## ABSTRACT

We consider the problem of program clone search, i.e. given a target program and a repository of known programs (all in executable format), the goal is to find the program in the repository most similar to a target program – with potential applications in terms of reverse engineering, program clustering, malware lineage and software theft detection. Recent years have witnessed a blooming in code similarity techniques, yet most of them focus on function-level similarity while we are interested in program-level similarity. Consequently, these recent approaches are not directly suited to program clone search. Indeed, our study shows that prior similarity approaches are either too slow to handle large repositories, or not precise enough, or yet not robust against slight variations introduced by compilers, source code versions or obfuscations. We propose a novel spectral analysis method for program-level similarity called Programs Spectral Similarity (*PSS*). In a nutshell, *PSS* one-time spectral feature extraction is tailored for large repositories of programs, making it a perfect fit for program clone search. We have compared the different approaches with extensive benchmarks, showing that *PSS* reaches a sweet spot in terms of precision, speed and robustness.

similarities (coined *program similarity* in the following), that is, computing a similarity index between whole programs which is capable of telling at which degree two programs are similar – with potential applications in terms of reverse engineering, program clustering, malware lineage and software theft detection.

Searching similarities between x86 or ARM binaries over a large program repository is necessary when the original program written in source code is unavailable, which happens with commercial off-the-shelf (COTS), legacy programs, firmware or malware. For example, detecting malware clones is a major issue [4, 17, 55, 71], as most malware are actually variants of a few major families active for more than five years<sup>1</sup>. Another application is the identification of libraries [3, 19, 31, 35, 67, 68], which is both a software engineering issue and a cybersecurity issue due to vulnerabilities inside dynamically linked libraries. The problem of library identification, while in between programs and functions in terms of size, is much closer to the case of program clones by its nature – libraries are not arbitrary collections of functions and require inter-procedural analysis.

*In all these cases, we see the function-level approach as only a proxy to a problem which is by nature at the level of programs. Moreover, it is necessary for patch and firmware analysis [73], or software theft detection [19, 31, 56], to consider a more global view of the code.*

Given its potential applications and challenges, the field of similarity detection has been extremely active over the last two decades, starting from the pioneering work of Dullien in 2004 [21, 22] on call-graph isomorphisms and the popular BinDiff tool for recognizing similar binary functions among two related executables. Other approaches include for example symbolic methods [27], graph edit distances [33, 42] and matching techniques [4, 71]. Interestingly, the last five years have seen a strong trend toward machine learning based approaches to binary function similarity [18, 50, 53, 72, 75].

**Program clone search.** Given a query composed of a *target program* and a repository, the *program clone search* ranks repository programs by their similarity to the target program. The search is successful if the most similar program is a *clone* of the target program. These clones could have been (i) compiled from the same source code with a different compiler chain, or (ii) produced using a slightly different version of the source code.

**The challenges.** Program clone search presents specific challenges compared to standard function similarity. (1) As already stated, it requires comparing programs, i.e. much larger objects than functions, hence similarity checks must be scalable in typical program sizes; (2) We do not consider two programs taken in isolation, but a target program and a (possibly large) program repository, hence the need

<sup>1</sup><https://www.cisa.gov/uscert/ncas/alerts/aa22-216a>

for very efficient similarity checks that will be iterated over all the programs in the repository; (3) The repository could contain similar but slightly different programs, due to variations in compilers or code versions. Clone search must be robust to such variations; (4) Finally, the technique must work equally well on stripped binary codes (where symbols have been removed at compile time), handle the case where external function names are unavailable (for example IoT device firmware), and handle lightweight obfuscations (such as adding deadcode, or hiding literal identifiers).

All these constraints do not fit well with prior work on similarity, as state-of-the-art is increasingly focused on *function-level* similarities<sup>2</sup>, with unclear scalability toward the program-level case. For example, we found in our experiments that SMIT [33] takes more than 43 hours to compute a similarity index between the main library of Geany and the cp command, while DeepBinDiff [20] is reported to take 10 minutes to compute basic bloc matching on small binaries from the Coreutils package.

**Problem and goal.** *From the program clone search point of view, there is a strong need for a binary-level program-level similarity technique that is precise, robust to slight variation, and fast enough to be able to operate over large code bases. This is exactly what we want to address in this paper.*

**Our proposal.** We explore the application of *spectral graph analysis* [13] to the problem of program clone search. It seems a very good starting point as, on graphs, it is both cheap and competitive against graph edit distances [64] in terms of precision. Yet, programs are not standard graphs: on the one hand programs seen as graphs can be very large (especially at the binary level), while on the other hand they are highly structured due to their function hierarchy.

We take advantage of this specificity and propose **Program Spectral Similarity (PSS)**, the first spectral analysis tailored to *program* similarity. The techniques extract *eigenvalues* related features from both function call graphs and control flow graphs, and take advantage of a *preprocessing* step (done once for the whole program repository) to achieve similarity checks in time *linear in the number of functions of the program* (done for each program in the repository), making it a perfect fit for program clone search – most prior works are at least quadratic.

We experimentally show that *PSS* outperforms state-of-the-art approaches and is resilient to code variations as well as lightweight obfuscations. Moreover, *PSS* does not rely on *literal identifiers* (e.g., function names, constant string values), making it robust against a range of basic obfuscations. In our experiments, a program clone search with *PSS* (optimized version) takes on average less than 3s (0.3s and 0.44s for Linux and IoT benchmarks). As a comparison, the function embedding Gemini [72] requires roughly 2 minutes per clone search.

We set up a strong comprehensive evaluation framework (14 competitors and 3 baselines) to systematically compare *PSS* with state-of-the-art methods, covering string based methods [67, 68], graph edit distance [26, 33], N-grams [32], vector embedding [18, 50, 53, 72], standard spectral methods [26] and matching algorithms [4, 71]. Our experiments cover our own dataset of diverse open-source

<sup>2</sup>According to Haq and Caballero [30], since 2014, among 40 binary code similarity approaches, only 7 approaches have taken programs as input.

projects along with classical Coreutils, Diffutils, Findutils, and Binutils packages along two dimensions (optimization levels and code versions) for a total of 950 programs. Moreover, we consider part of the BinKiT dataset [41] (96K samples), covering four optimization levels, 9 compilers, 8 architectures and 4 obfuscations. Finally, we gather 19, 959 IoT malware and 84, 992 Windows goodwares.

**Contribution.** As a summary, we claim the following:

- A novel technique named *PSS* (together with its optimization *PSS<sub>O</sub>*) for code similarity (Section 4), tailored to *program* clone search over *large* repositories. *PSS* is the first spectral technique tailored to program-level similarity. Especially, *PSS* takes advantage of a preprocessing step to perform latter similarity checks in time linear w.r.t. the number of functions in the program, making it a perfect fit for program clone search over large repositories;
- A comprehensive evaluation framework for program clone search (Section 5), encompassing (1) 97,760 programs from BinKiT [41], 19,959 IoT malware, 84,992 Windows programs and a smaller Linux dataset of 950 programs, and (2) three baselines and 14 state-of-the-art methods – 10 of them being reimplemented. *The complete framework is available online, which is rare in this field* [52];
- Experimental evidence (Sections 5) that *PSS* reaches a sweet spot in terms of speed, precision and robustness, making it a perfect fit for program clone search, where prior works in the field are more specialized to function-level similarity evaluation. Especially, *PSS* appears to scale well and to retain good precision in demanding clone search scenarios (cross-compilers, cross-architecture or obfuscation);
- Finally, as side results, we show that prior work targeting on function clone search cannot cope with the program clone search setting due to scalability issues, and we propose two simple (still, not yet identified) methods based on literal identifiers (constant string values and external function names), which despite their simplicity appear to perform rather well when these identifiers are available.

Besides providing a novel and efficient method for program clone search, our results also shed new light on prior work on code similarity. First, we make the case for the program clone search application scenario and show that it behaves differently enough than the well-studied pairwise function similarity setting, requiring dedicated methods. Second, we are the first to pinpoint the separation in prior work between techniques using literal identifiers and those that do not. We identify two simple methods (*FunctionSet* and *StringSet*) as competitive when such literals are available. Third, we show the potential of dedicated spectral methods for program clone search. Overall, we believe that these results pave the way for novel research directions in the field.

## 2 PROBLEM STATEMENT

### 2.1 Program clone search procedure

Given an unknown *target program P* and a *program repository R*, the goal is to identify a *clone of P* in *R*.

A clone of a program *P* is defined as follows:

Figure 1: Architecture of a program clone search procedure.

- A program  $Q$  compiled from the same source code  $S$  as  $P$ , but with a different compiler toolchain is a clone of  $P$ . For example,  $P$  has been compiled with GCC v9.1 using the optimization level  $-O0$  from the source code  $S$ , and  $Q$  has also been built from  $S$  using the same compiler but another optimization level, say  $-O3$ ;
- A program  $Q$  compiled from another version of  $P$  source code is a clone of  $P$ . For example, both instances of the git application compiled from two source code versions, say v2.35.2 and v2.37.1, are clones.

In the last case, we have to be a bit careful. Indeed, we can only consider incremental versions of an application or library, not major revisions that completely change the source code.

Figure 1 illustrates a clone search procedure architecture. Note that all along, we suppose that there is no exact copy of  $P$  in the repository  $R$ . The repository is a database containing enough information for a clone search procedure. As a result, in practice, a repository is quite an extensive program database w.r.t. the application domain (firmware, plagiarism, malware, etc.).

An evaluation of clone search procedures should take into consideration the three criteria below in order to be realistic:

- The efficiency w.r.t. both the size of the unknown target program and the size of the repository,
- The robustness not only to compiler toolchains but also to slight program variations coming from different source code versions,
- The ability to deal with stripped programs. Moreover, external symbols are not necessarily available when dealing with firmware, lightweight obfuscations, or yet from payload extracted from packers[12].

As we said previously, the main difference between program clone search and function clone search is the size of the binary codes, which is much larger in the case of programs.

At a high level, all program clone search procedures work in a similar way. The repository is already built, and the query process is divided into three steps:

- (1) **Query preprocessing.** Upon query, we receive the target program  $P$ . We can perform some preprocessing at this step, extracting relevant features for the rest of the procedure;
- (2) **Similarity checks.** For each program  $Q \in R$ , we perform a similarity check with a similarity metric  $M$  on  $(P, Q)$  – possibly taking advantage of the preprocessing – and record the computed similarity index  $M(P, Q)$ ;
- (3) **Decision.** The program  $Q_{best}$  with the highest similarity index is considered the most similar. The program clone search succeeds if  $Q_{best}$  is a clone of  $P$ , otherwise it fails.

Table 1: Clone searches results.

Framework	Score	Total runtime (preprocessing time included)
<i>Asm2Vec</i> [18] †	0.7	35h
<i>Gemini</i> [72] †	1	17h
<i>SAFE</i> [53] †	0.95	160h
<i>αDiff</i> [50] †	1	140h
<i>LibDB</i> [68] †	1	2h
<i>PSS</i>	1	<b>26s</b> (includ. 26s or preprocess)

† learning time not included

## 2.2 Motivating example

Let us consider a repository containing 1420 libraries obtained from the compilation of 20 libraries<sup>3</sup> with four optimization levels, five versions of GCC, four versions of clang, and to the 32 and 64 bits x86 platforms. Next, let us imagine we have the 20 libraries as targets (compiled for x86 32 bits with gcc 6.4 and the  $-O2$  optimization level).

Lifting function-level clone searches in order to detect program-level clones is attractive. However, to obtain a similarity index between two programs from function embedding methods, we need to match their functions. We define as the similarity metric:

$$F(P, P') := - \sum_{x \in \text{embeds}(P)} \min_{y \in \text{embeds}(P')} \|x - y\|_2$$

We consider the following function-level methods and lift them to program-level as just explained: *Asm2Vec* [18], *Gemini* [72], *SAFE* [53], *αDiff* [50]. We also consider *LibDB* [68], which is directly designed for libraries (i.e., large piece of code).

**Results.** We report in Table 1 the proportion of successes that we call the precision score, as well as clone searches total runtime. *PSS* is precise and successful in all clone searches. Most function-level methods can also find a clone in all clone searches. However, *PSS* takes only 26s in total, while pure function embedding methods take from 17h with *Gemini* to 160h with *SAFE*. Even with pre-filtering, *LibDB* is close to 2h. Moreover, *PSS* runtime is due to its preprocessing; the total similarity checks runtime is negligible. As a result, *PSS* scales up to large repositories with good precision.

## 3 BACKGROUND

**Graph similarity, GED and spectral distance.** As programs can be naturally seen as graphs, any good notion of graph similarity is in principle a good candidate for a good program similarity metric.

Graph edit distance (GED) is such a good notion [28]. GED is the smallest cost of an edit path between two graphs, i.e. the smallest transformation going from one of the graphs to the other. Graph edit operations typically include removing or adding a vertex or an edge. Yet, the main drawback of GED is that it is NP-hard. Worst, usual approximations have a complexity of  $O(n^3)$  [66] where  $n$  is the number of nodes in the graph, which is far too expensive for graphs coming from programs. As an example, the graph edit

<sup>3</sup>From packages libiconv, coreutils, libtool, gss, gdbm, libtasn1, gsl, libmicrohttpd, osip, readline, gsaal, lightning, recutils, gmp, libunistring, and glpk.

distance method *SMIT* [33] is the slower of all the tested methods in the results shown in Table 4, with 3634 hours of computation (our method takes 26 minutes).

The spectral distance between graphs provides an interesting trade-off, as it gives a rough approximation of the graph edit distance between graphs [70] for an affordable linear cost once eigenvalues are computed.

**Spectral Graph Analysis.** An undirected graph  $G = (V, E)$  of  $n$  vertices is represented by an  $n \times n$  adjacency matrix  $A$ , where  $a_{i,j}$  is one if  $(V_i, V_j) \in E$  and zero otherwise. Let  $d_i$  be the degree of the vertex  $V_i$ .

It is useful to compute the Laplacian matrix [13]  $L$  of  $G$ . An eigenvalue  $\lambda$  and its corresponding eigenvector  $\vec{u}$  is a solution to the equation:  $(L - \lambda I) \vec{u} = \vec{0}$ .

The spectrum is the set  $\{\lambda_1(G), \dots, \lambda_{|G|}(G)\}$  where  $\lambda_1(G) \geq \dots \geq \lambda_{|G|}(G)$  and where  $|G|$  is the number of vertices in  $G$ . The enhanced Lanczos algorithm [58] computes the spectrum in time  $O(dn^2)$ , where  $d$  is the average degree of  $G$ .

The starting motivation for using graph spectrum is that two isomorphic graphs have the same spectrum; however, the converse is not true. Nevertheless, the spectrum may be used to compare graph similarities. For this, we define the spectral distance between  $G_1$  and  $G_2$  (analogous to [38]):

$$sD(G_1, G_2) := \sqrt{\sum_{i=1}^{\min(|G_1|, |G_2|)} (\lambda_i(G_1) - \lambda_i(G_2))^2}.$$

## 4 PROGRAM SPECTRAL SIMILARITY (PSS)

Spectral analysis is a known approach to detect patterns and anomalies in graphs. Applying spectral analysis to the whole control flow would be firstly too resource costly because of the number of instructions and of basic blocks and secondly because it is not enough stable with respect to compiler toolchains, optimizations and obfuscations.

As a result, our key insight is that a program has more structure than a mere graph: there is a call graph over functions while local functions hold their own control flow graph. We take advantage of this hierarchical structure to devise a quick and stable similarity metric called *Program Spectral Similarity (PSS)*.

The *PSS* method is based on the combination of two criteria.

- The first measure is the spectral distance between call graphs, including both internal and external calls<sup>4</sup>. Moreover, compiler optimizations have a small-scale effect on the call graph, at least on external function calls.
- The second measure is a coarse spectral analysis of function control flow graphs, simply considering their number of edges, since it is related to the sum of the eigen-values as showed below.

By the way, we tried to consider only the control flow graphs, and we found that the results were worse than when both above criteria were considered.

The *PSS* method proceeds into two independent steps : preprocessing step, which is done once and for all and similarity check step, which is made for each candidate.

<sup>4</sup>Call graphs are useful on a number of tasks. For example, GraphEvo [69] has been able to understand software evolution through call graphs.

## 4.1 Preprocessing

Figure 2: A call graph.

Given a program  $P$ , the preprocessing first begins by building the function call graph  $CG$  of  $P$ , including local and external (API) calls. An example of a function call graph is given in Figure 2. It contains external calls such as a call to `mempcpy` as well as local functions such as `sub_403780`. From this, we extract two key vector-features  $(\vec{v}, \vec{w})$  of  $P$  as follows:

- From an undirected version of the call graph  $CG$ , we compute the spectrum  $\Lambda = \{\lambda_1(CG), \dots, \lambda_n(CG)\}$ , and we compute  $\vec{v} := \frac{\Lambda}{\|\Lambda\|_2}$ , the normalized spectrum of the call graph;
- We compute the number of edges  $E = (e_1, e_2, \dots, e_k)$  from each control flow graph  $F_i$  of local functions in descending order, and we normalize  $E$  as previously:  $\vec{w} := \frac{E}{\|E\|_2}$ . Note that the number of edges is kind of a spectral measure since it is related to the spectrum by the relation  $2 \times e_i = \sum \lambda_j(F_i)$ .

Recall that  $\|\cdot\|_2$  is the Euclidean norm. We normalize features  $\vec{v}$  and  $\vec{w}$  to deal with difference between program sizes.

## 4.2 Similarity check

Given two programs,  $P_0$  and  $P_1$ , the preprocessing step has computed features  $(\vec{v}_0, \vec{w}_0)$  from  $P_0$ , and  $(\vec{v}_1, \vec{w}_1)$  from  $P_1$ . The similarity check outputs a similarity index by averaging two measures. The first measure (1) is related to call graphs, while the second (2) is related to function control flow graphs. Then, the similarity metric *PSS* is defined as the average of both above measures (equation 3).

$$simCG(P_0, P_1) := \sqrt{2} - \sqrt{\sum_{i=0}^{\min(|\vec{v}_0|, |\vec{v}_1|)} (v_{0,i} - v_{1,i})^2} \quad (1)$$

$$simCFG(P_0, P_1) := \sqrt{2} - \sqrt{\sum_{i=0}^{\min(|\vec{w}_0|, |\vec{w}_1|)} (w_{0,i} - w_{1,i})^2} \quad (2)$$

$$PSS(P_0, P_1) := \frac{simCG(P_0, P_1) + simCFG(P_0, P_1)}{2\sqrt{2}} \quad (3)$$

## 4.3 An Optimization $PSS_O$

We propose  $PSS_O$ , an optimized version of *PSS*. Instead of computing the complete spectrum  $\Lambda$ , we compute only the first hundred greater eigenvalues so that  $\Lambda = \{\lambda_1(CG), \dots, \lambda_{100}(CG)\}$ . For this, we take advantage of matrices sparsity to use an implicitly restarted version of the Lanczos algorithm proposed by the ARPACK library [47].

**Table 2: Complexity of program clone search procedures**

Method	Class	Similarity <sup>†</sup> check	Preprocessing <sup>‡</sup>
<i>SMIT</i> [33]	GED	$O(n^4)$	$O(dn)$
<i>CGC</i> [71]	Matching	$O(n^4)$	$O(dn)$
<b><i>MutantX-S</i></b> [32]	<b>N-gram</b>	$O(1)$	$O(i)$
<i>Asm2Vec</i> [18]	Functions ML	$O(n^2)$	$O(n)$
<i>Gemini</i> [72]	Functions ML	$O(n^2)$	$O(n)$
<i>SAFE</i> [53]	Functions ML	$O(n^2)$	$O(n)$

<b><i>PSS<sub>O</sub></i></b>	<b>Spectral</b>	$O(n)$	$O(dn)$

$n$ : # functions,  $i$ : # instructions,  $s$ : # constant string values

$d$ : # calls per function,  $m$ : # basic blocks in a function,

<sup>†</sup> between two programs

<sup>‡</sup> performed once for the whole clone search

#### 4.4 Method runtimes

Recall that a repository is a database of preprocessed programs. A given unknown target program is first preprocessed, then, from the extracted features, a similarity check is made on the repository. It is clear that the query runtime depends multiplicatively on the size of the repository. In other words, if the runtime of a similarity check is  $T(n)$ , the preprocessing runtime is  $P_T(n)$ , and the repository size is  $M$ , then the complexity of a query is bounded by  $M \times T(n) + P_T(n)$ . As a result, all methods with similarity check runtime more than linear are not feasible, and this observation will be confirmed with benchmarks.

***PSS* and *PSS<sub>O</sub>* runtimes.** Graphs and Laplacian matrices are sparse in our application domain, offering quick eigenvalues computation. Nevertheless, the complexity of the query preprocessing, described in Section 4.1, is still  $O(dn^2)$ , where  $n$  is the number of functions and  $d$  is the average number of calls per function. However, once such preprocessing is done, the runtime of a similarity check, described in Section 4.2, is  $O(n)$ . Moreover, the runtime of the query preprocessing of *PSS<sub>O</sub>* is reduced to  $O(dn)$ .

**Comparison with prior work.** That is in contrast with function embedding methods which have a similarity check runtime of  $O(n^2)$  on this problem using a direct adaptation (see Section 2.2 for further details). Moreover, *DeepBinDiff* [20] contains a step with a linear assignment between basic blocs with a runtime of  $O(n^3m^3)$ . Worse, both the graph edit distance approximation *SMIT* [33] and the matching method of Xu et al. [71] have a complexity of  $O(n^4)$ . However, the runtime of *MutantX-S* [32], designed to scale up to large repositories, is only  $O(1)$  – yet experiments show its robustness is not fully satisfactory.

## 5 SYSTEMATIC EVALUATION

We evaluate the potential of *PSS* in terms of speed, precision and robustness – the ability to overcome changes in compilation.

**Then, we consider here the following Research Questions:**

RQ1 What are the fastest methods for clone search?

RQ2 What are the most precise methods for clone search?

RQ3 What are the most robust methods for clone search?

### 5.1 Datasets

**Basic dataset.** We first collect a limited dataset of 950 programs to study the full range of methods along different optimization levels and code versions. The average program has a size of 442 Ko. This dataset cover the Coreutils, Diffutils, and Findutils packages compiled with GCC v5.4 on the x86 architecture, and taken from the DeepBinDiff [20] dataset. Moreover, we add the Binutils package as well as 15 open-source projects, including *Bash*, *Code::Blocks Dia*, *Graphviz*, *Geany*, *Git*, *Lua*, *Make*, *OpenSSH*, *OpenSSL*, *Perl*, *Ruby*, *SDL*, *SVN*, and *VLC*, compiled by GCC v9.4 on an x86 architecture. Each unique source codes exists in four different *version levels*, and four different optimization levels.

**BinKit dataset.** To study scalable methods along different optimization levels, compilers, architectures, and obfuscations, we reuse two Linux programs datasets from BinKiT [41]:

- **Normal:** From 51 GNU software packages, 235 unique source codes were extracted. They are compiled with 288 different toolchains for a total of 67,680 programs of an average size of 201 Ko. It covers eight architectures (arm, x86, mips, and mipseb, each available in 32 and 64 bits), nine compilers (five versions of GCC and four versions of Clang), and the four optimization levels from -O0 to -O3;
- **Obfuscation:** Four obfuscation options (instruction substitution (SUB), bogus control flow (BCF), control flow flattening (FLA), and all combined) are considered using Obfuscator-LLVM as a compiler. The same architectures and optimization levels as before are covered, for a total of 30,080 programs of an average size of 514 Ko.

**IoT Malware dataset.** We consider 19,959 IoT malware samples from MalwareBazaar<sup>5</sup>, submitted between March 2020 and May 2022, spanning 8 architectures (mostly arm, mips, motorola and sparc). Using available meta-data from antivirus reports and YARA rules, we split the data into three families of clones: 12,357 Mirai, 5,842 Gafgyt, and 1,760 Tsunami.

**Windows dataset.** We assemble a dataset of 84,992 benign programs running under Windows operating systems (x86, Visual Studio). This amount to more than 50 GB of raw programs, with an average size of 771 Ko. Excluding security updates, the dataset contains more than 28,000 dynamic-link libraries. Samples are divided by target platforms (e.g., Windows 7).

### 5.2 Methodology

A *test field*  $(T, R)$  comprises targets set  $T$  and a repository  $R$ . We break down Basic datasets along version levels and optimization levels. For instance, the test field (-O0,-O1) of the subdataset "Coreutils

<sup>5</sup><https://bazaar.abuse.ch/>

Option" consists of a repository of Coreutils programs compiled with -O1 paired with the same programs but compiled with -O0 as targets. Similarly, we break down BinKiT datasets along optimization levels, compilers, architectures, and obfuscations.

**Measures of success.** Program clone search is an *information retrieval* task. The standard evaluation metrics of information retrieval are precision and recall. Because only some programs are similar, we focus on top-1 recall. We define the recall as equal to one if and only if a clone of the target is the most similar program in the repository, as ranked by a similarity metric. We define the precision *score* of a similarity metric as the average recall for (a) every target in a test field against a repository, and (b) the same when we exchange the targets set and the repository.

### 5.3 Competitors

We evaluate 14 competitors, 3 baselines and two new heuristics based on literal identifiers (constant string values and external function names) (cf. Table 3). 8 of these frameworks have been adapted (**A**) to the case of program clone search, as it was not their primary objective (e.g., function embedding). Moreover, 10 had to be reimplemented (**R**) because the original implementation was unavailable. As highlighted by Marcelli et al. [52], code similarity artifacts are rarely available, and even when they are, they are often incomplete.

**Baseline.** We first investigate basic heuristics such as  $B_{size}$ , the size of the program, and  $D_{size}$ , the size of the disassembled program. For instance, the similarity metric  $B_{size}$  is defined as  $B_{size}(a, b) := -|a - b|$ , where  $a$  and  $b$  are program sizes in bits. We also consider a crude shape of the call graph. Let  $n_1$  and  $e_1$  (respectively  $n_2$  and  $e_2$ ) be the number of vertices and edges of the first (respectively second) call graph. Then the similarity measure *Shape* is defined as:  $Shape(n_1, e_1, n_2, e_2) := \frac{\min(n_1, n_2)}{\max(n_1, n_2)} \times \frac{\min(m_1, m_2)}{\max(m_1, m_2)}$ .

**Standard spectral methods.** From the spectral method developed by Fyrbiak et al. [26], we derive two methods. The first, *ASCG* (**A**) (**R**), is based on the call graph. Let  $X$  and  $Y$  be the two spectrums in descending order of Laplacians of the two call graphs. There is a normalization  $X' := X/X_0$  and  $Y' := Y/Y_0$ . Then:  $ASCG(X', Y') := -\sum_{i=0}^{\min(|X'|, |Y'|)} |X'_i - Y'_i|$ . Likewise, we derive a method based on the control flow graph, *ASCFG* (**A**) (**R**). Instead of computing the spectrum from the call graph, we select the top 1000 eigenvalues from a reduced control flow graph as vectors  $X$  and  $Y$ .

**Graph edit distance.** We implement various basic GED-based methods. First, we implement *GED-0* (**A**) (**R**), a basic computation of the GED applied between call graphs. The algorithm goes back to the work of Sanfeliu and Fu [64]. Second, we implement *GED-L* (**A**) (**R**), a computation of the GED between call graphs with labels. The algorithm is presented by Fyrbiak et al. [26]. In our application, labels are sets of external function names. Third, we implement the specific GED computation of Hu et al. [33] called *SMIT* (**R**). We do not integrate the indexing tree of SMIT as we are more interested by their GED measure.

**Matchings.** We compare with the matching algorithm *CGC* (**R**) from Xu et al. [71]. This algorithm needs three parameters along with a complete classification of mnemonics. We perform preliminary works to find good values for these parameters.

**Table 3: Methods included in the evaluation.**

Framework	Class	A	R	Similarity check	LIR

A: Adapted for program clone search, R: Reimplemented

LIR: Some literal identifiers are required

**N-gram.** We reproduce *MutantX-S* (**R**) from the work of Hu et al. [32]. We extended it to multiple architectures. Each program is represented by the frequencies of 4-grams obtained from the opcode sequence. These frequencies are embedded into a 4096 dimensions vector by hashing.

**Function embeddings .** We define a simple similarity metric to compare embedding vectors sets. Let  $a$  and  $b$  be two sets of embedding vectors and  $F$  the similarity metric. We define:  $F(a, b) := -\sum_{x \in a} \min_{y \in b} \|x - y\|_2$ . We first consider *Asm2Vec* (**A**) [18]. We employ a unsupervised training strategy on the Basic dataset inspired by the original paper. Multiple training phases are performed with each time one optimization level for training, and one for testing. Then, we take *Gemini* (**A**) embedding from Xu et al. [72] in an optimistic setting. We build a version of the basic dataset retaining function names and employ these as ground truths for training. Moreover, we use the embedding of Massarelli et al. [53] with *SAFE* (**A**). We downloaded a pre-trained model made available by one of the authors. Lastly, we reproduce *αDiff* (**A**) (**R**) from the framework of Liu et al. [50]. It is tailored at binary function similarity between versions. We sample 25% of the *αDiff* dataset as our training set. *αDiff* incorporates external function names and in-out degrees in the call graphs.

**DeepBinDiff.** The framework *DeepBinDiff* from Duan et al. [20] attempts to match basic blocs between two binaries. The similarity metric computes the number of matched basic blocs by *DeepBinDiff* between two programs. Due to its runtime, we were unable to

perform experiments, and it is only considered inside the research question about speed.

**LibDX.** We reproduce the framework *LibDX* (R) from Kim et al. [67]. It extracts constant string values from well-defined read-only sections of programs. constant string values are compared with matchings and the tf-idf statistic.

**LibDB.** We reproduce the framework *LibDB* (R) from Kim et al. [68]. They combine function embeddings and matchings, while using constant string values as pre-filters. We re-implemented *LibDB* with our trained *Gemini* model and ScaNN [29] as the nearest vector search engine.

**String set method.** We invent a straightforward metric that compares constant string values inside programs. Let  $S_a$  be the set of all constant string values of a program  $a$ . The similarity metric is:

$$\text{StringSet}(a, b) := \frac{|S_a \cap S_b|}{|S_a \cup S_b|}.$$

**Function set method.** Xu et al. [71] describe a simple method that first matches functions between two programs by using only external function names and mnemonics similarities. Then, the similarity measure is computed by a distance over the two function sets. We simplify this idea and invent the similarity metric *FunctionSet*, which computes the Jaccard similarity index<sup>6</sup> between external function names. Let  $F_a$  be the external function names set of a program  $a$ . The similarity metric is:  $\text{FunctionSet}(a, b) := \frac{|F_a \cap F_b|}{|F_a \cup F_b|}$ .

We present in Table 3 the characteristics of the different methods considered here. We register the runtime complexity of a similarity check between two programs. We note as  $n$  the number of functions and  $m$  the number of basic blocs in a function CFG. We indicate whether a method requires literal identifiers. Note that machine learning approaches require a learning phase. Moreover, *Gemini* and *GCG* require manual classification of mnemonics.

**Implementation.** Disassembly is implemented by running the IDA Pro disassembler v7.5 along with a script from the Kam1n0 assembly analysis platform<sup>7</sup>. See the recent survey of Pang et al. [60] on disassembling for more details. Our experiments are run on a cloud server node containing two CPU with a frequency of 2.10 GHz and 20 cores per CPU. All reported runtimes are equivalent to runtimes using only one core.

## 5.4 Preliminary Evaluation, Method Selection

First, we want to identify methods unable to scale to large benchmarks, in order to not consider them in further analysis. We perform a speed assessment on the basic dataset of 950 programs, and remove the methods unable to achieve it in less than 1h30m.

**Results.** Results are presented in Table 4. Please note that we could not experiment on DeepBinDiff [20] (with an observed average of more than 10 minutes per similarity check, we estimate that it would have taken more than 20,000h to apply it to the whole basic benchmark), and the training time of ML-based methods is not counted in the reported timing.

Results show a significant dichotomy between methods, 10 of them being able to succeed in less than 1h30m (often far less), while the other ten methods require far more time (from 16h to 3634h).

**Conclusion.** This preliminary experiment shows that function-level clone search methods (typically based on ML) [18, 50, 53, 68, 72] or graph-edit distance approaches [26, 33, 64] cannot scale to program-level clone search. In the following, we will consider only the scalable-enough methods, namely our three baselines ( $B_{size}$ ,  $D_{size}$ , *Shape*), as well as *ASCG* [26], *MutantX-S* [32], *LibDX* [68] and our own  $PSS$ ,  $PSS_O$ , *StringSet* and *FunctionSet*.

## 5.5 RQ1: Evaluation of Speed

We report in Table 5 the runtimes and the preprocessing time on each dataset to be fully comprehensive.

**Basic.** On the Basic dataset containing 950 programs, our method is the slowest and takes 1h18m. Nearly everything is spent during the preprocessing. The adapted spectral method for call graph *ASCG* has similar runtimes.  $PSS_O$  takes only 15m8s, the optimization dividing the runtime of  $PSS$  by more than 5. *LibDX* takes 1m4s, and *StringSet* 38s. The N-gram method *MutantX-S* and the *FunctionSet* method are very fast and take less than ten seconds.

**Table 6: (RQ1) Runtimes per clone search (sec). Include preprocess. time. Significant preprocess. times reported in "( )"**

Dataset # Programs	Basic 1K	BinKiT 96K	IoT 20K	Windows 85K
<i>Bsize</i>	< 0.01	0.11	0.14	0.63
<i>Dsize</i>	< 0.01	0.11	0.14	0.63
<i>Shape</i>	0.02	0.05	0.06	0.31
<i>ASCG</i>	1.42 (1.42)	0.37 (0.21)	0.25 (0.06)	17.68 (16.60)
<i>MutantX-S</i>	< 0.01	0.57	0.64	3.00
<i>PSS</i>	1.41 (1.41)	0.49 (0.21)	0.39 (0.05)	19.17 (16.95)
<i>PSS<sub>O</sub></i>	0.27 (0.27)	0.30 (0.04)	0.44 (0.14)	2.29 (0.39)
<i>LibDX</i>	0.02s	5.09	1.40	12.43
<i>StringSet</i>	0.01s	1.40	1.69	18.47
<i>FunctionSet</i>	< 0.01	0.10	0.03	2.01

**BinKiT.** On the BinKiT dataset, which contains 97,760 programs of an average size of 313 Ko, *PSS* takes 190h, *PSS<sub>O</sub>* 116h, and *MutantX-S* is slower with 220h. With literal identifiers, *LibDX* and *StringSet* are much slower (1965h and 542h, resp.). *FunctionSet* is fast (37h).

**IoT Malware.** On the IoT dataset containing 19,959 IoT malware, *PSS* takes only 2h9m. It is faster than *MutantX-S* (3h34m). Surprisingly, *PSS<sub>O</sub>* is a bit slower than *PSS* and takes 2h26m. Among methods using literal identifiers, *FunctionSet* is fast, with less than 8 minutes in total. *LibDX* takes 7h47m, while *StringSet* is the slowest with 9h21m.

**Windows.** *PSS* takes 263h on the Windows dataset. That is far higher than *MutantX-S* (41h) and a bit higher than *StringSet* (253hh). However, *PSS<sub>O</sub>* takes less than 32 hours.

Table 6 reports average runtimes per clone search. We can see that *PSS* preprocessing time can sometimes be important, e.g., on large Windows binaries (16.95s vs. 2.22s on similarity checks). First, note that preprocessing time does not increase with the repository size. Second, *PSS<sub>O</sub>* is especially optimized for such cases, and its preprocessing time remains low in all cases.

#### Conclusion (RQ1)

*PSS* is often roughly as fast as *MutantX-S* on the larger datasets, yet it struggles on large Windows programs. *PSS<sub>O</sub>* remedies this default and is consistently faster than other approaches, but the baselines and *FunctionSet*. Interestingly, *StringSet* is slow on large benchmarks.

## 5.6 RQ2: Evaluation of Precision

We compute precision scores on each dataset. We report the results in Table 7.

**BinKiT.** *PSS* and *PSS<sub>O</sub>* attain a score of 0.621 on BinKiT, while the other spectral method *ASCG* has only 0.549. *MutantX-S* is well behind with 0.365. In fact, we show in Table 8 that it achieves scores of 0.01 in cross-architecture scenarios as well as against obfuscations. With literal identifiers, *StringSet* attains 0.970 and *LibDX* 0.884. The *FunctionSet* method has only a score of 0.491.

**IoT Malware.** *PSS* has a score of 0.863, close to *MutantX-S* (0.870). *PSS<sub>O</sub>* is very close with 0.862, while *ASCG* attains 0.759. With

**Table 7: (RQ2) Precision Scores**

Dataset	Basic	BinKiT	IoT	Windows
<i>Bsize</i>	0.17	0.176	0.819	0.196
<i>Dsize</i>	0.16	0.065	0.787	0.445
<i>Shape</i>	0.19	0.296	0.818	0.388
<i>ASCG</i>	0.24	0.549	0.759	0.444
<i>MutantX-S</i>	0.38	0.365	0.870	0.472
<i>PSS</i>	0.38	0.621	0.863	0.475
<i>PSS<sub>O</sub></i>	0.38	0.621	0.862	0.466
<i>LibDX</i>	0.70	0.884	0.707	0.044
<i>StringSet</i>	0.94	0.970	0.922	0.501
<i>FunctionSet</i>	0.87	0.491	0.624	0.426

literal identifiers, *StringSet* achieves a score of 0.922. Other literal identifier methods have some troubles. *FunctionSet* has a score of 0.624 because only very few external names are available. Moreover, *LibDX* attains 0.707 because *LibDX* extracts constant string values from read-only sections, which are scarce inside IoT firmware.

**Windows.** *PSS* attains a score of 0.475 on Windows, just above *MutantX-S* (0.472) and well above *ASCG* (0.444). *PSS<sub>O</sub>* is a bit behind *PSS* and *MutantX-S* with 0.466. Among methods with literal identifiers, *StringSet* attains 0.501. *LibDX* attains only 0.044. Again, *LibDX* extracts constant string values from well-defined read-only sections, which are not prevalent in Windows programs. As before, *FunctionSet* has a rather low score here of only 0.426.

#### Conclusion (RQ2)

*PSS* and *PSS<sub>O</sub>* are usually as precise as *MutantX-S* except in cross-architecture and obfuscations scenarios, for which *MutantX-S* fails. When literal identifiers are meaningful, *StringSet* is the most precise method in all datasets, while *FunctionSet* and *LibDX* struggle on IoT and Windows datasets.

## 5.7 RQ3: Evaluation of Robustness

The last evaluation measures the robustness of the ten clone search methods that survived the speedtest. For this, we consider four scenarios with (i) cross-optimizations, (ii) cross-compilers, (iii) cross-architectures and (iv) in the presence of obfuscations. The evaluation leans on the BinKiT dataset that we presented earlier.

**Results.** We report the most crucial test field scores in Table 8. When literal identifiers are available, *StringSet* and *LibDX* are very stable in our scenarios. *FunctionSet* is stable except in cross-architecture scenarios because external function names differ between architectures. Note that a strong limitation to this finding is that obfuscations used do not hide or encrypt literal strings or external calls (API). *PSS* and *PSS<sub>O</sub>* are much more robust than *MutantX-S* in cross-architecture and obfuscations scenarios. For instance, *MutantX-S* falls to 0.02 from the arm to mips architecture, while *PSS* maintains a score of 0.39. The more basic spectral method *ASCG* also falls to 0.08 in this scenario.

**Statistical analysis.** A common pitfall of similarity detection is that a method could in the end consider as similar two programs

**Table 8: (RQ2,RQ3) Precision scores on the BinKit dataset**

Category	Opt. level		Cross-compiler			Cross-architecture				vs. Obfuscation <sup>†</sup>

<sup>†</sup>: The BinKiT dataset does not consider any obfuscation of literal identifiers

**Table 9: (RQ3) Average rank-biserial correlation for *H*.**

Framework	Basic dataset	Framework	Basic dataset
<i>Bsize</i>	<b>0.02</b>	<i>PSS</i>	<b>0.06</b>
<i>Dsize</i>	<b>0.01</b>	<i>PSS<sub>O</sub></i>	<b>0.06</b>
<i>Shape</i>	<b>0.04</b>	<i>LibDX</i>	<b>-0.07</b>
<i>ASCG</i>	<b>0.08</b>	<i>StringSet</i>	0.45
<i>MutantX-S</i>	0.33	<i>FunctionSet</i>	0.20

based on some side aspects (e.g., architecture, compiler used or optimization version) considered as irrelevant from the clone search point of view. We evaluate the sensitivity of the different approaches to such bias through computing rank-biserial correlations between (a) similarity rank in new clone searches and (b) sharing an optimization level. We report average correlations in Table 9 (the lower, the better and less sensitive). *PSS*, *PSS<sub>O</sub>*, *ASCG* and *LibDX* have very small correlations of less than 0.08. On the other hand, the *StringSet* method correlation is moderate (0.45). The N-gram method *MutantX-S* has a lower correlation of 0.33 and *FunctionSet* has a small correlation of 0.20.

#### Conclusion (RQ3)

*PSS* and *PSS<sub>O</sub>* are robust to cross-optimization, cross-compiler, cross-architecture and obfuscation scenarios, while *MutantX-S* suffers significant precision loss in the cross-architecture and obfuscations cases.

## 5.8 Summary of our main results

**Key result.** Our novel spectral methods *PSS* and *PSS<sub>O</sub>* reach a sweet spot regarding the trade-off between speed, precision and robustness. They do not need any training phase, scale very well to large repositories and are very robust, even in cross-architecture or cross-compilers scenarios and in case of lightweight obfuscation. Therefore, they are the best candidates for intensive program clone search. Also, it is worth mentioning that direct adaptations of graph-based spectral methods lack precision compared to *PSS*, and that the

optimization *PSS<sub>O</sub>* is necessary over large programs. A summarized comparison with other methods is given in Table 10.

**Table 10: Overview of experimental comparisons**

Method	speed	precision	robustness	beware
<i>PSS/PSS<sub>O</sub></i>	+	+	++	
<i>MutantX-S</i>	+	+	--	
<i>StringSet</i>	--	++	++	string obf.
<i>FunctionSet</i>	++	-	-	fun. name obf. static linking

This large study also allowed to highlight that most prior approaches in the field [18, 50, 53, 72], mostly focused on *function-level* similarity, are far too slow for *program* clone search.

## 6 RELATED WORKS

Binary code similarities are extensively studied. As a testimony, the review of Haq and Caballero [30] reports numerous input and output granularities on which to study similarities.

**Pioneering approaches.** Dullien in 2004 [21] introduced a graph-based program diffing approach that constructs a call graph isomorphism. A follow-up [22] extended it to match basic blocks inside matched functions. These two results are the basis for the popular BinDiff program diffing plugin for the IDA disassembler. BinDiff aims to recognize similar binary functions among two related executables. In 2006, Kruegel et al. [44] presented an approach based on coloring small graphs with fixed size from the control flow graph to identify structural similarities between different worm mutations. In 2008, Gao et al. proposed BinHunt [27] to find differences between two versions of the same program. BinHunt employs symbolic execution with a constraint solver to prove that two basic blocks implement the same functionality.

**Program similarity.** The few recent works about program-level similarity [55, 73] have already been thoroughly discussed. Still, we can mention a few more approaches. N-gram methods compare instruction sequences [32, 39, 56, 65]. While we could have employed more fine-grained methods than *MutantX-S* [32] – for

example Exposé [56] considers trigrams inside a function matching, it quickly leads to serious scalability issues. Some other works explore similarities based on dynamic executions and input-output observations [2, 37, 49, 54]. Nevertheless, it is hard to thoroughly explore the execution space with dynamic traces – leading to poor precision, and handling large code repositories requires to automate the task of detecting the sources of input and output of all programs in the repository, which can be very complicated. Bruschi et al. [10] tackle the problem of detecting some malware inside a program by matching control flow graphs. But, again, this approach suffers from scalability issues (in the size of the programs) and is thus not amenable to the search over large code repositories. The symbolic method by Luo et al. [51] is robust to simple obfuscations as well as simple changes. However, the running time of symbolic execution is a critical issue on large programs, and anti-analysis obfuscation hinders symbolic approaches [6, 59]. We have already studied the matching method CGC [71]. A few other matching approaches [4, 9, 46] share the same strengths and weaknesses.

**Function similarity.** The last five years have seen a tremendous increase in the popularity of binary function similarity with machine learning [18, 50, 53, 72, 75]. Yet, as already discussed, these methods lead to poor scalability when applied to a program similarity setting. More expensive methods than function embeddings do exist. Notably, dynamic analysis seeks to build upon the semantics of binary codes instead of their mere structural properties. BinGo [11] analyzes various execution traces with concepts such as pruning. The work of Hu et al. [34] emulates binary functions to create semantic signatures. Pewny et al. [61] propose to translate binary code to an intermediate representation. This representation allows observing inputs and outputs of basic blocs. These frameworks suffer from the already mentioned pitfalls of dynamic execution: the exploration is either imprecise or very slow. Furthermore, it is unclear how to lift these methods to the case of program similarity, as comparing all functions between multiple codes is costly. Built on the idea of intermediate representation, several approaches [16, 45, 62] perform simplification before comparing. In FirmUp [15], the matching between intermediate representations incorporates multiple functions. The formula has to be transformed into an embedding. The larger the code segment it represents, the less precise the embedding is. Finally, other feature selection methods have been investigated: Rendez-vous [40] extracts statistical features at various granularities, while discovRE [23] and Genius [24] extract features such as the number of arithmetic instructions. Gemini [72] leverages static features from Genius into a machine learning framework.

**Source code similarity.** Computing source similarities can be performed with different structures such as Abstract Syntax Trees [7, 8, 74] or Program Dependency Graphs [8]. It is also possible to normalize instructions and compare code fragments [8, 36]. Matching tokens, fragments and structures is effective because there is no compiler optimization step which would introduce variations. Moreover, critical information such as types are lost by compilation, while data dependencies are harder to retrieve on binary programs.

**Graph similarity.** A key question in program similarity is how to compare graphs efficiently. New suggestions for graph similarities include novel graph kernels [25, 43, 57] and the use of machine learning to approximate intractable properties such as graph edit

distance [5, 48, 63]. Recently, the work of Bay-Ahmed et al. [1] introduced a new graph similarity metric incorporating both spectral information from the Adjacency Matrix and from the Laplacian. Moreover, the work of Crawford et al. [14] proposed spectral analysis as a similarity metric of real-world networks. Furthermore, the study of Fyrbiak et al. [26] reveals that spectral analysis can compete with more energy-intensive approaches such as GED.

**Library identification.** The pioneering BAT [31] has proposed three methods to library identification, based on strings, compression algorithms and edit distances between bit sequences. They report that edit distance computations are too costly, while strings can be easily obfuscated. OSSPolice [19] have developed similarity measures based on strings. The special structure of Java programs allows using properties such as class and package inclusions [3, 35] in order to identify Android libraries.

## 7 CONCLUSION

We consider the problem of searching program clones in large code repositories. While many works have been devoted to function similarity, the few existing techniques for program similarity suffer either from scalability issues over such large code bases, or low precision or low robustness to code variations. We propose a novel method called Program Spectral Similarity (*PSS*, and especially its optimized version *PSS<sub>O</sub>*) that reaches a sweet spot in terms of speed, precision, and robustness – demonstrating both high speed and good precision even in cross compilers or cross architecture set ups. This works open way to a more systematic study of spectral approaches for program clone search.
