17 **Abstract**

18

19 A combined geomorphological and geochronological investigation was carried out aiming at
20 determining the cause of the Darhad paleolake formation and dating the Darhad megaflood. Based
21 on the analysis of satellite image mapping, new data were obtained revealing conditions of glacial
22 dams along the Shishkhid Gol valley. We hypothesize that large glaciers in Khara-Baryangiin Gol
23 and Ikh-James Gol downstream of the Tengis Gol mouth were the main causes of the highest
24 Shishkhid Gol backwater. The estimated height of this glacial dam there was about 300 m. The
25 presence of paleolake shorelines at an altitude of 1713 m in the immediate vicinity of this glacial
26 dam confirms its dominant role for the formation of the Darhad paleolake. Based on cosmogenic
27 ^{10}Be exposure ages obtained on boulders from four fields of gravel dunes and of an erratic boulder
28 exposed within a bar along the Yenisei River valley in the Tuva Basin, we infer that two among
29 the three age peaks observed may correspond to megafloods at 36-38 ka and 18-23 ka.

36 **1. Introduction**

37

38 This study is aimed at identifying the cause-and-effect relationship regarding the Darhad
39 megaflood, its age and role of shaping landforms in southeastern Siberia and northern Mongolia.
40 The study of this phenomenon provides crucial information for understanding the development of
41 topography and deposits in the area impacted by Quaternary glaciation and makes it possible to
42 reconstruct paleolandscapes over a large area of northern Asia.

43 The global cooling in the late Pleistocene created conditions favorable for glaciation and
44 advancement of glaciers over large areas both in polar regions and in mountain belts of the world.
45 Within the ice sheets and in the territories adjacent to them, dammed proglacial lakes of various
46 sizes with volumes up to several thousand cubic kilometers were formed. However, the subsequent
47 climatic warming caused destruction of these glacial dams. The consequent glacial lake outbursts
48 led to catastrophic discharge of water downstream. Discharges in some cases are estimated to be
49 up to millions of m³/s or more (O'Connor and Costa, 2004; Baker et al., 1993; Komatsu et al.,
50 2009), and flood flows could have been up to 400-500 m deep (Rudoy, 2002).

51 In valleys and basins downstream of the proglacial lakes, specific relief forms of erosional and
52 depositional origins were formed due to the floodwater passage (Baker, 1973; Baker et al., 1985,
53 1993; Carling et al., 2002; Komatsu et al., 2009; Margold et al., 2018; Benito and Thorndycraft,
54 2020). Erosive landforms include canyons, whirlpools, waterfalls, hanging valleys and spillways,
55 and depositional landforms include gravel dunes and bars. Identification of these landforms have
56 been used to indicate the past occurrence of megaflooding.

57 Three large paleolakes are known to be responsible for megaflood occurrence in the mountains
58 of southern Siberia (fig. 1). These are Chuya-Kuray in Altay (Rudoy and Baker, 1993; Baker et
59 al., 1993), Darhad in northern Mongolia (Grosswald, 1987; Komatsu et al., 2009), and Vitim in
60 Transbaikalia (Margold et al., 2018). The collapsing of glacial dam is hypothesized to have led to
61 the catastrophic discharge of water from the Darhad paleolake down the Yenisei valley, and this

62 is considered to be one of the largest megaflood events in the southern Siberian mountains
63 (Grosswald, 1987; Komatsu et al., 2009, 2016; Batbaatar and Gillespie, 2016a). It is likely that the
64 megaflood was multiple events and the estimated maximum peak discharge rate is $\sim 3.5 \times 10^6$ m³/s
65 (Komatsu et al., 2009). The landscape formed by the Darhad megaflood is most fully represented
66 along the Yenisei valley in northern Mongolia and the Tuva Republic (southern Siberia) (Komatsu
67 et al., 2009, 2016; Arzhannikova et al., 2014). For instance, erosional and depositional landscapes
68 formed by the megaflood are found extensively within the Kaa Khem Uplands and Tuva (Kyzyl)
69 Basin. The study of megaflood landscape has made it possible to determine the conditions for
70 flood hydraulics.

71 The chronology of the Darhad megaflood has been inferred mostly from the timing of the
72 Darhad paleolake formation (Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009;
73 Batbaatar and Gillespie, 2016a, b). There have been limited attempts to determine the age of the
74 Darhad megaflood from a set of geological data (Arzhannikova et al., 2014). However, detailed
75 study has not been carried out yet to directly date the flood sediment.

76 There remain questions: in particular, 1) the precise timing of the Darhad megaflood, and 2)
77 whether the Tengis Gol glacial dam was able to impound the deep Darhad paleolake. Our research
78 is aimed at determining the timing of the Darhad megaflood and clarifying the conditions for the
79 Darhad paleolake formation. We combine remote sensing mapping of geomorphology, geological
80 studies, and in-situ ¹⁰Be dating of exposed flood transported boulders. The work used topographic
81 data from SRTM and TanDEM-X, geological survey maps of the USSR at a scale of 1:200,000,
82 topographic maps at a scale of 1:100,000, and high-resolution satellite images available from
83 Google Earth.

84

85 **2. Study area**

86

87 **2.1 A brief history of paleolakes studies in Darhad Basin**

89 The presence of ancient lacustrine sediments and coastlines in northern and northwestern
90 Mongolia testifies for the widespread occurrence of paleolakes during the Quaternary (Selivanov,
91 1967; Spirkin, 1970; Grunert et al., 2000; Komatsu and Olsen, 2002; Arzhannikov and
92 Arzhannikova, 2011; Stolz et al., 2012).

93 The largest was the proglacial Darhad paleolake in northern Mongolia (fig. 1). The lake was
94 named after the depression in which it resided. This ice- or possibly sedimentary-dammed lake
95 repeatedly formed in the Darhad Basin during the Pliocene and Pleistocene (Selivanov, 1967;
96 Selivanov, 1968; Spirkin, 1970; Uflyand et al., 1971; Grosswald and Rudoy, 1996; Krivonogov et
97 al., 2005; Gillespie et al., 2008; Komatsu et al., 2009). The morphology of the basin, surrounded
98 by mountains peaking above 3000 m and the only runoff through the Shishkhid Gol, are the most
99 favorable conditions for the formation of a lake basin.

100 According to Selivanov (1967), there were three stages in the formation of the paleolake. Two
101 of them were associated with volcanic lavas and the last one with the Tengis glacier dam. The
102 possible age of the existence of lakes is indicated only for the latter as the Lower-Middle
103 Quaternary. Instead, Spirkin (1970) hypothesized that there had been three stages in the
104 development of the paleolake: 1) Pliocene-Early Quaternary; 2) Late Quaternary - interglacial; 3)
105 Late Quaternary - glacial (fig. 2).

106 According to some ideas (Spirkin, 1970; Uflyand et al., 1969), Darhad Basin was formed in the
107 pre-Pliocene times (all dates are based on palynological analyses) or at the end of the Miocene and
108 the beginning of the Pliocene, when the deformation front from the Indo-Asian collision reached
109 this region (Jolivet et al., 2007). As a result of the mountain uplift to the west of the Darhad Basin,
110 Shishkhid Gol was dammed, and a small lake was formed. Then, the river cut within the uplifted
111 block, and the lake level lowered and the main elements of the valley were formed. Spirkin (1970)
112 noted that during the interglacial period of the late Pleistocene (MIS3) the Shishkhid Gol valley
113 had been dammed by volcanic lavas, leading to the formation of a small lake. However, $^{39}\text{Ar}/^{40}\text{Ar}$

114 dating of valley lavas showed an age of 6–4 Ma (Perepelov et al., 2017), which excludes the
115 Quaternary age of the paleolake by the lava damming. It has been hypothesized that the lake
116 reached its maximum level during the last phase of the Late Pleistocene glaciation (MIS2) due to
117 damming of Shishkhid Gol by a Tengis glacier. The thickness of the terminal moraine reached 200
118 meters and the coastline of the paleolake was at 1700-1720 m asl (Spirkin, 1970). Further detailed
119 studies of glaciation in the eastern Sayan and northern Mongolia significantly improved the
120 chronology of glacier advances during the Late Pleistocene (Gillespie et al., 2008; Arzhannikov et
121 al., 2012), and this led to a new discussion about the age of the glacial Darhad lake (Krivonogov
122 et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009; Batbaatar and Gillespie, 2016a, b).

123

124 **2.2 Glacial-dammed Darhad paleolake**

125

126 Researchers of Darhad Basin's Quaternary history have noted the widespread and well-
127 preserved lake shorelines (Selivanov, 1967; Ufland et al., 1969; Ufland et al., 1971; Spirkin, 1970;
128 Grosswald, 1987; Grosswald and Rudoy, 1996; Komatsu and Olsen, 2002; Krivonogov et al.,
129 2005; Gillespie et al., 2008; Komatsu et al., 2009, 2016). On the slopes of the ridges in the basin,
130 they are clearly traced up to a height of 1713 m asl (Krivonogov et al., 2005). Remote sensing data
131 show that this level (1713 m asl) dominates throughout the Darhad Basin. The tops of the ridges
132 and small extended ridges located within the basin have a system of encircling shorelines, which
133 indicates the presence of islands during the existence of the Darhad paleolake (fig. 3).

134 Lake terraces are located on the slopes of the basin, river valleys, and on the escarpment of the
135 Jarai terminal moraine. In total, there are 47 shorelines located on the right bank of the Shishkhid
136 Gol (Tengis Gol mouth) (Krivonogov et al., 2005). According to observational data (Krivonogov
137 et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009), the lake shorelines are limited by the
138 Tengis moraine (Tengis Gol mouth). Regarding the timing of the Darhad paleolake, there is no
139 clear consensus on this matter. Gillespie et al. (2008) believe that the glacier advances from the

140 mountains around the Darhad Basin occurred at 17-19 ka, 35-53 ka, and at least one more time
141 earlier. Krivonogov et al. (2005) consider that a large lake was formed 110-116 ka and probably
142 existed until 15 ka, changing in size with time.

143 Geological and geomorphological analyses, mapping and dating of Quaternary deposits showed
144 that the possible reason for the formation of the Late Pleistocene Darhad lake could have been
145 glaciers emerging from lateral tributaries of Shishkhid Gol (fig. 4), blocking the river flow down
146 the valley (Grosswald and Rudoy, 1996; Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu
147 et al., 2009, 2016). Krivonogov et al. (2005) considered one glacial dam in the area of the Tengis
148 Gol mouth. According to Gillespie et al. (2008), there were probably two glacial dams at the outlets
149 of Tengis Gol and Gadar-Usiyin Gol. Komatsu et al. (2009) and Batbaatar and Gillespie (2016a)
150 hypothesized three glacial dams. The most downstream of them was located at the mouth of the
151 Barangiin Gol. Highlighting different numbers of glacial dams, the researchers nevertheless agreed
152 that the main reason has been the glacier advancing from the Tengis Gol valley. The glaciers
153 downstream of Shishkhid Gol were thinner and could not account for the deep Darhad paleolake
154 (fig. 4) (Grosswald and Rudoy, 1996; Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu et
155 al., 2016).

156

157 **2.3 The Darhad megaflood**

158

159 While studying the glacial landscape of the Sayan-Tuva uplands (southern Siberia), scientists
160 discovered landforms resembling gravel dunes. Borisov and Minina (1982) characterized them as
161 ribbed and cellular ground moraines, an element of the Middle Pleistocene glaciation. However,
162 the advent of publications about gravel dunes found in Altai (Baryshnikov, 1979; Butvilovsky,
163 1982; 1985; Rudoy, 1984) and claiming them as the important elements of major hydrological
164 catastrophes (megafloods) initiated a search for similar landforms in other regions of mountains
165 in southern Siberia. The first geologist who recognized the complex of erosional-depositional

166 forms in the Yenisei valley as the result of high water discharge from the Darhad paleolake was
167 M.G. Grosswald. By comparing the data on the Darhad paleolake with a giant canyon (coulee)
168 carved in volcanic lavas and a system of gravel dune fields in the Tuva Basin formed in the glacial
169 time, Grosswald (1987) concluded that megaflooding had occurred in the past. Since then, the
170 Darhad phenomenon has attracted attention of the world scientific community. Various studies
171 were conducted, and field conferences were held. Some articles have been published on the
172 morphology, water flow dynamics and velocity, flow modeling, paleogeographic reconstruction,
173 etc. (Grosswald, 1987; Grosswald, 1996; Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu
174 et al., 2009, 2016; Arzhannikova et al., 2014; Batbaatar and Gillespie, 2016a, b).

175

176 **3. Methods**

177

178 **3.1 Mapping**

179

180 The production of geomorphological maps and schemes for the study area was based on relief
181 hillshading and visual interpretation of remote sensing data (SRTM V4 (spatial resolution 90 m),
182 ALOS (spatial resolution 30 m), TanDEM-X DEM (spatial resolution 12 m); topographic maps,
183 geological maps, satellite and aerial photographs of various scales) and published data
184 (Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009, 2016; Batbaatar and
185 Gillespie, 2016a, b). Satellite image analysis, identification of landforms and mapping were carried
186 out in programs Google Earth and QGIS. The analysis was carried out on the territory of the
187 Yenisei valley and the adjacent areas spanning over the Darhad Basin to the Sayano-Shushenskoye
188 reservoir. Attention was paid to the study of the lake terrace complex and glacial landforms located
189 in the Darhad Basin and in the Shishkhid Gol valley. In order to obtain information about the
190 Darhad megaflood, Yenisei terrace complexes and gravel dune fields in the Tuva Basin were
191 analyzed in detail.

192 The process of mapping proceeded as follows. The primary analysis was conducted based on
193 SRTM (spatial resolution 90 m) data. Then, ALOS data (spatial resolution 30 m) and TanDEM-X
194 DEM data (spatial resolution 12 m) were also used. Using Google Earth and QGIS we
195 superimposed satellite images of various scales (Google Earth and QGIS) on topographic data to
196 obtain high-quality three-dimensional imagery. This way, we were able to perform a detailed
197 analysis of erosional and depositional features caused by the megaflood. Landforms associated
198 with other lithological factors (i.e., not by the megaflood) were excluded using geological maps.
199 Geological data also provided information on the extent of Quaternary deposits, which was
200 important in interpreting the distribution of Darhad megaflood sediments. Topographic maps were
201 the source of information regarding names of main topography in the study area, as well as the
202 basis for the correcting absolute heights (m asl) for radar-derived topographic survey data (SRTM,
203 ALOS, TanDEM-X DEM). Due to the fact that all radar data have errors in altitude, we checked
204 the control points (trigopoints) on topographic maps, and if there were errors, we made a
205 correction.

206

207 **3.2 ^{10}Be exposure dating**

208

209 We used beryllium (^{10}Be) in-situ dating (Wagner, 1998; Gosse and Phillips, 2001) to determine
210 the age of exposed gravel dune boulder surfaces. The accumulation of ^{10}Be atoms occurs under
211 the action of cosmic rays on the surface of rocks. It accumulates in silicate minerals, especially
212 quartz, and is therefore suitable for dating exposed surfaces. Since the in-situ production in quartz
213 (bedrock: granite, quartzite, quartz vein) is low (~ 4 at/gSiO₂/y) (Borchers et al. 2016), 10–30 g of
214 quartz is required for analysis (Wagner, 1998). The half-life of (^{10}Be) is 1.387 Ma (Chmeleff et
215 al., 2010; Korchinek et al., 2010), which makes it possible to date surface rocks over a wide time
216 range.

217 One of the main conditions for obtaining high-quality data is the immobility of the dated
218 boulder from the moment of its exposure. The boulder exposure should coincide with the end time
219 of the megaflood, and its location (orientation in space) should be maintained until the moment of
220 sampling. However, from the moment of exposure, exogenous processes begin to work, affecting
221 its safety and stability on the surface of gravel dunes. These include river erosion (bottom and
222 side), thermokarst, solifluction, denudation, wind action and desquamation. Bottom and side
223 erosion of streams significantly deforms the surface of gravel dunes. However, water erosion is
224 localized in a narrow area, forming a valley that is excluded from the sampling sites. The
225 development of thermokarst leads to surface deformation and the appearance of small depressions.
226 Near-horizontal surfaces of a large area indicate the absence of any active thermokarst processes
227 within them for a long time and the boulders in the area can be used for sampling.

228 Another factor that can affect the accuracy of determining the exposure of a sample is its
229 shielding of the surrounding topography. The degree of topographic shading can be determined by
230 simple circular measurement of the angles and strike of shadow sectors from mountain peaks or
231 extended ridges, which is taken into account later in dating (Gosse and Phillips, 2001).

232

233 **3.2.1 Sampling**

234

235 Four fields of gravel dunes were chosen for sampling, located over a distance of 150 kilometers
236 along the Yenisei valley (fig. 13 c, d). A peculiar attention was paid to the sample position at a
237 maximum distance from nearby slope to exclude solifluction flow and at where no thermokarst is
238 observed. The geographic position and altitude of each sample were obtained using a portable GPS
239 (horizontal uncertainty $\pm 5\text{m}$). The topographic shielding was also measured for each sample.

240 *Gravel dune field I* (51°33.883N; 93°59.016E) (fig. 5 a) is located on the right bank of the
241 Yenisei River and its dimension is 8 x 2 km. Gravel dunes occur at several terrace levels with a
242 total area of 11.5 km². The maximum level above the Yenisei River is 30-40 m, the minimum level

243 is 14-16 m. The continuous transition of gravel dunes from higher to lower levels indicates their
244 simultaneous formation. The presence of a depression in the rear part of the dunes in the area of
245 contact with the slope and its absence at the head of the dunes indicates possible existence in the
246 past of a terrace level 10–12 m high, buried during the Darhad megaflood. This fact implies a thick
247 deposit (~20 m) formed by the Darhad megaflood in this part of the Yenisei valley. The swell-like
248 structure of the dunes is distinguished in the longitudinal and transverse profiles. Ridges 1-2 m
249 high prevail on the surface of the gravel dunes and their heights increase towards the central part
250 up to 6-8 m. 5 samples (Tuva-16-1, 2, 3, 4, 5) were taken from the surface of boulders located in
251 the dunes.

252 *Gravel dune field II* (51°43.101N; 94°33.670E) (fig. 5 b) is located on the right bank of the
253 Yenisei River. There are two levels of gravel dunes at 35 and 70 m. The total area is 12 km². The
254 height of the gravel dune ridges is on average 2-4 m, or rarely reaching 4-6 m. On the surface,
255 many boulders up to 1 m in size, and in some places 2-4 m, are found everywhere. In the eastern
256 part of Gravel dune field II, 5 samples were taken from the surface of boulders (Tuva-16-6, 7, 8,
257 9, 10).

258 *Gravel dune field III* (51°40.020N; 94°53.032E) (fig. 5 c). This is one of the largest gravel dune
259 fields in the Yenisei valley. It is located on the right bank of the river. Its area is more than 20 km².
260 The gravel dunes are positioned at three levels at 14, 30-40 and 70 m relative to the Yenisei River.
261 5 samples (Tuva-16-12, 13, 14, 15, 16) were taken from the surface of boulders on a gravel dune
262 located on the 30 m terrace.

263 *Gravel dune field IV* (51°40.020N; 94°53.032E) (fig. 5 c). The sampling field is the surface of
264 a gravel dune located 14 m above the current water level in the Yenisei River. The height of the
265 ridges is 0.5-0.7 m. 5 samples were taken from this level (Tuva-16-17, 18, 19, 20, 21).

266 An additional sample was obtained from, the bar area (51°18.397N; 95°44.375E) (fig. 5 d), on the
267 right bank of the Yenisei River, in the western part of the Kaa Khem Uplands. This sample (Tuva-
268 16-11) was taken from a boulder measuring 8 x 4 m and 2-2.5 m high. The mass of the boulder is

269 estimated to be about 172 tons. The sampling point is located on the 25 m terrace. The dimensions
270 of the granite boulder testify for the significant power of the water flow, as the nearest bedrock of
271 granites is located 15 km upstream.

272 Overall, we collected 21 samples from the surface of gravel dunes with heights of 12-14 m, 30
273 m, 40-50 m and from the surface of a 25 m terrace within the bar.

274

275 **3.2.2 Samples preparation and measurements; Exposure ages calculation**

276

277 Samples preparation was done at LN2C, the French National Laboratory for Cosmogenic
278 Nuclides located at CEREGE (Aix en Provence).

279 Samples were crushed and sieved (0.25 to 1 mm fraction) then purified with a mixture of
280 hydrochloric and fluorosilicic acids (2/3 – 1/3 ratio) until pure quartz was obtained. Three leaching
281 steps in diluted HF were then performed to eliminate the adsorbed atmospheric ^{10}Be , resulting in
282 the loss of ~30% of the initial material.

283 A weighed amount (~0.1 g) of ^9Be solution (3025 ± 9 ppm) was added to the decontaminated
284 quartz. Beryllium was subsequently separated from the solution by successive anionic and cationic
285 resin extractions and precipitations. The final precipitates were dried and heated to 800°C to obtain
286 BeO which was finally mixed with niobium powder prior to analysis by Accelerator Mass
287 Spectrometry at ASTER (Cerege, Aix en Provence). The beryllium data were calibrated directly
288 against STD11 standard (Braucher et al., 2015) with a $^{10}\text{Be}/^9\text{Be}$ ratio of 1.191×10^{-11} ($\pm 1.09\%$).
289 Uncertainties on measurements include the counting statistics, the standard variability during the
290 run, the uncertainty on STD11 standard (1.09%) and an external machine uncertainty of 0.5%
291 (Arnold et al., 2010). $^{10}\text{Be}/^9\text{Be}$ samples ratios are 8 to 82 times higher than the chemical blank
292 ratio (5.8×10^{-15}).

293 To calculate the exposure ages, a sea level high latitude production rate of 4.02 at/g/a was used
 294 and scaled to the latitude and altitude of the studied area using the Stone (2000) polynomial law.
 295 The muons scheme follows Braucher et al. (2011).

296 The general equation used to model ^{10}Be concentrations considering the three types of
 297 particles involved is given by eq. (1):

298

$$\begin{aligned}
 300 \quad N(x, \varepsilon, t) = & \frac{P_n \cdot e^{-\frac{\rho x}{\Lambda_n}} \left(1 - e^{-t \left(\frac{\rho \varepsilon}{\Lambda_n} + \lambda \right)} \right)}{\frac{\rho \varepsilon}{\Lambda_n} + \lambda} + \frac{P_{\text{slow}} \cdot e^{-\frac{\rho x}{\Lambda_{\text{slow}}}} \left(1 - e^{-t \left(\frac{\rho \varepsilon}{\Lambda_{\text{slow}}} + \lambda \right)} \right)}{\frac{\rho \varepsilon}{\Lambda_{\text{slow}}} + \lambda} + \frac{P_{\text{fast}} \cdot e^{-\frac{\rho x}{\Lambda_{\text{fast}}}} \left(1 - e^{-t \left(\frac{\rho \varepsilon}{\Lambda_{\text{fast}}} + \lambda \right)} \right)}{\frac{\rho \varepsilon}{\Lambda_{\text{fast}}} + \lambda} \\
 299 \quad & + N(0, \varepsilon_2) \cdot e^{-\lambda t} \text{ (eq.1)}
 \end{aligned}$$

301

302 where P_n , P_{stop} and P_{fast} are the production of neutrons, stopping and fast muons respectively, ρ
 303 is the material density, $\square \square$ is the denudation rate (set to zero in this study), t is time, Λ_{neut} , Λ_{stop}
 304 and Λ_{fast} are the attenuation lengths of neutrons (150 g/cm^2), stopping (1500 g/cm^2) and fast
 305 muons (4320 g/cm^2), respectively. The term $N(0, \varepsilon_2)$ is a potential inheritance coming from a
 306 previous exposure. λ is the radioactive decay constant ($\lambda = \ln 2 / \text{half-life}$).

307

308 4. Results

309

310 4.1 The water level of the Darhad paleolake according to the interpretation of satellite images 311 and radar-derived topographic data

312

313 The analysis of shorelines of the Darhad paleolake based on satellite images and SRTM data
 314 shows that the highest coastline of the paleolake corresponds to an altitude of 1713 m asl. The
 315 most interesting result of remote sensing in the area of the Shishkhid Gol valley is the presence of
 316 shorelines of a paleolake observed downstream of the Tengis Gol mouth. These shorelines are well
 317 identifiable on the slopes of the valley up to a height of 1713 m asl. For example, on the right bank

318 side of the Shishkhid Gol valley, 12 km downstream the Tengis Gol mouth, lake terraces are
319 clearly visible, tracing slopes of the main valley and partially visible on slopes of lateral tributaries
320 (figs. 5, 6). Several shoreline features are clearly visible starting from the Tengis mouth down the
321 Shishkhid Gol valley (figs. 6 a, b, c, d, 7). Each extended shoreline visible on the satellite image
322 corresponds to an isoline, with its characteristic height, determined from the SRTM and ALOS
323 data and refined from the topographic maps of the USSR.

324 Shoreline group I (fig. 6 a) is located 2.2 km downstream of the Tengis mouth. The slope of the
325 valley is terraced along a distance of 1.2 km between 1680 and 1713 m asl. Shoreline group II (fig.
326 6 b) is located in the valley of the right lateral tributary of Shishkhid Gol. On one of the capes
327 formed by the main valley and tributary, a series of shorelines 1.4 km long is visible, and they are
328 positioned from 1640 to 1713 m asl. Shoreline group III (fig. 6 c) is located 7 km downstream
329 from the Tengis Gol mouth. On the slope of the western exposure, the terrace levels of the
330 paleolake, 0.7 km long, are clearly visible at two levels. They are concentrated between 1550 and
331 1713 m asl. Shoreline group IV (fig. 6 d) is located 12 km downstream from the Tengis Gol mouth.
332 On the slope of the right tributary in its mouth part, a series of parallel coastlines 1 km long is
333 clearly visible. They are positioned between 1520 and 1713 m asl. An abraded slope 1.2 km long
334 downstream from the mouth of this tributary is also clearly visible (fig. 6 d).

335 The shorelines were formed also on a slope in the Sarig Gol valley (the left tributary of
336 Shishkhid Gol). Furthermore, there is a fragment of the Tengis terminal moraine (fig. 8 f). This
337 indicates that the height of the Tengis glacier, which dammed the Shishkhid Gol valley, did not
338 block it up to the height of 1713 m asl. This should have allowed the formation of a paleolake bay
339 in this valley, which is marked by Krivonogov et al., 2005. In Darhad Basin, in the border parts
340 and in the inner area, there are small ridges and hills. During the existence of the paleolake, they
341 were peninsulas and islands. Coastal ridges and terraces formed on their slopes when the water
342 level changed.

343 Analysis of satellite images and DEM data showed that the highest paleoshoreline was not
344 constant in elevation and varied from 1713 m asl down to 1686 m asl (figs. 7, 8). For example, the
345 upper lake line is traced at an altitude of about 1705-1703 m asl on the southern slopes of a small
346 ridge located north of Dood-Nur and Targan-Nur lakes (fig. 8 g, h, j, k). If we move to the
347 southwest, we see that the height of the upper coastline changes to 1696 m asl, and further south
348 it changes to 1686 m asl (fig. 8 l, m). Thus, the change of the upper paleolake shoreline elevation
349 possibly indicates significant tectonic deformations within the Darhad Basin that have occurred
350 since its drainage.

351

352 **4.2 Tectonic and gravitational deformations**

353

354 The Darhad Basin is part of the southwestern segment of the Baikal rift zone and is
355 characterized by its latitudinal extension. The Darhad Basin is controlled by normal faults
356 extending from the east and west. The thickness of the sedimentary cover is 300-400 m (Logachev,
357 1993). The analysis of satellite images and DEM data made it possible to detect seismogenic
358 ruptures and gravitational displacements within the Darhad lake basin (fig. 9). The activation of
359 faults apparently occurred both during the existence of the lake and after its drainage. In the
360 northern part of Darhad Basin, a fault of meridional strike was found with a displacement
361 amplitude from 25 m in the south to 60 m in the north. The displacement along the fault led to
362 partial subsidence and burial of the Khogorgyn Gol valley (fig. 9 a). A latitudinal normal fault
363 with a displacement amplitude of about 50 m is located to the north of Lake Dood Tsagan Nur. It
364 extends from the Khogorgyn Gol valley, crossing the southern part of the meridional fault and
365 ends in the region of Lake Targan-Nur (fig. 9). Another complex of deformations is located to the
366 east and is represented by a NE-trending scarp on the southern slope of a small ridge (fig. 9 b).

367 The revealed seismogenic faults in the eastern part of the Darhad Basin (fig. 7), in the area of
368 the Jarai terminal moraine (Logachev, 1993), indicate ongoing active tectonic movements in this

369 area. Seismogenic ruptures with a maximum amplitude of 8 m displaced proluvial, colluvial, and
370 glacial deposits. The length of the fault visible on the surface is 13 km. Along with the faults
371 displacing bedrock and sedimentary deposits, landslides are widespread, which are located at the
372 foot of small ridges within the Darhad Basin.

373

374 **4.3 Reconstruction of glacial dam No. 1 at the Tengis Gol outlet**

375

376 The main landforms that help in reconstructing dimensions of a glacier are terminal and lateral
377 moraines, spillways and meltwater channels. The absolute height of the left (1715-1737 m asl) and
378 right (1720-1745 m asl) lateral moraines located at the Tengis Gol mouth and the height of the
379 spillway thalweg (1700-1740 m asl) suggest the possibility of dam formation in the Shishkhid Gol
380 valley by the Tengis glacier (Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009,
381 2016; Batbaatar and Gillespie, 2016 a, b;). This is confirmed by the fact that some part of the
382 terminal moraine is located on the opposite side of Shishkhid Gol at the mouths of its left
383 tributaries. Here, the absolute height of the terminal moraine is 1640 m asl. We can assume that
384 there were two levels of standing of the Tengis glacier in MIS2, based on the presence of spillways
385 with different absolute heights in the mouth part of Tengis Gol and also ¹⁰Be ages (Gillespie et al.,
386 2008; Batbaatar and Gillespie, 2016b).

387 The Level I standing of the Tengis glacier is determined by upper spillways (1700-1740 m asl),
388 fragments of the terminal moraine (1640 m asl), abraded slopes and meltwater channels on the
389 right and left banks of Shishkhid Gol (fig. 10 a, b, c, d). The Level II standing can be reconstructed
390 from a lower spillway (1657 m asl) and lake terraces located on the slopes at the Tengis Gol mouth
391 (fig. 11). Level I in front of the Tengis Gol mouth had a height of 1750 m asl. However, as the
392 Tengis glacier entered the Shishkhid-Gol valley, its level dropped to 1650 m asl. This is the height
393 of the terminal moraine and the height of the upper part of the abraded slope on the left bank of
394 Shishkhid Gol (fig. 10, profiles AB, CD). The exposure age of the terminal moraine in the Sarig

395 Gol valley (Batbaatar and Gillespie, 2016b) characterizes the glacier advance in the LGM (MIS2).
396 The reconstruction of the Tengis glacier on profile CD (fig. 10) shows that Level I on the left bank
397 of Shishkhid Gol was significantly lower than the maximum (1713 m asl) transgression of Darhad
398 paleolake.

399 Paleolake terraces are widespread on the right slope of the Shishkhid Gol valley at the mouth
400 of the Tengis Gol. They abrade the surface of glacial deposits of Level I. The terraces are not
401 covered by moraine deposits (fig. 11). Their location and height suggest a significant decline in
402 the glacial level (meltwater channel 1657 m asl, fig. 11). The exposure age (^{10}Be , 20.7 ± 1.1 ,
403 18.2 ± 1.0 ka) of the melt water channel (Gillespie et al., 2008) agrees with MIS2 after LGM (fig.
404 11). The AB and CD profiles (fig. 11) show a significant reduction in the Level II ice within the
405 Tengis dam.

406

407 **4.4 Glacial features and parameters of glacial dam No. 4 at the Khara-Baryangiin Gol and** 408 **Ikh-Jams Gol mouths (right and left tributaries of Shishkhid Gol)**

409

410 Khara-Baryangiin Gol is the right tributary of Shishkhid Gol (fig. 4). The valley is located
411 within a mountain range with elevations over 3000 m asl. Glacial cirques and troughs are
412 widespread in the upper reaches of this river basin. There are different levels of lateral moraines
413 on the slopes of the valleys. In the mouth part of the river there is a large terminal moraine, and
414 there are lateral moraines in the valley. They are clearly visible both on satellite images and on the
415 ALOS DEM. The absolute height of the left lateral moraine in the Khara-Baryangiin Gol valley
416 (at the mouth) is 1890 m asl (figs. 4, 12 a).

417 Ikh-James Gol is the left tributary of Shishkhid Gol. The ice-catchment is located within a
418 mountain range with elevations of 2700-3000 m asl. On the slopes of the river valley, fragments
419 of lateral moraines have been preserved, giving information about the thickness (300-500 m) of

420 the glacier. The elevations of the glacier at the mouth on the left and right slopes are 1770 m asl
421 and 1745 m asl, respectively (fig. 12 b).

422 The mouths of these tributaries (Khara-Baryangiin Gol and Ikh-James Gol) are located opposite
423 to each other. The glaciers joined in the Shishkhid Gol valley and formed a large glacial dam with
424 the level corresponding to 1715-1720 m asl (fig. 12 c). The altitude of the glacial dam is determined
425 from the elevation of the melt water channel (fig. 12 d) on the left side of Shishkhid Gol. Additional
426 evidence for the presence of a glacial dam is a series of erosional grooves on the slope, which
427 record a decrease in the elevation of the glacier in this part of the Shishkhid Gol valley.

428

429 **4.5 The main erosional and depositional landforms of the Yenisei valley**

430

431 The Yenisei valley in the Tuva Basin (fig. 1 b) presents the existence of two main erosional-
432 depositional landforms formed during and after the Darhad megaflood (fig. 13). The main
433 landscape elements formed after the Darhad megaflood include low and high floodplains (fig. 13
434 c, d), which have special features distinguishing them from other erosion-depositional forms. The
435 combination of bottom and lateral erosion led to the formation of clearly defined escarpments of
436 terraces, meanders and oxbow lakes. The seasonal rise of water in the river resulting from rains
437 and melting of snow lead to changes in channel configuration, death of old and birth of new
438 meandering channels and islands.

439 The second complex of erosional-depositional landforms is positioned 12 m above the low
440 relief (fig. 13 c, d). The distinguishing characteristics are the absence of meanders and the presence
441 of linear structures on the surfaces of high terraces, which indicates the formation of this relief
442 with certain dynamic conditions. These linear structures are a system of gravel dunes (or giant
443 current ripples, terminology in old literature) (fig. 13) as described in Komatsu et al. (2009), who
444 also documented their morphology, topographic setting and correlations with megaflood
445 hydraulics.

446 The nature of the Yenisei valley within the Tuva Basin predetermined the wide distribution and
447 preservation of terraces of various levels. Some of them were formed by the Yenisei cutting into
448 deposits of the Darhad megaflood; in other cases, megaflood deposits cover or lie on the surface
449 of ancient terraces. The width and length scales of the terrace surfaces are kilometers and even a
450 few tens of kilometers. In the Yenisei valley, there are a low floodplain (2–4 m), a high floodplain
451 (6–8 m) and terrace levels of 12–14, 18–20, 30, 40–50, and 100 meters (fig. 13). On all levels of
452 the terraces, except for the low and high floodplains and the 100 m level, gravel dune fields are
453 observed. There is even a level of gravel dunes located at an altitude of 70 m above the level of
454 the Yenisei River.

455

456 **4.6 Water level and depth of the Darhad megaflood in Tuva Basin**

457

458 Based on the analysis of satellite images and DEM data, we discovered and subsequently
459 examined in the field a series of terraces formed in the process of lateral erosion during a decrease
460 in the water level of the paleoflow along the Yenisei valley (fig. 14 c). These terraces are horizontal
461 levels, more than 5 km long, and formed into colluvial-diluvial deposits overlying Jurassic
462 sedimentary rocks and Paleozoic granodiorites (fig. 14 a, b). It should be noted that we are talking
463 about high-level terraces (about 100 m, relative to the current water level in the Yenisei River).

464 In total there are 7 levels of different preservation. The highest of them were recorded at a
465 height of 725 m asl. In (fig. 14 a, b), and elements of terraces with well-defined horizontal surfaces
466 and escarpments are clearly visible both from the Yenisei side and in temporary streams. Such relief
467 elements can often be seen on the slopes of artificial reservoirs with seasonal fluctuations in water
468 levels. The terraced surface contains poorly rounded fragments of various metamorphosed and
469 igneous rocks. Outcrops of Jurassic rocks are located in the lower part of the ledge of a 50-meter
470 terrace. Analysis of geomorphological profiles (fig. 14 c, d) drawn along lines AB and CD
471 covering the complex of terraces and different levels of gravel dunes showed that the depth of the

472 Darhad megaflood stream above the present level of the Yenisei River was 90-100 m and above
473 the lowest level of gravel dunes at 60-65 m.

474

475 **4.7 Morphological analysis of gravel dunes**

476

477 A large volume of water and various topographic conditions of the Yenisei valley (from wide
478 depressions to narrow canyons) along the path of the glacial superflood created a complex of
479 erosion-depositional landforms. First of all, it is necessary to note that fields of gravel dunes are
480 widespread in the Tuva Basin. Gravel dunes are a system of extended ridges and depressions
481 oriented perpendicularly or at an angle to the general direction of the water flow (fig. 15 a, c).
482 Gravel dunes are composed of sand, gravel, pebbles and boulders (fig. 15 b). And the composition
483 varies within a single gravel dune field, which is influenced under conditions of different water
484 flow rates.

485 On the surface of the gravel dunes many boulders up to a few meters in diameter can be
486 encountered. Sometimes there are stone "monsters" up to 8-10 m in size. The basalt fragments
487 found in gravel dune surfaces showed that the movement of boulders 0.5-1 m in size (fig. 16 f)
488 could have occurred over a distance of over 100 km. The height of the gravel dunes varies from 1-
489 2 m to 6-7 m. Their length can reach several hundred meters. These gravel dunes are essentially
490 bedforms of diluvial flows. The main area of gravel dune formation is concentrated in Tuva Basin
491 along the Yenisei valley from the Kaa Khem Uplands to the river's entrance to the canyon of the
492 Western Sayan Ridge (fig. 13 c, d). The total length of the river stretch with observed gravel dune
493 fields reaches for more than 200 km, and their number approaches two dozen.

494 The periodicity of the Darhad paleolake formation (Gillespie et al., 2008; Komatsu et al., 2009)
495 suggests that there could have been several catastrophic discharges of water from this lake. The
496 surviving gravel dune fields are in many cases located in the stream shadow zone created by the
497 bend of the river and the protruding cape of bedrock as observed by Komatsu et al. (2009). In some

498 cases, in the zone where gravel dune deposits adjoin bedrock slopes, there are depressions in the
499 relief, representing a through or blind valley, on the surface of which gravel dunes are also located.
500 The granulometric composition of the gravel dunes ranges from pebbles mixed with boulders to
501 gravel and well washed horizontally-lying sand. Coarser sediment is often found in areas of shade
502 along river bends. Downstream of the river, the dimension of alluvium decreases to gravel and
503 sand fractions.

504 The deposits formed by the Darhad megaflood are concentrated within the Tuva and Minusa
505 Basins, and partly in the river valleys located in the Western Sayan Ridge and Kaa Khem Uplands
506 (Komatsu et al., 2009, 2016; Arzhannikova et al., 2014). The deposits are represented by clastic
507 material of various sizes: sand, gravel, pebble, boulder and hummock (fig. 16 a-g). Sandy sediment
508 occurs as large in-situ units (fig. 16 a, b) and as heavily wind-blown (fig. 16 c) (aeolian sand units).
509 In-situ sand units are usually located in the narrowing zones of the valley, in the peripheral mouth
510 parts of lateral tributaries, and at the exits from narrow valleys into its wide parts or into
511 depressions (Arzhannikova et al., 2014). A typical in-situ sand unit (6–8 m) located on the right
512 bank of the Yenisei valley is represented by horizontally stratified deposits of various thicknesses
513 from 2–3 mm to 15–20 cm with inclusions of rare pebbles (fig. 16 a), which occur on pebbles and
514 covered with loess-like light sandy loams.

515 In sandy deposits, there are blocks that are also composed of sand, however, having a different
516 texture from their surrounding sediments. The intactness of the blocks suggests their frozen state
517 during transport by water, as evidenced by subsidence of overlying sediments after the blocks have
518 melted and compacted (fig. 16 b). In some cases, unconformities of sands with underlying
519 sediments are recorded (fig. 16 b). Perhaps they indicate multiple episodes of discharge from the
520 Darhad paleolake.

521 Aeolian sand unit are located both in the Yenisei valley and beyond. They were formed by
522 intense eolian processes. In present day, some units of sand sea (fig. 16 c) are located 100 km from
523 their original formation site.

524 Gravel and pebble units are widespread within gravel dunes (fig. 16 d, e). In some sections,
525 deformed gravel deposits with rare large pebbles overlain by sandy loams are recorded. Such
526 deformations are recorded in deposits about 1 m thick. They may be associated with strong paleo-
527 earthquakes and represent seismic convolutions. A high degree of seismic activity is indicated by
528 numerous falls in mountainous areas in the immediate vicinity of the deformed deposits.

529 Boulder units are located in terrace outcrops and on the gravel dune surfaces. Their sizes vary
530 from 0.5 m to 1 m (fig. 16 f, g). Some of them are well rounded and have a spherical or ellipsoidal
531 shape. Other boulders have a low degree of roundness and are represented by angular large
532 fragments.

533 Hummock units occur within gravel-pebble deposits and on the surface of gravel dunes (fig. 16
534 h, g). The size of such fragments reaches 8 m.

535

536 **4.8 ^{10}Be surface exposure dating**

537

538 For the gravel dunes in the Yenisei River valley, the exposure age was obtained for 19 samples
539 out of 21 selected. Two samples did not have enough quartz for dating. The exposure age was
540 distributed over a large time range from 137.5 to 18.6 ka (table 1). We interpret these ages to
541 reflect the formation timing of the gravel dunes and thus approximate the formation chronology
542 of the Darhad megaflood.

543 The samples were collected from terrace surfaces with height levels of 40, 30, 25 and 15
544 m (fig. 13 c, d) with the intention to determine exposure ages of boulders composing gravel dunes
545 at various topographic positions.

546 The Gravel dune field I samples (T1, T3, T4, T5) obtained in the western part of the Yenisei
547 River valley (fig. 13 c) has a significant scatter of exposure ages (Table 1). The oldest of them at
548 ~79.5 ka (T1) and ~137.5 ka (T5) were sampled from bedrock granitic rocks located within the

549 gravel dunes. There are two samples (T3, T4) taken from boulders that have similar exposure ages
550 of ~31 ka and ~30 ka and the ages belong to the final MIS3.

551 The Gravel dune field II samples (T6, T7, T8, T9, T10) were located on the surface of a
552 30-m terrace 45 km east of the I group (fig. 13 d). The ages of these samples refer to the periods
553 of MIS 3 and MIS 2. The closest ages are for samples T7 (~26.9 ka) and T10 (~27.8 ka). It is
554 possible to distinguish samples T6 (~31.1 ka) and T8 (~37.6 ka), which are also close in time. The
555 T9 sample has a younger age of ~18.6 ka. The sample T11 was taken from a large boulder at the
556 eastern edge of the gravel dune fields (fig. 13 d). The exposure age of this sample is ~20.3 ka and
557 it can be considered valid and reliable (even though it is a single sample) since its position and
558 dimension (fig. 16 j) exclude movement of the boulder during the entire history of its exposure.

559 The Gravel dune field III samples (T12, T13, T14, T15, T16) were located on a 30-m high
560 terrace (fig. 13 d). The exposure ages of the boulders have a significant scatter ranging from ~94.7
561 ka to ~20.2 ka, which indicates a complex exposure history.

562 The Gravel dune field IV samples (T17, T18, T19, T20) were located on a 15-m high
563 terrace (fig. 13 d) and they are characterized by a significant scatter of exposed ages ranging from
564 ~72.6 ka to ~23.7 ka. The samples T18 (~23.7 ka) and T20 (~29.3 ka) have the closest ages.

565 Our exposure age analysis of the gravel dune surfaces shows a significant time spread. In some
566 cases, older age is likely because the sample was taken from a remnant of bedrock embedded
567 within the gravel dunes. The wide time range might also be indicative of a complex exposure
568 history associated with significant movements in space of the dated boulders. On the time scale,
569 older samples are represented by dates ranging from 137 ka to 51 ka (fig. 17 b). These samples
570 were ignored in further analysis because they should have significant inherited numbers of atoms.
571 The rest of the samples make up three age groups (three peaks): series of the samples I is 36-38 ka
572 (3 samples) corresponding to MIS3; series of the samples II is 27-31 ka (7 samples) corresponding
573 to MIS3-MIS2; series of the samples III is 18-23 (4 samples) corresponding to MIS2.

574

575 **5. Discussion**

576

577 **5.1 Conditions of the Darhad paleolake formation**

578

579 The existence of paleolakes in the Darhad depression during the Late Pleistocene is recorded
580 from ancient lacustrine terraces and a sedimentary complex. The main backwater site for the
581 Darhad paleolake has been considered to be the Tengis Gol mouth, where traces of a glacial dam
582 are preserved (Krivonogov et al., 2005; Gillespie et al., 2008; Komatsu et al., 2009; Batbaatar and
583 Gillespie, 2016a).

584 However, our newly discovered evidence for the existence of a paleolake extension downstream
585 of the Tengis Gol mouth (fig. 6) indicates a more complex system of dams in the Shishkhid Gol
586 valley than it was previously accepted. The lake shorelines discovered below the Tengis dam are
587 identical in elevation (1710-1713 m asl) to the maximum level of the Darhad paleolake (fig. 7). In
588 this case, a question arises whether the Tengis glacier was the main dam for the Darhad paleolake?
589 Determining the parameters of the glacier based on the elements of the glacial features at the
590 Tengis Gol mouth is important for checking the possibility of forming a glacial dam for the
591 formation of the Darhad paleolake.

592 At the Tengis Gol mouth there are glacial and lacustrine features. Glacial features include lateral
593 moraines, terminal moraines and meltwater channels. All of them provide information about the
594 parameters of the glacier. The lacustrine features include ancient shorelines preserved on the slopes
595 of Shishkhid Gol testifying for the level and water contact with bedrock (figs. 10, 11).

596 The elevation of the lateral moraines at the Tengis Gol mouth, exposure age of the terminal
597 moraine at the left tributary, melt water channels, and lake shorelines on the slope of the Shishkhid-
598 Gol valley provide evidence for two elevational levels of the glacial dam at MIS 2 (figs. 10, 11).
599 This has been pointed out (Gillespie et al., 2008) by giving the upper glacial level an older
600 indeterminate age. The exposure age of boulders (20.8 ± 1.1 ka and 18.2 ± 1.0 ka) within the melt

601 water channel (Gillespie et al., 2008) characterizes the late stage of development of the Tengis
602 glacier (fig. 11). The exposure age of boulders (23.8 ± 1.5 ka and 20.7 ± 1.4) from the terminal
603 moraine (fig. 10 d) of the left tributary of Sarig Gol (Batbaatar and Gillespie, 2016b) belongs to
604 the early stage and correlates with LGM. However, based on the reconstruction results, doubts
605 arise whether the Tengis glacier could really have been a dam for the Darhad paleolake, since the
606 observed shorelines of the paleolake there are positioned at higher elevations than the surface of
607 the glacier (figs. 10, 11).

608 The analysis of satellite images and topographic data provided new information on the
609 conditions of formation and size of the Late Pleistocene Darhad lake. The existence of abrasion
610 lake levels upstream and downstream of the Tengis dam, as well as their coincidence in elevation
611 (1713 m asl), suggests the presence of a large backwater below the confluence of Tengis Gol and
612 Shishkhid Gol. We identified the confluence area of the Khara-Baryangiin and Ikh-Djams glaciers
613 as a likely backwater site (fig. 12). Here a large 300-m high dam was formed in the Shishkhid Gol
614 valley. Prior to this work this glacial dam was identified by Komatsu et al. (2009) and Batbaatar
615 and Gillespie (2016a), but they did not distinguish it as the main dam for the Darhad paleolake
616 since its elevation was considered to be much lower than the 1713 m paleolake (fig. 4). The
617 conditions for the glacial dam formation are determined by the parameters of ice-catchment and
618 the thickness of glaciers in both valleys. We think that the combining of the two glaciers in the
619 area of dam No. 4 (figs. 4, 12) in the Shishkhid Gol valley led to the stable glacier standing, thereby
620 providing a stable high backwater conditions for the formation of the Darhad paleolake at the 1713
621 m level.

622

623 **5.2 The maximum water level in the Darhad paleolake during the Late Pleistocene and lake** 624 **shoreline deformation after its drainage**

625

626 The maximum water level recorded on satellites and topographic data corresponds to 1713 m
627 asl (the western side of the Darhad Basin) and 1711 m asl (fig. 7) (the eastern side of the Darhad
628 Basin, Gillespie et al., 2008) with an uncertain level of ~1825 m pointed out by Gillespie et al.
629 (2008). The 1825 m asl level is debatable since it is not identifiable in the areal photo-
630 interpretation. All other maximum high levels in the inner water area of the paleolake are much
631 lower and vary from 1713 m asl up to 1686 m asl.

632 The difference in the elevation of the upper terrace may indicate the existence of large tectonic
633 subsidence within the Darhad Basin, which could have led to significant deformation of the
634 paleoshorelines. If the main tectonic movements took place after the drainage of the basin and the
635 terrace complex was affected, this can complicate the lake level interpretation.

636 According to (Gillespie et al., 2008), in MIS 2 there was a lake with a level of 1679 m asl. This
637 level was suggested based on the lake terrace elevation within the Jarai terminal moraine (17-19
638 ka; Gillespie et al., 2008). However, on the eastern side of the Darhad lake in the area of the Jarai
639 moraine, there are seismogenic deformations with a normal fault amplitude of 8 m (Logachev,
640 1993; Bacon et al., 2003). Thus, the 1679 m asl level may not be a true indicator of the level of the
641 paleolake, instead resulting from tectonic deformation. Moreover, beach sands with an elevation
642 of 1711 m asl (Gillespie et al., 2008), which may correspond to the 1713 level m asl on the western
643 shore of the lake, were found on a foothill slope 2 km south of the Jarai moraine. In this regard,
644 consideration of various paleolake levels can be rather complicated.

645

646 **5.3 Age and number of Darhad megafloods recorded in the Yenisei Valley**

647

648 As a result of ^{10}Be dating boulders from the surface of gravel dunes, three series of dates were
649 obtained. For analysis and their correlation with the main events of the Late Pleistocene, we present
650 a diagram with the distribution of exposure samples (^{10}Be) dating the main stages of glacier
651 advances in the East Sayan Ridge of the southern Baikal region and northern Mongolia (Gillespie

652 et al., 2008; Arzhannikov et al., 2012; Arzhannikov et al., 2015; Batbaatar and Gillespie, 2016b)
653 (fig. 18 a). Another diagram shows exposure age of boulders from gravel dunes (our work), from
654 the moraine surface in the Sarig Valley (Batbaatar and Gillespie, 2016b) and from melt water
655 channel boulders (Gillespie et al., 2008), luminescence ages of sand units in the Darhad core,
656 stages of the marine isotope scale (MIS), and the Darhad paleolake stages according to Gillespie
657 et al., 2008 (fig. 18 b).

658 As can be seen in (fig. 18 b), series of the samples I and III correspond to MIS 3 and MIS 2.
659 The most numerous series of the samples II is located in the transition zone between these stages.
660 The correspondence of series I and III to the timings of the Darhad paleolake existence (17-19 ka
661 and 35-53 ka, Gillespie et al., 2008) indicates the spatial and temporal relationship between
662 glaciation and outburst flood events. A good example sample for the megaflood in MIS 2 is a giant
663 boulder (8 x 4 x 2.5 m) with an age of 20.3 ± 1.7 ka located on the 25 m terrace surface (fig. 16 j).

664 In our opinion, the two groups of exposure ages (samples I and III series) correspond to two
665 megafloods that occurred in the periods 38-36 ka and 23-18 ka (fig. 18 b). This is indirectly
666 confirmed by drilling data in the Darhad Basin. The analysis and dating of the core showed that in
667 the periods of 34.7 ± 8.1 and 19.5 ± 2.6 ka, there were dramatic changes of the lake depth (the depth
668 decreased significantly) and sands with a large proportion of the heavy fraction began to
669 accumulate (Batbaatar and Gillespie, 2016b).

670 The exposure age of the samples from series II could be the result of a more complex exposure
671 history of the boulders exhumed during the first and second megaflood events. One can propose
672 that these boulders were not well anchored in the sediment and might have subjected to further
673 movements or partial burial. Then when stabilized in the landscape they were exposed to cosmic
674 rays and were able to accumulate cosmogenic nuclide until present day.

675 The depth of the megaflood flow in the Tuva Basin was at least 60-65 m. This is determined by
676 the difference in the elevation of the upper terrace (fig. 14 a, b), located on the right side of the
677 Yenisei valley and resulting from lateral erosion, and the minimum elevation of the gravel dunes

678 (fig. 14 c, d). The unconformity observed in alluvial deposits (fig. 16 b) on the high 30 m terraces
679 may indicate several stages (at least two) outbursts flood from the Darhad paleolake.

680 We believe that the last megaflood took place in the winter or in a colder month. This is
681 evidenced by sand blocks laid within this environment. The melting of these blocks during the
682 warm season led to subsidence of the overlying deposits and the formation of bending
683 deformations.

684 Summing up the above, we present a new vision of the Darhad paleolake formation and the
685 Darhad megafloods. The formation and development of the Darhad paleolake coincided with the
686 periods of glacier advance in northern Mongolia (Gillespie et al., 2008; Batbaatar et al., 2018).
687 Based on the parameters of the two levels of the Tengis glacier (figs. 10, 11) and the distribution
688 of lake terraces below the Tengis dam (figs. 6, 7), we can state that the Tengis glacier was not
689 responsible for the highest stand (1713 m asl) the Darhad paleolake. The main damming role was
690 played by a large glacier located downstream of the Tengis dam at least for the presumed highest
691 paleolake level of 1713 m asl. The destruction of this dam occurred during periods of global
692 warming (Batbaatar et al., 2018) which probably led to the occurrence of megafloods at least twice
693 in MIS 3 and MIS 2. The influence of megafloods was reflected in the formation of a new
694 erosional-depositional features (canyons, hanging valleys, gravel dunes, sand massifs, etc.) in the
695 Yenisei valley and adjacent territories.

696

697 **6. Conclusion**

698

699 The studies carried out in the Darhad and Tuva basins and the dating of gravel dunes in the Yenisei
700 valley made it possible to reconstruct the conditions of the Darhad paleolake formation and
701 determine the stages of the Darhad outburst floods:

702 - satellite image interpretation and radar-derived topographic data analysis suggest
703 significant deformations of the Darhad paleolake paleoshorelines. The maximum elevation

704 of the shoreline at 1711-1713 m asl, located along the periphery of the Darhad Basin,
705 decreases to 1686 m asl in the interior of the depression. The deformation of the shoreline
706 is associated with tectonic deformations as expressed as recent normal fault earthquakes.
707 The deformation of the shoreline occurred after the drainage of the lake;

- 708 - lake shorelines were found on the slopes of the Shishkhid Gol valley (downstream of the
709 Tengis Gol outlet), identical to the shorelines of the Darhad lake with a maximum elevation
710 of 1713 m asl;
- 711 - reconstruction based on the analysis of glacial and lacustrine landforms at the Tengis Gol
712 outlet showed that there were 2 glacier levels in MIS 2. The upper level corresponds to
713 LGM and the lower level is later than LGM. The Tengis glacial dam, although it formed
714 backwater, was not the main one responsible for the maximum level of the Darhad
715 paleolake at 1713 m asl;
- 716 - analysis of remote sensing data made it possible to identify a glacial dam at the mouths of
717 the Khara-Baryangiin and Ikh-James Gol rivers and position it as the main backwater in
718 the formation of the highest Darhad paleolake;
- 719 - the main source of the Darhad megaflood formation was the Darhad glacial lake. The
720 reason for the drainage of the lake was the destruction of glacial dams in the Shishkhid-
721 Gol valley.
- 722 - in the Tuva Basin (the Yenisei valley), a series of erosion terraces was found, formed by
723 the outburst of the Darhad paleolake. These terraces are the highwater marks indicating the
724 maximum depth of the Darhad megaflood. The height of the upper terrace is estimated to
725 be 100 m above the present-day water surface in the Yenisei River and 60-65 m above the
726 surface of the lowest level of gravel dunes;
- 727 - exposure dating of boulders (^{10}Be) sampled from gravel dune surfaces in the Yenisei valley
728 allows identifying two stages in the formation of the Darhad megaflood at 36-38 ka and
729 18-23 ka.

890 Fig. 1. Locations of the three largest paleolake basins (Chuya-Kuray, Darhad, Vitim) hypothesized
891 to be the sources of megaflooding in southern Siberia. Their megaflood routs are also shown
892 (dotted lines). The bottom figure shows the study area of this article.

893 Fig. 2. The Pliocene-Quaternary history of the Darhad Paleolake development (Spirkin, 1970).

894 Fig. 3. This satellite image (Google Earth) clearly shows ancient shorelines of the Darhad
895 paleolake, located on ridge slopes.

896 Fig. 4. Interpretation of the glacial dam locations in the Shishkhid Gol valley by various authors
897 (Gillespie et al., 2008; Komatsu et al., 2009; Batbaatar and Gillespie, 2016a). Pictures and profiles
898 were built using SRTM V4 data.

899 Fig. 5. Terrace levels, gravel dunes and bars indicated on a digital elevation model (TanDEM-X
900 DEM). The red dots show sampling site locations for ^{10}Be dating (a, b, c, d). The color symbols
901 and the position of the red squares are the same as in fig. 13. Photos (e, f) show examples of dated
902 boulders.

903 Fig. 6. Satellite images a, b, c, d (Google Earth) show the locations of ancient shorelines that
904 indicate paleolake levels. All satellite images show the right bank side of the Shishkhid-Gol valley,
905 located downstream of the Tengis Gol outlet.

906 Fig. 7. The map of the Late Quaternary glaciation and locations of key study localities within the
907 Darhad paleolake and the Shishkhid Gol valley discussed in this paper. SRTM V4 data were used
908 as the base map.

909 Fig. 8. Satellite images (Google Earth) show shorelines (the location of each image is indicated in
910 Fig. 7) and their elevations are given. The variability of the lake terrace elevations along the
911 periphery of the Darhad Basin probably indicates intense tectonic deformations.

912 Fig. 9. The digital elevation model (SRTM v4) and satellite images a, b (Google Earth) show linear
913 tectonic deformation features observed in the northern part of the Darhad Basin.

914 Fig. 10. Paleogeographic reconstruction of the glacial dam in the Tengis Gol mouth, which existed
915 during the Last Glacial Maximum (MIS2). A – meltwater channel located on the right bank of
916 Tengis Gol. B - meltwater channel, located on the left bank of Tengis Gol. C - reconstruction of
917 the Tengis glacier level (left side of the mouth part of Tengis Gol) during the LGM. D - the left
918 bank of Shishkhid Gol (Sarig Gol mouth) and elements of the glacial landforms (an abraded slope
919 by the glacier and a fragment of the Tengis terminal moraine). On the digital topography map, the
920 camera symbols indicate orientations of satellite images (A, B, C, D) and the positions of the
921 topographic profiles (below) are also shown. The topographic profiles show parameters of the
922 reconstructed Tengis glacier and reflect its role in the dam formation of the Darhad paleolake. The
923 figure uses SRTM v4 data and Google Earth satellite images.

924 Fig. 11. The glacial dam reconstruction at the Tengis Gol outlet after the LGM (20-18 ka). The
925 topographic profiles show the glacier levels and the surface of the Darhad paleolake.

926 Fig. 12. Reconstruction of the glaciers that formed the Darhad paleolake dam. The Khara-
927 Baryangiin and Ikh-James glaciers network (a, b, c) is shown with the ALOS DEM. This satellite
928 image illustrates the dam area and the elevation of the meltwater channel (d).

929 Fig. 13. The photographs show a gravel dune field and a 30-meter terrace scarp capped by gravel
930 dunes (a, b). The geomorphological map is based on the interpretation of TanDEM-X DEM data,
931 revealing the nature of the erosional-depositional activity of the Darhad megaflood and Yenisei

932 River in Tuva Basin (c, d). The red squares are the sampling sites for ^{10}Be dating (c, d). They are
933 shown in more detail in Fig. 5. The yellow rectangle is the location of the terraces formed by the
934 Darhad megaflood (Fig. 14).

935 Fig. 14. The photographs show a complex of terraces up to 100 m high above the current Yenisei
936 River, formed as a result the Darhad megaflood erosion (a, b). The location of high terraces in the
937 Yenisei valley (c) and their relationship with gravel dune fields (e).

938 Fig. 15. The photographs and satellite image (Google Earth) reveal the morphology and structure
939 of gravel dunes distributed in the Yenisei valley (a, b, c).

940 Fig. 16. Sedimentary complex of various fractions, formed in the Yenisei Valley as results of the
941 erosion-depositional activity of the Darhad megaflood (a, b, d, e, f, j, h, g) and aeolian processes
942 (c).

943 Fig. 17. Plot of the in-situ exposure age (^{10}Be) distribution obtained from the boulders within
944 gravel dunes of the Yenisei River valley.

945 Fig. 18. Plot (a) displays the exposure ages of glacial deposits of the Eastern Sayan Ridge and
946 northern Mongolia. Plot (b) shows three peaks of exposure ages (^{10}Be) associated with two Darhad
947 megafloods and one with the loss of ^{10}Be atoms due to changes in boulder exposure during the
948 second Darhad megaflood event. The red circles indicate the ages of significant change in the
949 fraction of the Darhad paleolake deposits. The green circles show the exposure ages of the
950 maximum advance of the Tengis glacier (LGM MIS2). The white circles show the formation ages
951 of the meltwater channels.

952

953 Table 1. Description of samples dated by ^{10}Be cosmogenic nuclides.

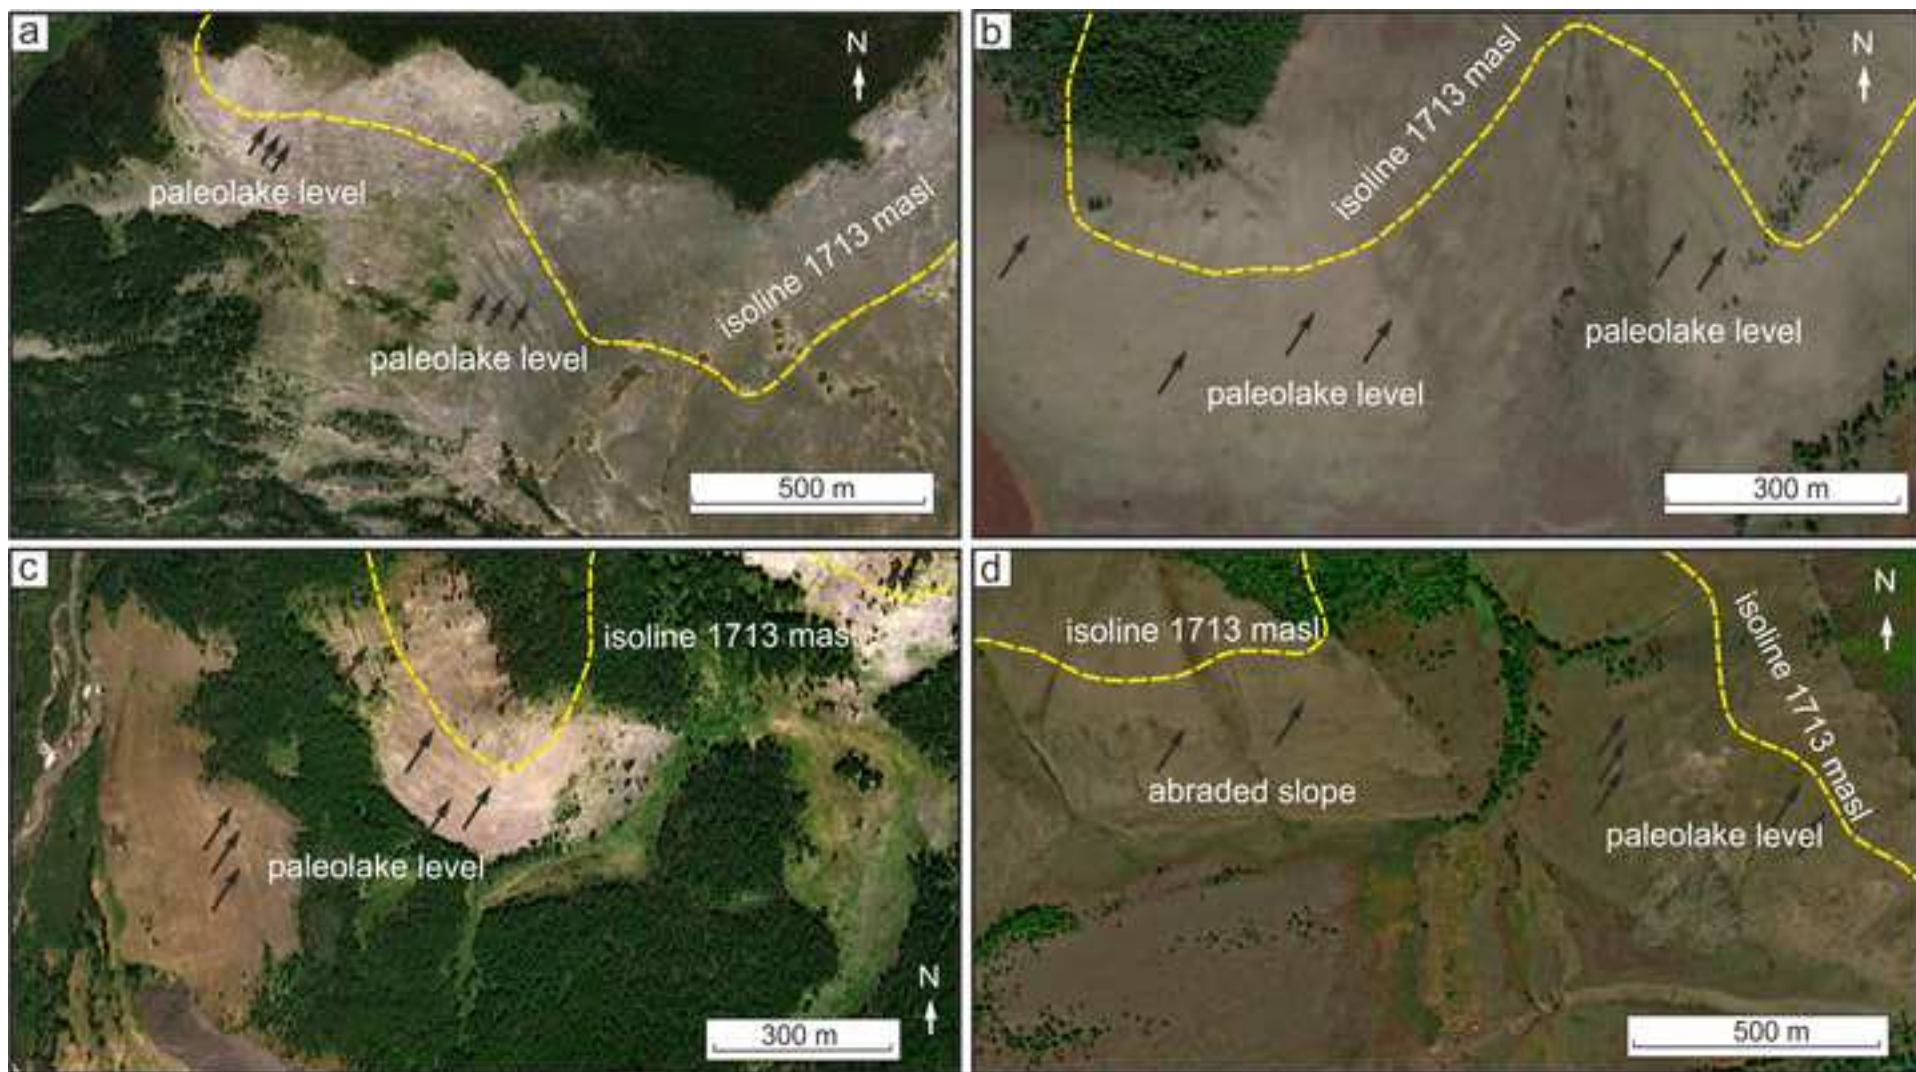

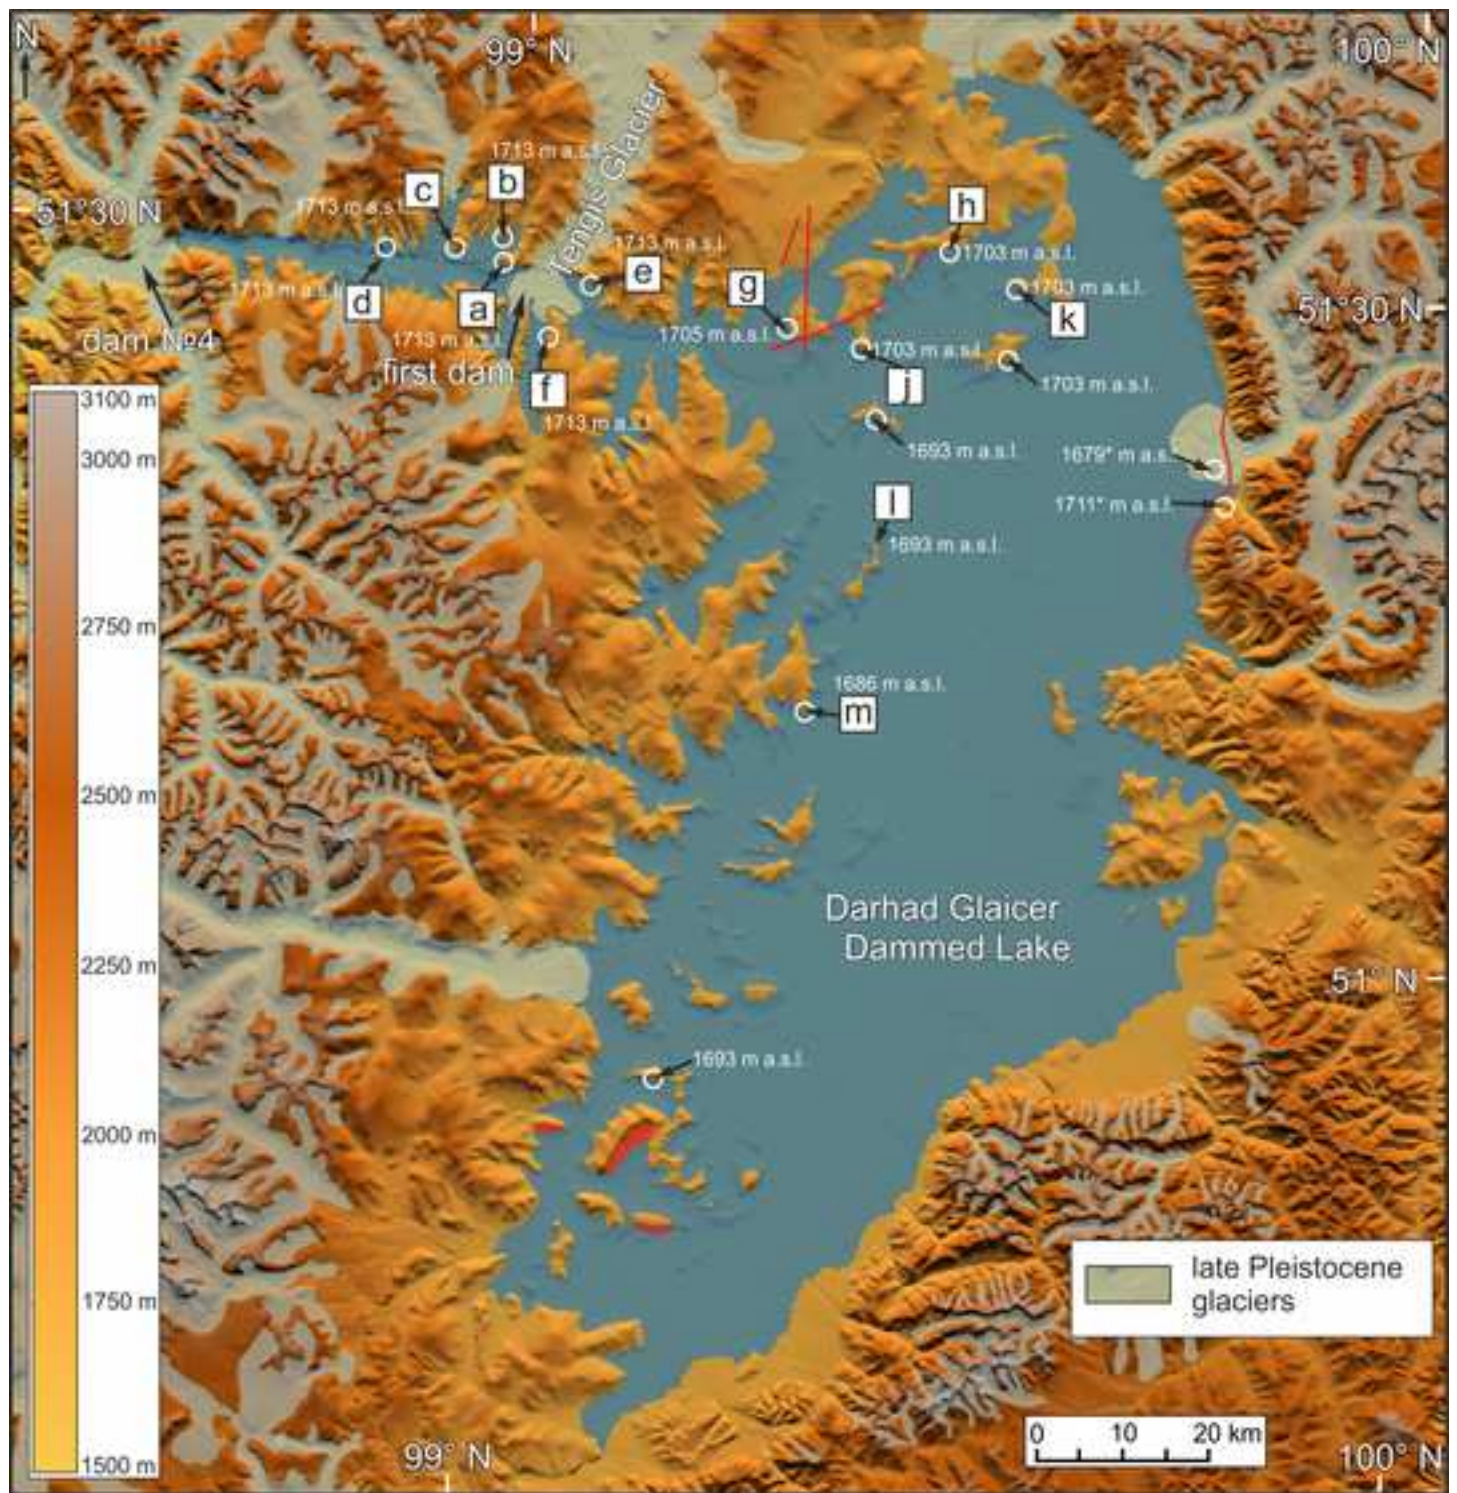

Sample	Latitude (N) (decimal degrees)	Longitude (E) (decimal degrees)	Altitude (m asl)	¹⁰ Be (at/g)	Uncert	Min Age (yr)	Uncert (yr)
T1	51.567367	94.015250	624	574 981	32 819	79 536	4 540

Samples have a density of 2.5 and are ~3 cm thick. Samples were crushed, sieved (0.5-1mm) and chemically etched. Pure quartz was dissolved in HF in the presence of ⁹Be carrier (100 µg of 3.025 x 10⁻³ g/g ⁹Be solution). Ion exchange columns (Dowex 1x8 and 50Wx8) were used to extract ¹⁰Be. ¹⁰Be/⁹Be ratios were measured by accelerator mass spectrometry at ASTER the French National Facility (CEREGE, Aix en Provence). Concentrations are reported relative to NIST SRM4325 standard, using an assigned value for the ¹⁰Be/⁹Be ratio of 2.79x10⁻¹¹ and a ¹⁰Be half-life of 1.387 Ma (Korschinek et al., 2010). A sea level high latitude spallation production rate of 4.49 ± 0.29 atoms g⁻¹ y⁻¹ and the stone scaling factors (Stone, 2000) were applied. Muons scheme is based on Braucher et al., (2003).

Declaration of interests

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

The authors declare the following financial interests/personal relationships which may be considered as potential competing interests:

Author Agreement Statement

We the undersigned declare that this manuscript is original, has not been published before and is not currently being considered for publication elsewhere. We confirm that the manuscript has been read and approved by all named authors and that there are no other persons who satisfied the criteria for authorship but are not listed. We further confirm that the order of authors listed in the manuscript has been approved by all of us. We understand that the Corresponding Author is the sole contact for the Editorial process. Arzhannikov S. is responsible for communicating with the other authors about progress, submissions of revisions and final approval of proofs Signed by all authors as follows:

Arzhannikov S.

Arzhannikova A.

Regis Braucher

Goro Komatsu

AS, AA, RB devised the research concept, planning, and ideas. AS, AA, participated in field work. AS took the lead in writing the manuscript. RB did the dating (^{10}Be). GK guided the structure and editing of the results and discussion. All authors contributed to the analysis and helped shape the study.
