. 13 and Fig. 14 show that while B increases, the “hard”/“easy” axis deviate from a direction close to TD/RD respectively ($-15^\circ < \beta < +15^\circ$) towards a direction forming a significant angle with TD/RD respectively ($15^\circ < \beta < 40^\circ$).

B. The coercive permeability $[\mu_c(B, \theta)]$ - discussions

The identification procedure for each component of $[\mu_c(B, \theta)]$ is summed up with the equations (17) below:

$$\mu_{c,TD}(B_{TD}) = \frac{\pi f B_{TD}^2}{\gamma P_{fh}(B, \theta = 90^\circ, f = 5\text{Hz})} \quad (17a)$$

$$\mu_{c,RD}(B_{RD}) = \frac{\pi f B_{RD}^2}{\gamma P_{fh}(B, \theta = 0^\circ, f = 5\text{Hz})} \quad (17b)$$

$$\mu_{c,TRD}(B, \theta) = \frac{\mu_{c,TD}(B_{TD}) \sin^2 \theta + \mu_{c,RD}(B_{RD}) \cos^2 \theta}{2 \cos \theta \sin \theta} - \frac{\pi f B^2}{\gamma P_{fh}(B, \theta, f = 5\text{Hz})} \quad (17c)$$

Fig. 11 and Fig. 12 show the identifications of $[\mu_{cr}]$ similarly to $[\mu_{sr}]$. We notice a significant increase of $\mu_{cr,TRD}$ and hysteresis loss when $15^\circ < \theta < 45^\circ$, which partly corresponds to the low values of $\mu_{cr,TRD}$ at its maximum compared to $\mu_{sr,TRD}$.

Fig. 15 and Fig. 16 show that while B increases, the “hard”/“easy” axis deviate from a direction close to TD/RD respectively ($-10^\circ < \beta < +10^\circ$) towards a direction forming a significant angle with TD/RD respectively ($10^\circ < \beta < 30^\circ$).

A. The dynamic magnetization property $[A(B, \theta)]$

The identification procedure for each component of $[A(B, \theta)]$ is explained in § II.D.2) and with the equations in (13). In Fig. 17, Fig. 18, Fig. 19 and Fig. 20, we notice the Nucleation/activation of specific domains with walls (**DWN**) and magnetization mechanisms at specific B values. Around 0.2 T: walls between new nucleated domains (Lancet and out-of-plane 45° - 90° domains, A_{TD}) and source couplings between TD and RD (loss reduction, $A'_{TRD} < 0$) start appearing with the **DWD** mechanism when magnetizing the sample with a significant TD component ($\theta \geq 45^\circ$). Around 0.6 T: walls between previously nucleated domains start **Fusing** with lower density and mobility (**DWF**). The non-dissipative couplings between TD and RD (absorption of reactive power, A''_{TRD}) and the dissipative couplings ($A'_{TRD} > 0$) start increasing when magnetizing in a direction forming an angle $30^\circ < \theta < 45^\circ$. Around 1 T: No more **DWD** and RD component of domains (A_{RD}) play any role when magnetizing the sample closer to TD ($\theta > 45^\circ$). It is replaced by the **DMR** and A_{TD} . At 1.3 T and above: domains with RD components (A_{RD}) still play a role when magnetizing closer to RD ($\theta < 45^\circ$) but the activated **DMR** mechanism with TD components becomes predominant (A_{TD}).

Fig. 9. Components of $[\mu_{sr}(B, \theta)]$ identified as a function of the magnitude value of flux density B for the whole angles θ ($0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$).

Fig. 10. Non diagonal component $\mu_{sr,TRD}(B, \theta)$ of $[\mu_{sr}]$ identified as a function of angle θ given the magnitude values of induction B (0.2 T, 0.5 T, 1 T, 1.5 T).

Fig. 11. Components of $[\mu_{cr}(B, \theta)]$ identified as a function of the magnitude value of flux density B for the whole angles θ ($0^\circ, 15^\circ, 30^\circ, 45^\circ, 60^\circ, 75^\circ, 90^\circ$).

Fig. 22: Model discrepancies with misoriented flux ($\theta = 45^\circ$) for the estimation of iron losses @ $f = 50$ Hz as a function of B .

V. CONCLUSION AND FORTHCOMING

A mesoscopic tensor $H(B)$ model dedicated to the description of the 2-D vectorial magnetic behavior and losses within quasi-static and magneto-harmonic working conditions is proposed. It is based on microscopic properties of magnetic domains and walls by separating the 2D vector magnetic field in three components. The latter involve tensor properties ($[\nu_s]$, $[\nu_c]$ and $[A]$) derived from physical energies. In the frequency domain, macroscopic eddy currents can be taken into account through the field diffusion-like equations. Analytical solutions of this 1-D problem within the sheet thickness but with in-plane fields in two directions are used to identify the magnetic properties by fitting the permeability or/and the losses measured. Identification are performed by magnetizing a GOES material at various angles θ between the flux and RD . It is shown that significant non linear non diagonal components of each tensor must be considered to include the couplings between TD and RD . The components of $[A]$ explain the role played by the magnetic domains, walls and the two main mechanisms **DWD** and **DMR** during a misoriented magnetization sequence. While B increases, the equivalent “hard”/“easy” axis for $[\nu_s]$ and $[\nu_c]$ deviate from a direction close to TD/RD towards a direction at 50° - 70° from RD/TD which corresponds the 60° found in the literature. The methodology will be useful when investigating recrystallization processes or surface treatments. The same model could be used for NGOES. Experiments show that the role played by non diagonal components is less significant in NGOES than in GOES. The model fits well the iron losses in all directions but requires improvements to estimate better the permeability and predict hysteresis loops in each direction θ .
