SPIRAL2
DESIR
Radioactive ion beam

We report on the conception and first tests of the General Purpose Ion Buncher (GPIB), the radio-frequency beam-cooler and buncher that will supply the DESIR (Decay, Excitation and Storage of Radioactive Ions) experimental hall to be constructed to complement the SPIRAL1 and SPIRAL2 facilities in GANIL. Its goals are both to reduce the emittance and if necessary to bunch the radioactive ion beam from the GANIL production facilities to adapt it to the needs of the different experimental setups in the DESIR hall. The mechanical design is similar to the existing ISCOOL quadrupole at ISOLDE but the new radio-frequency system enables a much stronger radial confinement. The GPIB is developed at LP2i Bordeaux¹ in parallel with the PIPERADE double Penning trap and a beamline has been constructed there to characterize both. The cooling of a 30 keV beam to an emittance of 3π .mm.mrad and a transmission above 80% in continuous mode is demonstrated for currents up to a few nA. Some first results concerning the bunching mode are also shown though this mode is still under development.

1. Introduction

The progress in the knowledge of the atomic nucleus has for decades been strongly correlated to the advances of the production of more and more exotic nuclei. Among the new generation of facilities presently under construction is the SPIRAL2 one at GANIL which will make new regions of the chart of nuclides accessible and deliver beams of exotic nuclei with sufficiently high production rates to make precision studies possible where only limited measurements were feasible up to now. A new low-energy experimental hall will be constructed from 2023 onwards in the framework of this project. As pictured in Fig. 1, the DESIR hall [1, 2] will receive beams from the upgraded SPIRAL1 [3] installation, from the low-energy branch of the new Super Separator Spectrometer (S^3) [4] also part of SPIRAL2 and from a production building that could be constructed on a longer timescale. All these beams are ISOL-like, being extracted either from a target-ion source system or from a gas catcher. These beams thus have a low energy (typically below 60 keV), a good optical quality and generally a 1+ charge state (potentially also 2+ for cryogenic temperature gas catchers).

SPIRAL1 will produce mostly light ions from fragmentation and possibly heavier ions with fusion-evaporation reactions. S^3 will produce neutron-deficient nuclei from light $N=Z$ nuclei up to superheavy ones that will be stopped in a gas cell. The production building would deliver mainly fission fragments but possibly also fusion-evaporation products. DESIR will accordingly benefit from a large variety of exotic nuclei with high intensities and in a very wide range of masses to investigate nuclear structure, nuclear astrophysics or fundamental interactions. For these purposes, state of the art setups are being developed to use decay or laser spectroscopy as well as various electromagnetic traps (Paul, Penning and MR-ToF-MS).

Most of these setups put strong constraints on the beam characteristics as will be detailed in the next section. A low transverse emittance is also often desirable because it is only for efficient transport at low energy through the beamlines. This is the reason why it was decided to develop a general purpose ion cooler and buncher (referred to as "GPIB")

¹LP2i Bordeaux was known as Centre d'Études Nucléaires de Bordeaux-Gradignan (CENBG) before the name was changed in 2022

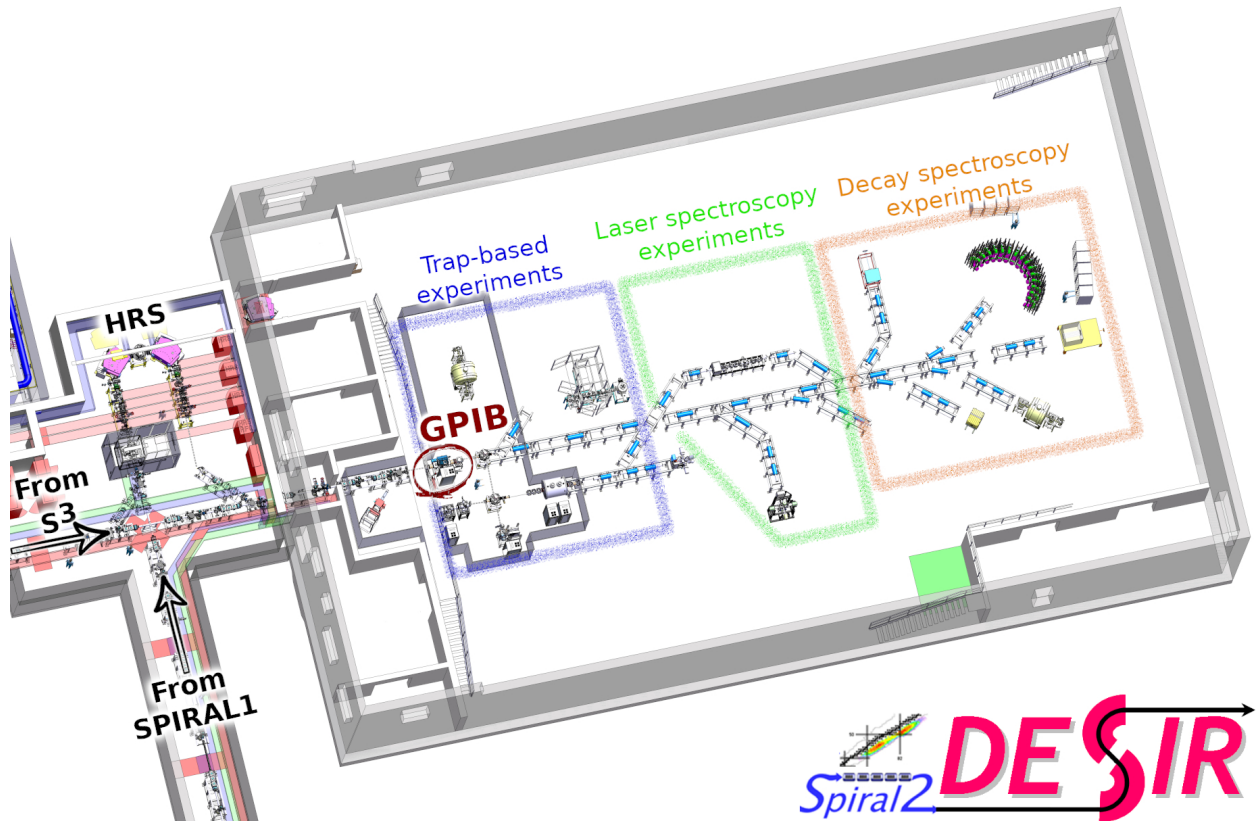

Figure 1: Overview of the future DESIR hall in GANIL. The beams coming from S³ and SPIRAL1 arrive respectively from left and bottom left, can pass (or not) through a high-resolution magnetic separator (HRS) and then enter the DESIR hall passing through the GPIB (circled in red). Many parts of the hall equipment (HV cages, cranes, laser room, some detectors...) have been omitted for clarity.

48 hereafter¹) that will be placed at the entrance of the DESIR hall and through which all the beams delivered to DESIR
 49 will pass.

50 Radiofrequency quadrupole (RFQ) coolers were first developed for Penning-trap mass spectrometry and laser spec-
 51 troscopy by the ISOLTRAP collaboration [5] and the JYFL-IGISOL team [6]. These devices are now widespread and
 52 have become standard tools at radioactive-ion-beam facilities delivering low-energy beams. RFQ coolers provide a
 53 transverse radiofrequency (RF) quadrupole field to confine injected ions that cool from collisions with buffer gas. An
 54 axial DC field is also required to push the cooled ions towards the end of the structure where an accumulation volume
 55 can be present if the cooler has also a bunching function. Many designs exist [7–14] with a large variety of inner
 56 diameter and length, in the shape and segmentation of the electrodes providing the axial DC and/or RF potentials, in
 57 the waveform of the radiofrequency signal or in the temperature of operation. Among these, ISCOOL [15–18] was
 58 devised as a general-purpose cooler and buncher for the High Resolution Separator beamline at the ISOLDE facil-
 59 ity and features segmented DC electrodes that are separate from the (continuous) RF system avoiding the need of a
 60 matching circuit. It also has rather large dimensions which is beneficial to reduce space charge effects, especially
 61 when bunching is desired. Apart from a few minor improvements, the GPIB follows the same mechanical design
 62 choice as ISCOOL while a different option was chosen concerning the radiofrequency generation so as to allow higher
 63 RF-voltage amplitudes and frequencies to improve the confining power.

¹Not to be confused with the old IEEE-488 interface bus

Setups	Energy dispersion	Time dispersion	Repetition rate
Laser spectroscopy	< 1 eV	< 10 μ s	1 - 200 Hz
Penning trap	a few eV	$\sim \mu$ s	1 - 30 Hz
MR-ToF-MS	< a few 10 eV	< 100 ns	50 - 100 Hz

Table 1

Rough estimates of the characteristics of the ion bunches needed for various types of setups.

2. Requirements

Radiation safety constraints limit the incoming beam intensity in DESIR to around 10^8 ions per second for most of the produced radionuclides though it can go up to 10^{10} ions per second in some specific cases. The GPIB was then designed to handle up to some nA of continuous beam while maintaining a high transmission. In addition, many of the experiments in the DESIR hall require bunched beam with up to 10^5 ions per bunch and repetition rates between one and a few hundreds bunches per second. The GPIB has thus to be able to trap large samples of ions for durations ranging from milliseconds to seconds and release them in a well controlled way. Such a large capacity is also desirable in the case of highly contaminated beams (as is often the case for very exotic nuclei) though in the present version of the layout the incoming beam can be cleaned by passing through a high resolution magnetic dipole separator (see Fig. 1) if desired.

The quality of a particle beam can be described by both transverse and longitudinal emittances. The first one, taking into account both the transverse spread of the ions and their angular deviation to the beam axis, is crucial as low emittance is necessary to limit the beam losses during the transport especially when injection in a strong magnetic field is needed as in a Penning trap. The spatial spread of an ion cloud after injection in a trap is directly linked to the beam transverse emittance and it is desirable to limit this spread to avoid probing both the electric and magnetic field imperfections that increase away from the center of the traps. The different setups in the DESIR hall need a transverse emittance lower than a few π .mm.mrad be it in continuous or bunched mode. The incoming beam will typically have a transverse emittance of the order of several tens of π .mm.mrad if it has not been cooled before. The GPIB specifications were defined so as to reduce the transverse emittance from 80 down to 3 π .mm.mrad for a 60 keV beam.

For bunched beams, the longitudinal emittance combines energy and time spread. In these domains, the various setups have different needs rough estimates of which are given in table 1. The most stringent requirements for energy dispersion are due to laser spectroscopy as the precision of the measurement is directly linked to this spread. The MR-ToF-MS is the most demanding application concerning time dispersion for the same reason. Concerning the Penning traps the specification on these spreads is mainly a matter of efficiency. Some other experiments need continuous beam and the GPIB can thus be operated in cooling-only mode. As all the beams used in the DESIR hall will pass through the GPIB, it is crucial to keep a good transmission be it in continuous or bunching mode. Finally, as the incoming beam can be continuous hence preventing the use of a pulsed drift tube to slow it down without losses, the GPIB must be operated on a high-voltage platform.

3. Mechanical design

The mechanical design of the GPIB (see Fig. 2) is very close to the ISCOOL cooler and buncher developed at CERN and in operation on the HRS beamline at ISOLDE since 2008. ISCOOL is extensively described in [15]. The RF and DC voltages are decoupled as RF is applied on four unsegmented rods while a DC gradient along the beam axis is created thanks to 25 electrodes surrounding the rods with four wedges entering the quadrupole structure. Far from the entrance and exit the DC part of the potential on axis is approximately one quarter of the potential applied to the electrode at the same axial position. Two plates (last injection and first extraction electrodes) close the structure with holes having 9 mm diameter at the entrance and 3 mm at the exit. The overall length of this closed structure is 796 mm. The minimal distance between the optical axis and the RF rods is $r_0 = 20$ mm. Additional pairs of aperture electrodes are placed immediately before and after the structure to ensure good injection and extraction of the beam. They are mechanically separated from the rest of the RFQ and the small apertures ensure both a good confinement of the buffer gas and a reduced fringe field out of the RFQ.

The first main difference with ISCOOL is the alignment system which was identified as a weakness. The new

Figure 2: CAD view of the GPIB showing the different electrodes and the new alignment system going through the vacuum chamber lid. The beam is coming from the left and goes first through a conical grounded electrode electrically connected to a hollow cylinder with an exit aperture of 12 mm diameter. It then enters the GPIB itself through three injection electrodes whose central holes have diameters of 8, 4 and 9 mm. Inside the GPIB, the twenty-five DC segments can be seen (light blue). Finally the beam exits the GPIB through three extraction electrodes whose central holes have diameters of 3, 3 and 10 mm and a grounded electrode similar to the entrance one. The top-left inset is a cut showing only the central part of the GPIB to highlight the shape of the DC segments and show the RF feedings (in orange) to the quadrupole rods (in dark grey) through the 13th (top and bottom rods, also visible on the global drawing) and 14th (left and right rods) segments. The buffer gas is injected through the 12th electrode (the feeding pipe is not pictured).

106 system of the GPIB has been designed at LP2iB so that the alignment can be performed from outside the vacuum
 107 chamber. The DC segments, RF rods and end plates form a rigid assembly attached to the vacuum chamber lid by
 108 a mechanical system allowing for lateral and longitudinal movement. The first two injection and last two extraction
 109 electrodes are connected to the vacuum chamber itself.

110 The second modification is the connection between the RF supply system and the quadrupole rods. Since much
 111 higher voltages are applied to the rods compared to ISCOOL, the connectors had to be moved from the extremity to
 112 the middle of the rods (passing through DC electrodes). Bigger insulators had also to be used to avoid sparking. The
 113 twenty-five DC segments have various lengths along the beam axis, depending on the precision needed on the shape of
 114 the DC gradient that guides the ions towards the exit of the GPIB. Segments number 1, 2, 20 and 21 are 19 mm long,
 115 segments 3 to 19 are 39 mm long and the last four segments (22 to 25) have a much smaller length (9 mm) to be able
 116 to define precisely a potential well when bunching is desired (see section 5.3). The segments are separated by Al₂O₃
 117 spacers on the outer part of the assembly as can be seen in Fig. 2.

118 4. Gas injection and pumping systems

119 4.1. Helium injection system

120 The buffer gas injection system uses a standard 50 L gas cylinder lying on the side of the vacuum chamber (at high
 121 voltage) with a standard pressure regulator which is then connected to a mass flow controller (Brooks SLA5850S) to
 122 regulate the amount of He injected inside the GPIB. A stainless steel tube is used between the mass flow controller and
 123 the vacuum chamber to ensure a leak-tight connection and thereby keep the He (grade 6.0) pure. Inside the chamber a
 124 PEEK tube carries the gas to the mid-point of the RFQ to ensure both flexibility for alignment and electrical insulation.
 125 The RFQ has a closed geometry so the gas is quite well confined inside the trapping volume and escapes mainly from

126 the two ends. The response time of the flow regulation is of the order of a second. At its maximum opening, the flow
 127 controller delivers $50 \text{ cm}^3 \text{ min}^{-1}$ of He in standard conditions for temperature and pressure. According to Molflow+
 128 simulations [19] this corresponds to a pressure in the center of the GPIB of roughly 1.6 Pa (i.e. 1.6×10^{-2} mbar).
 129 Molflow+ is a Monte-Carlo code the optimal reliability domain of which is when collisions can be neglected (ballistic
 130 regime). This is clearly not the case in the center of the GPIB as it operates at typical pressures for which the gas flow
 131 can be considered neither viscous nor molecular. The agreement between simulations and experimental results (Fig.
 132 9) however shows the MolFlow+ value is probably not too bad.

133 4.2. Pumping system

134 The pumping system is crucial as He gas is continuously injected in the center of the GPIB while good vacuum
 135 must be maintained elsewhere in the beamline. Primary vacuum is achieved in the chamber by means of two dry scroll
 136 pumps of respectively $15 \text{ m}^3/\text{h}$ and $35 \text{ m}^3/\text{h}$. High vacuum is maintained by three turbomolecular pumps:

- 137 • one $\varnothing 250 \text{ mm}$ 2200 L/s pump mounted directly on the main vacuum chamber (see Fig. 2)
- 138 • two $\varnothing 200 \text{ mm}$ 1600 L/s pumps attached to the 4-way crosses on either sides of the main chamber

139 These are able to maintain a pressure around a few 10^{-7} mbar in the beamline out of the GPIB chamber while He is
 140 injected in the RFQ at full flow.

141 5. Electrical design

142 5.1. HV platform

143 The GPIB sits on a high-voltage platform the voltage of which (typically 29.9 kV for a 30 keV beam) is set in
 144 reference to the ion source HV platform through a 0-400 V DC power supply (Delta Elektronika SM 400-AR-4).
 145 This way the ion energy is subject only to the small fluctuation of this power supply (ripple and noise of the order of
 146 15 mV) and independent of the stability of the HV power supply (ripple of the order of 30 V). Two 5 kV A isolation
 147 transformers, one for the ion source and one for the GPIB, decouple the electronics from the wall-plug ground. A third
 148 platform is used downstream that can be either grounded to transport the beam at the nominal energy or set 3 kV below
 149 the voltage of the GPIB platform. In this last case, the ions are extracted from the GPIB at 3 keV which is useful for
 150 two main reasons:

- 151 • when injecting into a Penning trap the final energy of the ion when reaching the center of the trap must be
 152 smaller than its charge times the trapping voltage (typically a few 10 V). With an initial energy of 3 keV rather
 153 than 30 keV the deceleration can be smoother allowing low losses in the transfer,
- 154 • electrostatic (i.e. mass independent) ion optics can more easily be used to deflect and focus the beam after the
 155 GPIB extraction electrodes.

156 5.2. RF circuit

157 5.2.1. Frequency range

158 The equations of motion of an ion inside the RFQ take the form of Mathieu's differential equations [20–22]. These
 159 have stable (i.e. not diverging) solutions only for limited ranges of the two Mathieu dimensionless parameters q and a
 160 linking the trap parameters and the ion mass to charge ratio as follows

$$\begin{cases} q = \frac{QU_{RF}}{\pi^2 m r_0^2 f^2} \\ a = \frac{QU_{DC}}{\pi^2 m r_0^2 f^2} \end{cases} \quad (1)$$

161 where Q and m are the charge and mass of the ion, U_{RF} is the amplitude of the RF voltage applied with 180° phase
 162 difference to the two pairs of rods, r_0 is the distance between the axis and the RF poles, f is the frequency and U_{DC} can
 163 either be a DC voltage applied between the pair of rods or between axial electrodes. When no DC voltage is applied

164 between the pairs of RF rods and if the DC gradient along the axis is neglected (i.e. $a = 0$), a stable trajectory can be
 165 achieved if $0 \leq q \lesssim 0.908$.

166 If one looks for a stronger confinement to counter the effect of Coulomb explosion when a high number of ions
 167 are accumulated in the trap, a higher U_{RF} is needed as in the low q region the maximum density of ions that can be
 168 trapped scales with the square of U_{RF} and inversely with the square of f [23]. To keep the stability it follows from
 169 the condition on q that f must also be increased. This can be simply understood as if the confining force due to the
 170 RF electric field is higher in one plane, the deconfining force in the orthogonal plane is similarly higher. It is then
 171 necessary to switch the polarity faster to keep the ions confined in a small distance from the axis. The lighter the ions
 172 are the higher the frequency must be.

A widely used quantity to estimate the cooler confining power is the pseudopotential, classically defined by:

$$D = \frac{QU_{RF}^2}{4\pi^2mr_0^2f^2} = \frac{qU_{RF}}{4} \quad (2)$$

173 In this approximation, it is considered that the average effect of the oscillating RF potential over one period results
 174 in a simple harmonic restoring force confining the ions around the axis. The ion motion is then simply approximated
 175 by a fast and low-amplitude motion at the RF driving frequency (micromotion) superimposed with a slow and large-
 176 amplitude oscillation in the potential well (secular motion). The depth of the potential well thus gives an estimate of the
 177 strength of the confinement that can be compared directly to the transverse energy per charge unit of the ions. It should
 178 however be pointed out that the aforementioned approximation is fully valid only while the micromotion amplitude
 179 is negligible compared to the secular motion one, i.e. while a and $q^2 \ll 1$. This is usually not the regime in which
 180 the GPIB works (see subsection 7.3). If one calculates the pseudopotential regardless of this, the depth obtained as an
 181 example for ^{39}K and $q = 0.7$ is $D \approx 200$ V if $U_{RF} = 1125$ V and $D \approx 500$ V if $U_{RF} = 2900$ V (maximum value of the
 182 RF voltage for such a mass). At its highest RF voltage for such a mass and q value, the pseudopotential in ISCOOL
 183 would in comparison be around 35 V.

184 The GPIB being designed to handle large samples of ions with masses from a few up to a few hundreds of atomic
 185 mass units, the maximum voltage amplitude was chosen to be $U_{RF}^{(max)} = 3.9$ kV (7.8 kV difference at max between two
 186 adjacent rods). Keeping this voltage at all times would result in minimal working frequencies ranging from 600 kHz
 187 ($m = 250$ u) to 4.7 MHz ($m = 5$ u) to stay in the stability region. It is also worth mentioning that this can be worsened
 188 when the ion density is increased as space-charge has a similar effect as adding a DC potential between the pairs of
 189 poles (meaning the Mathieu a parameter is no longer 0). This thereby tends to reduce the range of the q parameter for
 190 which ion trajectories are stable down to $q \approx 0.68$ at which value the maximum charge density the RFQ can confine
 191 is reached [24]. Such an upper limit on q would shift the minimal working frequency range to 700 kHz-5.4 MHz if a
 192 4 kV amplitude was kept. As will be seen in section 5.2.2, this exceeds the circuit's capabilities and such an amplitude
 193 will be accessible only below 1MHz as illustrated in figure 3.

194 5.2.2. Design

195 The RF power circuit of the GPIB was designed taking inspiration from the SHIRaC2 RFQ cooler [25] developed
 196 at LPC Caen in the framework of the SPIRAL2 project. As can be seen in Fig. 4 it is composed of the following
 197 elements:

- 198 • A function generator (Agilent 33500B) which drives the frequency with 10 V maximal output.
- 199 • A 500W class-A solid-state amplifier (Prâna GN500). Its frequency band extends from 100 kHz to 200 MHz
 200 which covers the whole range of frequency needed. As the power at the input must be limited to 10 dBm (i.e.
 201 10 mW) which is lower than what the function generator can deliver, an attenuator is placed in between for safety
 202 purpose. A second one is used at the output of the amplifier when working at intermediate voltages ($U_{RF} \lesssim$
 203 2 kV) to minimize the wear of the amplifier that works best around full power. It can be removed within minutes
 204 if very high RF voltages are needed.
- 205 • A custom-made transformer balun circuit (see Fig. 5) so as to both balance the signal between the two pairs
 206 of rods in the RFQ and rise the voltage. It is a RLC circuit the capacitance of which is the combination of the
 207 intrinsic RFQ capacitance and the one of a motorized accordable capacitor ranging from 50 to 2200 pF (National
 208 Electronics CVB 2300AS/15). This latter enables tuning the circuit so that it operates at resonance whatever

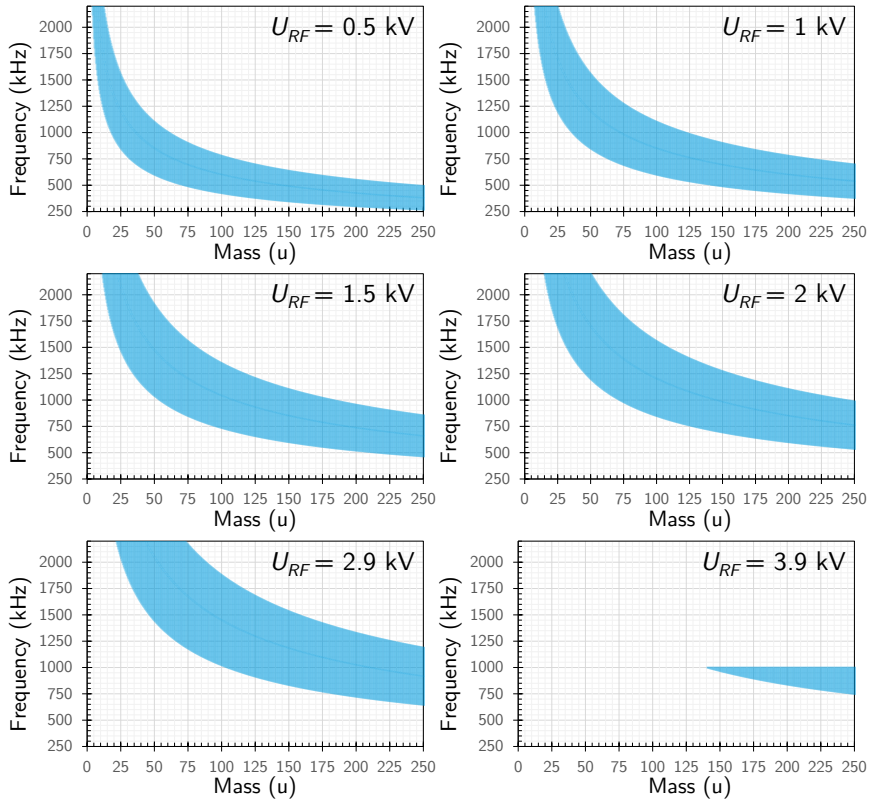

Figure 3: The coloured bands represent the frequency range for which the Mathieu parameter meets the condition $0.2 \leq q \leq 0.68$ (see subsection 5.2.1 for details) as a function of the mass of the singly-charged ions trapped in the GPIB shown for different RF voltage amplitudes. The upper frequency bound corresponds to the maximal frequency reachable with the S24-24 windings while the lower bound is the minimal frequency for the S38-38 windings. For the last plot, the frequency range is cut at 1 MHz as 3.9 kV is the maximal voltage reachable by the S32-32 circuits and cannot be reached by the S24-24 one (see table 2).

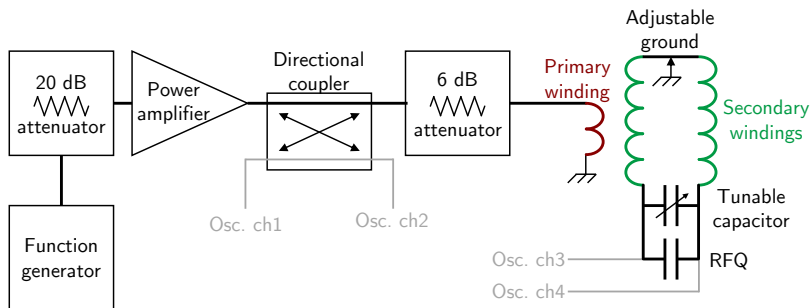

Figure 4: Schematic of the RF system of the GPIB. The measurement channels are pictured in gray. The first attenuator is to ensure that the maximum input voltage of the amplifier can not be reached. The second one is removable and only used to minimize the wear of the amplifier when working at intermediate voltages ($U_{RF} \lesssim 2 \text{ kV}$).

209 the frequency needed to confine the ions in the RFQ. The inductance part is that of the transformer coils formed
 210 around a PTFE hollow cylinder (air-coupling). The resulting coupling coefficient is close to 60%. Air coupling
 211 was chosen to avoid heating of the core which was found to be enough to demagnetize ferrites.

212 Three different air-coupled windings have been designed to be able to reach resonance for frequencies between
 213 260 and 2150 kHz corresponding to masses between 10 and several hundred atomic mass units (see table 2).

Circuits	S38-38	S32-32	S24-24
Mandrel \varnothing (mm)	40	40	20
Primary (turns)	2	2	2
Secondary (turns)	2×38	2×32	2×24
Inductance (μH)	≈ 165	≈ 85	≈ 17
Frequency range (kHz)	260-720	350-1000	750-2150
RF power transmission efficiency (%)	92-100	97-100	75-85
Max voltage (V)	± 4600	± 3900	± 2900
Mass range (u)	>190	>100	20-170

Table 2

Characteristics of the three circuits used to cover the whole frequency range of the GPIB. The mass range is indicative and calculated for $q = 0.5$ and $U_{RF} = 2 \text{ kV}$.

Note that the mass ranges indicated in the table correspond to a specific q value and a given RF voltage. The mass ranges can be shifted for example downwards either by choosing a higher q value or by decreasing the RF voltage. Each circuit is mounted inside an air-cooled plastic box that is directly plugged into banana plug sockets connected to the RF rods so that it can be changed very easily and within a few minutes.

- Two HV probes (LeCroy PPE4KV) with a divider ratio of 100:1 are connected to the symmetrized branches of the secondary circuit to monitor on an oscilloscope both the voltage and the symmetry on the two pairs of rods inside the RFQ. The ground of the secondary circuit can be adjusted (by translation along a copper bar connecting the two secondary windings) to restore the symmetry between both pairs if needed. Above 4 kV peak-to-peak ($U_{RF} = 2 \text{ kV}$) applied on the rods, these probes could be damaged and other probes based on Rogowski coils are under development to overcome this limitation.
- A -50 dB directional coupler is placed in between the amplifier and the balun circuit to measure the transmitted and reflected powers with an oscilloscope. At the maximum power delivered by the amplifier (57 dBm) the subtracted power is no more than 7 dBm (5 mW) that represents a voltage amplitude of only 0.7 V on the 50Ω input of an oscilloscope. Minimizing the reflected power by changing the capacitance of the accordable capacitor enables tuning the balun circuit so as to reach the best impedance matching at the desired working frequency.

The maximum voltage amplitude U_{RF} that can be applied to the rods is given in good approximation by:

$$U_{RF} = \sqrt{2P_d Z} = \sqrt{2PR} \frac{2Z}{Z + R} \gamma \quad (3)$$

where P_d is the maximum power transmitted to the balun circuit, P is the maximal output power of the amplifier, $R = 50 \Omega$ its output impedance, $Z \approx 500 \Omega$ is the impedance of the balun circuit close to resonance and γ is the transformer ratio that depends on the chosen windings. This maximum amplitude can also be found in table 2.

5.3. DC circuit

In addition to the four RF rod-electrodes, the GPIB is composed of 3 injection electrodes, 25 DC segments and 3 extraction electrodes (see Fig. 2) that can be biased independently to create voltage gradients to guide the ions in and along the RFQ and trap or release them at the end. Grounded electrodes placed immediately upstream and downstream complete this electrode system. The 25 segments as well as the last injection and first extraction electrodes (INJ03 and EXT 01) are biased using a 32 channels 0-500 V power supply (ISEG EHS 20105p) with positive polarity. The 4 outer injection and extraction electrodes are biased with a 4 channels 0-10 kV power supply (ISEG EHS 40100n) with negative polarity. Both power supplies have a ripple and noise level below 10 mV peak-to-peak. The last four segments and the first extraction electrode can be pulsed to bunch the beam.

Two bias states – an "open" one at low voltage (a few volts) and a "closed" one at high voltage ($>100 \text{ V}$) – switch alternately on a common output channel connected to the chosen electrodes of the GPIB by a RG59 BNC cable with 75Ω characteristic impedance and low linear capacitance. The switching is obtained using a half-bridge transistor

Figure 5: (Left) Global view of the balun circuit corresponding to the right-hand side of Fig. 4. The air-coupled windings are inside the ventilated plastic box on the left, the tunable capacitor is in the middle and its motor inside the metal box on the right. One of the HV probes is visible in the foreground. (Right) The three different windings respectively suited for very high frequencies i.e. low masses (top), high frequencies/intermediate masses (middle) and low frequencies/heavy masses (bottom).

245 assembly associated with a bootstrap capacitor which provides a virtual reference for the correct operation of the
 246 transistor in the upper part of the half-bridge. This is based on MOSFET technology components (STP11NM60ND
 247 from STMicroelectronics) able to withstand up to 600 V amplitude. The switching dynamics (90-10% criterion) is
 248 optimized by an RC load integrated at both inputs and at the common output of the board so that:

- 249 • the rise time from the switching to the blocking state is less than 15 ns when the amplitude is greater than 100 V,
- 250 • the reciprocal fall time is at maximum 90 ns and of the order of 30 ns for amplitudes greater than 100 V,
- 251 • both dynamics are associated with low ripples (<5% over 7 μ s) and negligible over- or undershoot voltages
 252 (<10% over 10 ns),
- 253 • the noise is attenuated by at least -50 dB relative to signal (-80 dB on average for amplitudes greater than 50 V)
 254 over the bandwidth from 20 Hz to 100 MHz.

255 Though it can operate at higher rate, the main constraint of the switching circuit is at very low duty cycle operation
 256 : 1 Hz to 10 Hz sequences of opening gates between 10 μ s to 100 μ s as in such a situation the MOSFET transistor
 257 controlling the switch must be kept closed most of the time (>99%). A high capacitive load (1 μ F) is therefore used
 258 to provide the necessary energy reserve so that the gate-source bias of this transistor is maintained. The switch is
 259 controlled via an optical coupler (PC817) by a TTL logic signal doubly rectified by a logic gate (CD4011BE) in order
 260 to ensure the best possible dynamic control signal. The latter drives a power component ("driver" IR2113BPF) which
 261 provides the gate-source bias voltages necessary for opening and/or closing the transistors. The control signal is a
 262 3.3 V "low TTL" type coming from modules (National Instruments NI9215) of a CompactRio Programmable Logic
 263 Controllers (PLC) associated with the pulse pattern generator (PPG) through which the user defines the time sequence
 264 of the switching. Since this module does not have enough current to activate the photodiode of the optical coupler of
 265 the switch, an intermediate TTL signal amplification board had to be installed. The amplification level thus allows the
 266 switching delay of each switch to be adjusted and fixed by an integrated potentiometer.

267 6. Operating system

268 6.1. Instrumentation

269 DESIR beamlines and setups are mainly composed of electrostatic devices and as described in subsection 5.3, the
270 GPIB itself requires 36 High-Voltage DC Power Supplies (HV-DC PS). ISEG Multichannel crates are used for several
271 reasons. The first one is the large variety of low noise, precise and stable HV PS proposed with module ranges from
272 500 V to 30 kV maximum voltages. The second one is its ability to concentrate a large number of HV channels in a
273 single crate. The GPIB Electronics is in a dedicated rack on a 30 kV HV Platform: a small 19" crate is used to host
274 the GPIB HV PS. The third reason is the CC-24 ISEG crate controller with its built-in EPICS Server (see 6.2). We
275 developed a SPIRAL2-like EPICS Records Database used on all DESIR ISEG Crates.

276 The GPIB RF field generation is described in section 5.2. The instruments controlled are the function generator,
277 the RF power amplifier and the AKM Kollmorgen brushless motor equipped with an absolute encoder to tune the
278 RF circuit capacitor. Measurements to adjust and monitor the RF circuit resonance (both transmitted and reflected
279 RF voltage amplitude and phase) are done using a standard oscilloscope. Beam measurements are done downstream
280 and upstream from the GPIB using Faraday cups (FC), beam profile monitors (BPM) and chevron-stack Topag MCP-
281 MA33/2 microchannel plates (MCP). The beam position and size are monitored with GANIL-SPIRAL2 BPM [26]
282 based on secondary electron emission (PREMS) from a mesh of 47 tungsten wires (0.5 mm steps) in both horizontal
283 and vertical directions.

284 The beam current is measured on GANIL-SPIRAL2 Faraday cups with a -90 V biased electron repeller. These
285 Faraday cups are equipped with high sensitivity "Picolin" transimpedance amplifiers developed by GANIL for the
286 low-intensity CW SPIRAL2 beamline measurements. The highest gain (1 pA V^{-1}) with a filtered signal of 0.5 Hz
287 bandwidth makes it possible to observe variations of 10 fA on Faraday cups. The output signal is acquired with a
288 National Instruments NI9215 ADC module used with a 9012 CompactRio controller. Another Digital I/O module is
289 also used to select remotely one of the 8 possible ranges from 1 pA V^{-1} to $10 \mu\text{A V}^{-1}$.

290 A second variable gain and high speed transimpedance amplifier (Femto DHPCA-100) is used on the Faraday
291 cup downstream from the GPIB to monitor bunched beams. GPIB bunches with sufficient intensity are "scoped"
292 with a Red Pitaya acquiring this Femto amplifier output signal. This amplifier is also controlled by the Red Pitaya
293 since FPGA developments have been done at LP2iB. The Australian Synchrotron EPICS driver support (see next
294 subsection) has been completed and is used to run the FaradayCup EPICS server in the Red Pitaya itself. Another
295 Red Pitaya development named "RedpiToF" [27] has been conducted in our lab to implement high speed counting and
296 time-of-flight capabilities. We are now using this new development coupled with the MCP detector to measure the
297 low-intensity GPIB bunched beam and time dispersion.

298 6.2. Control System

299 The *experimental physics and industrial control system* (EPICS) [28] was chosen to be the basic framework for the
300 SPIRAL2 control system in 2006 [29]. As the GPIB will be part of the main SPIRAL2/DESIR hall beamline, all the
301 equipment needed to operate the GPIB has to be remotely controlled under EPICS [27].

302 EPICS is based on clients (operator interfaces) and servers (input/output controllers or IOC) communicating to-
303 gether sharing *process variables* (PVs) on an Ethernet network using a dedicated communication protocol named
304 *channel access* (CA). The architecture of the GPIB EPICS control system is illustrated on Fig. 6. Most of the GPIB
305 electronics is embedded on its high-voltage platform. An optical fiber coupled with Ethernet switches ensures galvanic
306 isolation and TCP communication of the equipment with the EPICS IOCs running on a CentOS Linux PC.

307 Some IOCs are embedded in equipment: this is the case of the ISEG HV multichannel crate (ISEG CC24 Con-
308 troller) and the Red Pitaya used for beam intensity and time dispersion measurements. Shared software development
309 tools are used such as the SPIRAL2 version of CSS/BOY (CSS-Dev) for defining most of the graphical user interfaces
310 (GUIs) and central services like the data archiver or the alarm handler systems. The SPIRAL2 EPICS distribution and
311 equipment databases already used at GANIL are shared using GANIL Subversion (SVN) Server.

312 EPICS with its CA protocol makes it easily possible to monitor and control any beamline equipment through its
313 process variables in many programming languages. Specific Python GUIs needed for the commissioning phase of
314 the GPIB have been developed. For example the homemade "Plotpot" application plots in real time the longitudinal
315 electric field seen by the ions along the GPIB axis with respect to the voltage applied on the 31 DC electrodes.

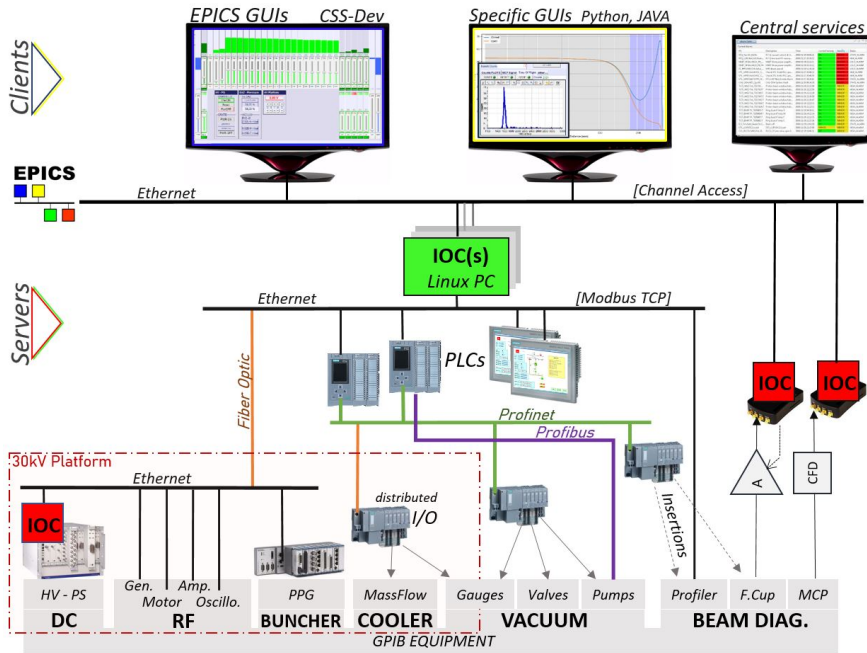

Figure 6: GPIB control system layout. Black lines represent Ethernet connections while the orange one symbolizes an optical fiber, the green ones the Profinet network and the purple one the Process Field Bus. The CentOS Linux PC on which the EPICS IOCs are running is pictured as a green box.

316 **6.3. Automation**

317 The SPIRAL2 vacuum systems and interlocks are controlled using dedicated Siemens S7-1500 programmable
 318 logic controllers (PLC). The Profibus field bus is used by the GPIB vacuum PLC to communicate with turbo-molecular
 319 pumps and Profinet (Profibus on Ethernet Network) is deployed to manage input-ouput terminal modules (ET 200S)
 320 distributed along the beam-line and on the high-voltage platforms. Each PLC has its own HMI (Human Machine
 321 Interface) on a dedicated Touch Panel. These local HMI can be managed from authorized people on distant machines
 322 through a remote desktop or a WinCC user interface. For the commissioning phase of this project, the Profinet network
 323 shares the laboratory Ethernet network but at DESIR a dedicated Profinet network will be deployed to secure and
 324 harden this Automation system. The Modbus-TCP protocol is used to share parameters managed by the PLC such as
 325 the vacuum pressures and beamline valves status with an EPICS Server (soft IOC running on a Linux machine). The
 326 control of the GPIB buffer gas injection system, valves or diagnostics insertions are thus easy to reach from any EPICS
 327 Client interface.

328 **7. Simulations and first experimental tests**

329 **7.1. PIPERADE beamline at LP2iB**

330 The GPIB is being developed at LP2iB in parallel and close collaboration with the PIPERADE Penning trap [30]
 331 which will also be installed in the DESIR hall. A beamline, pictured on Fig. 7, has been mounted at LP2iB to test both
 332 devices with stable beams and to compare the results with simulations that are presented below in subsection 7.2. A
 333 Forced Electron Beam Induced Arc Discharge (FEBIAD) ion source is first used to generate ions either from the alkali
 334 elements naturally present on the inner surfaces of the source or from gas injected in the source with a regulated flow.
 335 During the measurements reported below, it was used exclusively in the first mode (surface ionization) producing a ^{nat}K
 336 beam. The source is on a high-voltage platform set typically at 30 kV so that ions are naturally accelerated to 30 keV
 337 towards the grounded beamline downstream. All the ion optical elements are electrical so that the settings are mass-
 338 independent. The beam first goes through two pairs of horizontal and vertical steerers enabling rectification of both a
 339 misalignment and a tilt of the source with respect to the beamline axis. One of the steering electrodes can be quickly
 340 switched to deflect the beam towards the beam pipe so as to form a poor man's beam gate. A first quadrupole triplet

Figure 7: CAD view of the PIPERADE test beamline at LP2iB with the main optical elements and beam diagnostics. If the deflector [31] on the far right is not used the cooled beam goes straight to the PIPERADE Penning traps [30]. Otherwise the beam can be made to turn 90° either to the left where an emittance meter will be placed or to the right to the SPIRAL2 High Resolution Separator [32, 33] also developed at LP2iB.

341 follows immediately to be able to focus the beam on a first retractable Faraday cup allowing for current measurement.
 342 Another X-Y steerer and a second quadrupole triplet follow. The latter is the prototype of the triplets that will be used
 343 in the DESIR hall beamlines. The beam profile can be imaged about 20 cm downstream with the help of a retractable
 344 multiwire secondary emission monitor ("BPM" on Fig. 7). The beam finally goes through a grounded electrode formed
 345 of a conical outer part in which a central cylindrical electrode can be slid (see Fig. 2) to precisely set the potential
 346 close to the entrance of the RFQ which follows immediately. The GPIB itself sits on a second HV platform operated
 347 a few tens of volts below the one of the source as described in subsection 5.1.

348 Everything after the GPIB is on a third platform that can be either grounded if a 30 keV beam is wanted or biased
 349 with a 3 kV power supply with respect to the first one to extract the beam at 3 keV (the platform voltage with respect
 350 to earth is then ≈ 27 kV). At this energy a 90° deflector [31] can be used to make the beam turn towards either a
 351 pepper-pot emittance scanner (Pantechnik 1D EMD-PP V02) or the SPIRAL2 High Resolution Separator [32, 33] also
 352 developed at LP2iB. If no bending voltage is applied in the deflector the beam goes straight to the PIPERADE Penning
 353 traps located about 2 m downstream.

354 7.2. Ion optics simulations

355 Simulations of ion trajectories were conducted with the SIMION code [34] that uses a finite difference method
 356 to solve the Laplace equation for an array of points and hence calculate the electric field at these points. Both the
 357 RF oscillation of the electric field and the effect of the buffer gas are included via an external LUA script called by
 358 SIMION. In the simple hard sphere model we used, the collisions of ions with He atoms are purely elastic with no
 359 charge exchange, the gas atom velocities follow a Maxwell-Boltzmann distribution and the buffer gas is not affected
 360 by the collisions.

361 The GPIB being designed to cope with high-charge bunches, a special attention was paid to the space charge effects.
 362 This can be handled by SIMION at the cost of much heavier and longer calculations but this becomes impractical on
 363 a standard computer for numbers of ions larger than $\sim 10^4$. A much lighter solution is offered by SIMION with a
 364 scaling procedure that assigns a $n+$ charge to each of the N ions flown to simulate the Coulomb effects in a $N \times n$ ions
 365 cloud. We first benchmarked the reliability of the scaling method in our case up to $\sim 10^4$ ions (see table 3) and found
 366 an agreement on the simulated emittance for a given total charge well within the error bar (that was of the order of 10%
 367 for 1000 ions). This shows that simulations with 1000 particles are enough to get reliable trends when scanning the
 368 parameters and as we are not seeking better precision we thus performed most of the simulations with 1000 particles
 369 with a scaling factor of 100 on the Coulomb effects to simulate bunches of 10^5 ions. Due to the large dimensions of

Number of simulated ions	Simulated emittances (π .mm.mrad)	
	10^3 particles flown	10^4 particles flown
10^3	4.41 ± 0.44	-
10^4	4.36 ± 0.44	4.48 ± 0.02
10^5	4.68 ± 0.47	4.72 ± 0.02

Table 3

Illustration of the consistency of the scaling method for Coulomb repulsion in the SIMION simulations. The five simulations were performed under the same conditions of initial ion geometric and velocity distributions, buffer gas pressure and voltages. Only the number of particles actually flown and the scaling factor is changed.

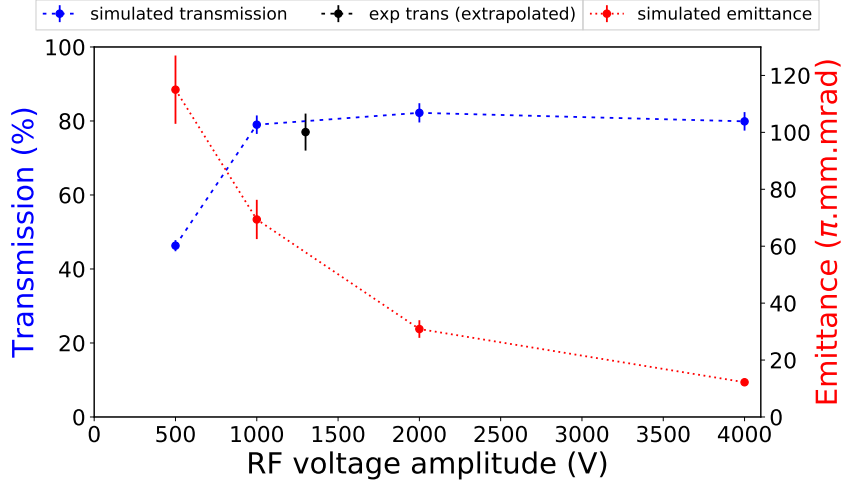

Figure 8: Simulated effect of the RF voltage U_{RF} on the transverse emittance at $\sqrt{6}$ -RMS (i.e. including 95% of the ions) and on the transmission through the whole GPIB when the beam is extracted at 3 keV. The emittance ($\sqrt{6}$ -RMS) of the incoming 30 keV beam before entering the GPIB is set at 25 π .mm.mrad. The buffer gas pressure is fixed at 2 Pa. The frequency is varied from 0.489 to 1 MHz so that the Mathieu parameter remains constant at $q = 0.5$ for a mass $m = 102$ u. 10^3 particles were flown in the simulations with a scaling factor of 100 representing 10^5 singly-charged ions. The lines are only a guide for the eye. An experimental point measured with a natural potassium beam is also displayed for comparison, however as the 2 Pa pressure can not be reached with the current flow meter, the value was extrapolated using the trend of Fig. 9.

370 the GPIB, the effect on the emittance is small when the number of ions is increased (a few %) as can also be seen in
 371 table 3. It can nonetheless be seen for the simulations with 10^4 particles as the uncertainty is then only 0.4%.

372 Simulations were performed to get the trends on transmission and transverse emittance after the GPIB as a function
 373 of the buffer gas pressure, the quadrupole field frequency and the RF voltage. The extraction was chiefly simulated at
 374 3 keV but as we are in a non-relativistic regime the emittance at that energy can simply be converted to what it would
 375 be at 30 or 60 keV by:

$$\varepsilon(E_2) = \sqrt{\frac{E_1}{E_2}} \varepsilon(E_1) \quad (4)$$

376 where $\varepsilon(E_i)$ denotes the emittance at energy E_i . The emittances reported in Fig. 8 and 9 must thus be divided by a
 377 factor of respectively ≈ 3.2 and ≈ 4.5 to compare them with the specifications at 30 keV and 60 keV.

378 7.3. GPIB in CW mode

379 The first tests of the GPIB were performed in continuous beam (CW) mode as it is less demanding for material
 380 (no HV fast switches needed) as well as for the control system. It is anyhow a mode in which the GPIB will have to

Figure 9: Simulated effect of the pressure of buffer gas on the transverse emittance at $\sqrt{6}$ -RMS (95% of the ions) and on the transmission through the whole GPIB when the beam is extracted at 3 keV. For these simulations, the emittance ($\sqrt{6}$ -RMS) of the incoming beam before entering the GPIB is set at 25π .mm.mrad, $U_{RF} = 2$ kV, $f = 979$ kHz ($q = 0.5$ for mass $m = 102$ u). 10^3 particles were flown in the simulations with a scaling factor of 100 representing 10^5 singly-charged ions. The lines are only a guide for the eye. An experimental scan using a natural potassium beam is also displayed for comparison, the coloured band indicating the 1σ confidence interval. In that case, the pressure is deduced from the flow controller settings as described in section 4.1.

381 work for some of the experiments that do not want bunched beams in DESIR. In such a configuration, transmission
 382 is one of the key issues while the cooling is expected to be worse than in bunched mode as the ions spend less time
 383 in the buffer gas (a few 100 μ s, depending on initial energy, gas pressure, DC ramp...). It was however not observed
 384 to depend strongly on the beam current up to at least a few nA (i.e. the upper limit of what is expected for DESIR
 385 radioactive ion beams) as the ion density stays low in CW mode.

386 An electrical sweep type emittance scanner [35] initially built for testing the COLETTE RFQ emittance reduction
 387 [12, 36, 37] was used to measure the transverse emittance before and after the GPIB in both the horizontal and vertical
 388 planes. It was first installed after the quadrupole triplet immediately following the ion source (see Fig. 7) and then 1 m
 389 after the GPIB. The ion source has an emittance of 18π .mm.mrad ($\pm 25\%$) in each plane at 30 keV quite typical of
 390 a FEBIAD source but a little lower than what is expected from the GANIL accelerators. When the line is grounded
 391 downstream from the GPIB (meaning the ions have a 30 keV energy) the measured emittance (Fig. 10) is (2.9 ± 0.5)
 392 π .mm.mrad consistent with what was expected from the simulations and in compliance with the needs of the setups
 393 downstream in the DESIR hall.

394 The transmission was measured as a function of various parameters (HV platform voltage, buffer gas pressure,
 395 frequency, RF voltage, beam current...) and especially the Mathieu q parameter with a $^{nat}\text{K}^+$ beam using the Faraday
 396 cups before and after the GPIB to get an absolute measurement of the beam current. These are wide enough (40 mm
 397 diameter) to intercept all the ions with the correct optical settings. For the q parameter scans the frequency was kept
 398 constant as it is difficult to adjust quickly due to the balun circuit and the voltage was thus varied. The transmission
 399 depends on all the aforementioned parameters but it was systematically observed to be bad below $q = 0.2$ and frequently
 400 an optimum was found close to $q = 0.65$ (see Fig. 11). In addition to the intrinsic transmission of the GPIB, the injection
 401 through the narrow opening has also been observed to be a key point for the global transmission. This last point can
 402 be tricky as it is not perfectly reproducible from one measurement to another if the source has been switched off in
 403 between. This is probably due to the combination of thermal effects playing on the alignment of the beam with respect to
 404 the beamline axis and of the small opening of the first quadrupole triplet. A record transmission efficiency of 96(1) %
 405 was observed in CW mode after patiently optimizing all the optics upstream from the GPIB but transmissions above
 406 70% are routinely achieved without much effort. The transmission was also studied with an extraction at 3 keV and
 407 similar efficiencies were observed. It is also worth noting that this transmission curve is not much affected by the beam

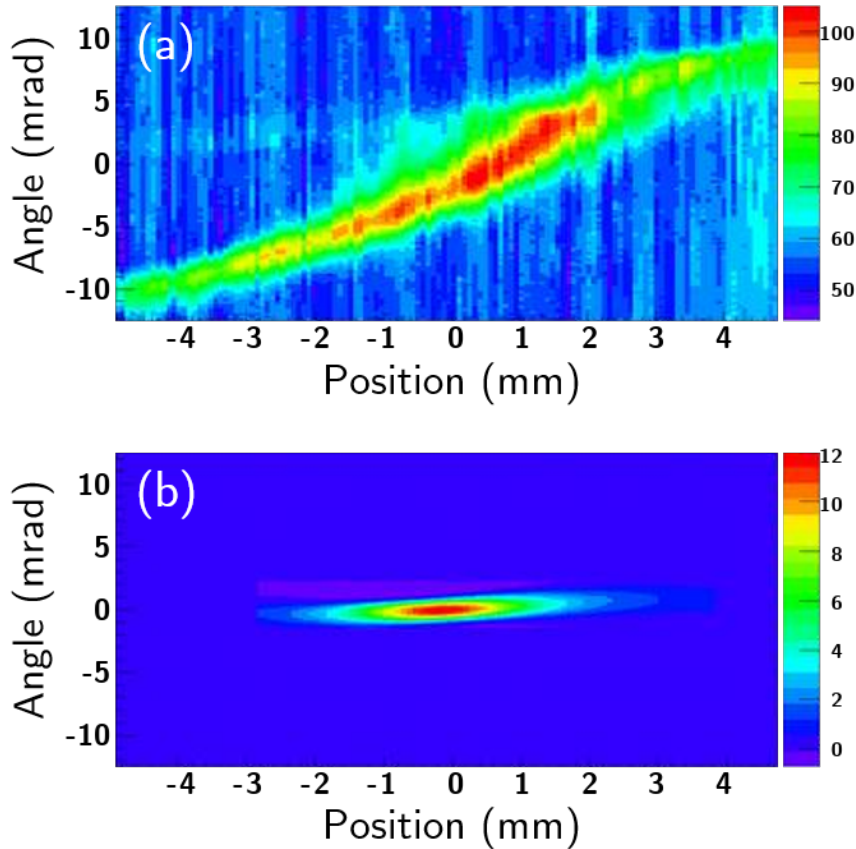

Figure 10: Emittance measured with an electrical sweep type emittance scanner before (a) and after (b) the GPIB in the horizontal plane (x, x') at 30 keV. The absolute color scale is not directly comparable between the two images as the control and command system was modified in between to help reduce the fluctuations. A much shorter time was thus necessary to obtain the same statistical precision on each point. The $\sqrt{6}$ -RMS emittance (95% of the ions) is 18π .mm.mrad before the GPIB while it is only 3π .mm.mrad after. The same reduction is observed in the vertical plane with quite similar pictures. During these measurements, the beam current was 1.2 nA.

408 current up to at least a few nA, the measured curves fitting inside the bounds of the "long-term fluctuations" of Fig. 11.

409 The experimental transmission data is plotted as a function of buffer gas pressure in Fig. 9 only above 0.16 Pa
 410 (10% of the range of the He flow controller). At this value the number of collisions is large enough to disturb the ion
 411 motion but not to cool it efficiently leading to a very poor transmission. The latter then improves as the cooling gets
 412 more efficient with increasing pressure as expected from the simulations. We did not investigate specifically charge
 413 exchange issues as it is expected to be negligible with a singly-charged potassium beam in ultra-pure helium at the low
 414 energies involved.

415 7.4. Preliminary studies of the GPIB in bunching mode

416 Though the final control system will enable switching five electrodes at a time at the exit of the GPIB the first
 417 bunching tests have hitherto been carried out switching only one electrode as all the fast switches needed were not yet
 418 available. In bunching mode, the time of flight distribution of the ions is measured either with the Faraday cup (large
 419 peak current) or with the MCP (if the number of ions is lower than a few 10/bunch). Typical bunch durations are in
 420 agreement with what was expected from the simulations with only one switched electrode ($\sim 1 \mu\text{s}$).

421 The energy distribution can also be investigated using a retarding grid placed in front of the MCP detector. Due
 422 to the compact geometry of the detector and in order to avoid sparks, the grid can not be biased much higher than

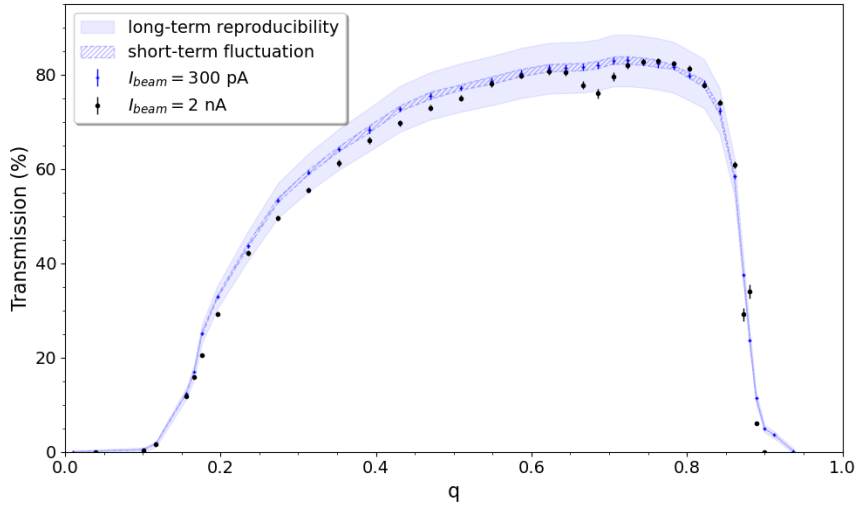

Figure 11: Example of measured transmission of a $^{\text{nat}}\text{K}$ beam through the GPIB in CW mode as a function of the Mathieu q parameter (assuming $m = 39$ u) for $f = 900$ kHz, $P \approx 0.8$ Pa for a beam current of 300 pA (1.9×10^9 ions/s) corresponding to $\approx 7.5 \times 10^5$ ions inside the volume of the GPIB at once. The coloured band labelled "short-term fluctuation" indicate the 1σ confidence interval for each measurement point while the hatched one shows an estimate of the reproducibility based on measurements performed in apparently similar conditions but several days apart (the beamline being shut down, restarted and returned in the meantime). It can be noted that the transmission does not fall to 0 at the higher limit of the first stability region ($q > 0.908$) due to the small fraction of ^{41}K (also observed in the Penning traps) for which the q parameter is lower meaning the true limit above which no transmission should be seen is $q_{\text{max}} \approx 0.908 \times 39/41 \approx 0.95$. A measurement performed with a beam current of 2 nA (1.3×10^{10} ions/s) is also displayed showing there is little transmission loss if any.

423 2 kV. The energy spread measurements are thus performed with an extraction energy below 2 keV (downstream HV
 424 platform biased at a voltage >28 kV). An example of simultaneous measurements with the MCP of the time and
 425 energy distributions is shown in Fig. 12. Note that the observed energy spread may be somewhat overestimated due to
 426 inhomogeneities of the voltage in the grid plane that are currently under investigation on a dedicated test bench.

427 SIMION simulations have shown the GPIB should be able to meet the requirements of the experiments foreseen
 428 in the DESIR hall. Either time or energy dispersion can be favoured playing especially on the timing sequence of
 429 the switching of the five exit electrodes. Many other parameters have nonetheless an impact on the time and energy
 430 distributions of the extracted ion bunch: number of trapped ions, RF voltage, shape and amplitude of the DC ramp
 431 inside the GPIB, width and depth of the potential well created at the end of the GPIB, gas pressure... A detailed study
 432 concerning the extensive tests in progress will be published later.

433 8. Conclusion and perspectives

434 The future cooler and buncher of the soon-to-be-built DESIR low-energy hall at GANIL has been assembled at
 435 LP2i-Bordeaux and tested with a 30 keV $^{\text{nat}}\text{K}^+$ beam. The transmission and reduction of the emittance expected based
 436 on SIMION simulations have been demonstrated in continuous mode even with the highest beam current that will be
 437 authorized in DESIR. The systematic characterization of the GPIB is however still ongoing in particular concerning
 438 the effect of higher voltages on the performances and the different bunching modes to fit the needs of each of the setups
 439 in DESIR. None of the data collected so far however indicate that the GPIB would not be able to reach the requirements
 440 eventually. The development is at the moment focused on the coupling with the PIPERADE double Penning trap as
 441 the whole beamline at LP2iB is now operational. The move to GANIL is presently planned for 2025.

Figure 12: Time and energy distributions of $^{\text{nat}}\text{K}^+$ bunches released by the GPIB, simply switching the first extraction electrode with an extraction energy of 1.89 keV as measured with the MCP detector and its retarding grid. The cooling time inside the GPIB was 20 ms, the RF parameters were $f = 999$ kHz and $U_{RF} = 1125$ V corresponding to $q = 0.71$ for $m = 39$ u and the buffer gas flow was set at 50% of the controller range (≈ 0.8 Pa according to simulations). The energy FWHM is $\Delta E = 27$ eV while the time of flight FWHM is $\Delta t = 0.7$ μs .

442 Acknowledgements

443 Funding: The PIPERADE project including the GPIB was supported by Région Aquitaine (convention 2011 1604
444 001), Agence Nationale de Recherche (ANR-2011-BS04-020-02) and the Max Planck Society.

445 The technical drawings of ISCOOL on which the mechanical design of the GPIB was based were provided by
446 CERN. Expert advices given by J.-F. Cam from LPC Caen have been a great help in designing the RF system of the
447 GPIB as was the assistance provided by L. Lasne from the University of Bordeaux with both the balun circuit and the
448 electronics of the switches. We are also grateful to F. Delalee and L. Serani for their help in the early stages of the
449 project.
