## 11    **Highlights**

- 12     • Palygorskite-bearing marlstone is suitable for a use as a SCM
- 13     • Palygorskite-bearing marlstone exhibits a higher dihydroxylation (<sup>27</sup>Al MAS NMR),  
14     self-reactivity in water and compressive strength in cementitious media than smectite-  
15     bearing marlstone.
- 16     • Pozzolanic reactivity was significantly higher for systems with calcined palygorskite  
17     than calcined smectite only, as shown both by portlandite consumption (XRD) and C-  
18     (A)-S-H formation (<sup>29</sup>Si MAS NMR).

26 **Abstract**

1  
2 27  
3  
4 28 This article focuses on the use of two calcined marlstones as supplementary cementitious  
5  
6 29 materials, one with palygorskite and smectite (MS1) as clay phases and the other with smectite  
7  
8 30 only (MS2). The calcination and the reactivity of these two materials were first analysed by X-  
9  
10  
11 31 ray diffraction (XRD) and Magic Angle Spinning Solid State Nuclear Magnetic Resonance  
12  
13 32 (MAS NMR). The two calcined marlstones were combined with Portland cement to produce  
14  
15  
16 33 mortars and measure compressive strength. The XRD and <sup>27</sup>Al MAS NMR results showed that  
17  
18 34 800°C is an optimal calcination temperature and that both calcined marlstones can be used as  
19  
20  
21 35 supplementary cementitious materials. The reactivity of MS1 was found to be higher than that  
22  
23 36 of MS2. This was confirmed with compressive strength measurements which showed superior  
24  
25  
26 37 performance for mortars blended with calcined MS1 rather than calcined MS2. This difference  
27  
28 38 between MS1 and MS2 is due to the presence of palygorskite in MS1, which greatly improves  
29  
30  
31 39 the reactivity and final mechanical performances. Therefore, palygorskite bearing marlstones  
32  
33 40 are suitable for a use as SCM and this suggests that palygorskite exhibits a significant  
34  
35  
36 41 pozzolanic reactivity.

## 1. INTRODUCTION

In order to comply with the Paris climate agreements, and to limit the global temperature increase below 1.5°C compared to pre-industrial levels, the most polluting industrial sectors need to reduce significantly their greenhouse gas emissions (may their CO<sub>2</sub> emissions). It is estimated that 5 to 8% of global anthropogenic CO<sub>2</sub> emissions comes from the cement industry [1]. In this context, cement producers are seeking to reduce their carbon footprint.

The use of Supplementary Cementitious Materials (SCMs) to replace part of the clinker is now seen as one of the major solutions to reduce the environmental footprint of the cement industry [2]. Blast furnace slag [3, 4] and power plant fly ash [5–7] are the main examples of SCMs used today that reduce the environmental footprint of cement. However, blast furnace slag resources remain limited, preventing large-scale deployment of this technology, and fly ash reserves from coal combustion will continue to decline in the coming years as the energy transition legitimately limits their availability [2].

Among alternative SCMs, calcined clays are gaining in popularity. The resources of clays potentially viable as SCMs after calcination are abundant and well distributed around the world, especially in developing countries where the demand for cement is constantly growing [2]. The numerous studies carried out on the subject have shown that metakaolin (from the calcination of kaolin) has the highest reactivity in cementitious media [8–11], whereas calcined smectites [12–14] and illites [15–17] are much less reactive. These results led to a growing interest in the use of calcined kaolins (rock composed of kaolinite, quartz and minor accessory minerals) as SCMs, and to the development of Limestone Calcined Clay Cements (LC3) [18, 19].

Only few studies have looked at other types of clays than kaolinites, smectites and illites [20, 21], mainly because of industrial competition (which leads to higher prices) and lower availability. Furthermore, the majority of studies focused on relatively "pure" samples, which

78 are mainly composed of clay minerals, quartz and other accessory minor minerals. Yet it is  
79 common to find clay minerals associated with other compounds, especially carbonates. If the  
80 proportion of carbonates is high, this mixture of clay minerals and carbonates is named  
81 marlstone.

82 Marlstones are often neglected by manufacturers of fired clay materials such as bricks because  
83 of their high content of calcium carbonate. They are considered as waste by many industries  
84 and supplies are increasing [22]. However, these materials contain a significant proportion of  
85 clay minerals, which can become pozzolans upon calcination. The use of marlstones as SCMs  
86 could therefore make it possible to recover mining wastes (and/or overburdens) while reducing  
87 the environmental footprint of cement production. Numerous studies looked at the use of  
88 marlstones as SCMs [23–27] , but the great variability of this type of material limits the  
89 possibility of global analyses. For each type of marlstones considered as a potential SCM, it is  
90 imperative to understand the evolution of each phase (clay minerals and carbonates) composing  
91 the marlstones during its calcination, as well as its influence on the reactivity and the final  
92 mechanical performances of calcined marlstone-cement blends.

93 This study focuses on the use as SCMs of two marlstones considered as waste by the mining  
94 industry. The first objective is to determine whether these materials can be used as SCMs. The  
95 second objective is to study the physico-chemical changes taking place during the calcination  
96 and the reaction of these new pozzolans and to correlate this information with the final  
97 mechanical performances. The last objective is to determine how palygorskite (an  
98 unconventional clay contained in one of the two materials) contributes to the pozzolanic  
99 reactivity.

100

101

## 2. MATERIALS AND EXPERIMENTAL METHODS

### 2.1. Materials

The materials studied (MS1 and MS2) are two marlstones considered as waste by the mining industry. The samples were received as loose blocks and mechanically crushed before analysis. Table 1 shows the results of the chemical analysis (performed by X-Ray Fluorescence (XRF)). The proportions of each element are expressed in weight percent.

Table 1. Chemical analysis of MS1 and MS2.

	Element	O	Ca	Si	Mg	Al	Fe	K	P	Na	Ti	V
MS1	wt. %	55.5	14.2	15.6	6.0	4.7	1.5	1.0	0.6	0.2	0.2	0.1
MS2	wt. %	56.0	16.4	16.2	5.5	3.8	1.2	0.2	0.2	0.2	0.2	0

MS1 and MS2 have a very close chemical composition, especially regarding the proportions of silicon, calcium, magnesium and aluminium. These similarities in the chemistry of MS1 and MS2 are not surprising as both materials originate from the same sedimentary deposit. X-ray diffraction analysis (XRD) was performed to highlight the mineralogical composition MS1 and MS2 and the different phases were quantified using the Rietveld refinement technique (see supporting information). Table 2 shows the results of the quantitative phases analysis for MS1 and MS2.

Table 2. wt.% of the crystalline phases of MS1 and MS2.

	Phase	Dolomite	Palygorskite	Smectite	Biotite	Hydroxylapatite	Quartz
MS1	wt.%	54	17	16	2	3	8
MS2	wt.%	59		27	1	2	11

119 MS1 and MS2 have a relatively close mineralogy, they are both mainly composed of dolomite  
1 associated with clay phases (smectite and biotite), quartz and hydroxylapatite. The main  
2  
3  
4  
5 121 difference is the occurrence of palygorskite in MS1, which replaces part of the smectite.  
6  
7  
8 122

9

## 10 11 123 **2.2. Marlstone calcination**

12  
13  
14 124 MS1 and MS2 were calcined at 600, 800 and 900°C in alumina crucibles using a laboratory  
15  
16  
17 125 furnace. The choice of these temperatures was made in accordance with the first study on  
18  
19 126 calcination carried out on MS1 [28]. The materials were heated at a heating rate of 300°C/h and  
20  
21  
22 127 then maintained for 1 hour at maximum temperature. They were then left to cool until room  
23  
24 128 temperature with the furnace door closed.  
25  
26

27 129

## 28 29 30 130 **2.3. Hydration of calcined marlstones**

31  
32  
33  
34 131 The calcination and hydration of MS1 have already been the subject of two previous studies  
35  
36 132 [29, 30] which demonstrated the formation of several reactive phases after calcination, notably  
37  
38  
39 133 CaO. As MS2 has a very close mineralogy to MS1, it is very likely to have the same reactive  
40  
41 134 phases formed. Therefore, the pozzolanic activity of calcined MS1 and MS2 could not be  
42  
43 135 measured using the classical pozzolanic activity tests (Chapelle test [31] and R<sup>3</sup> [32]), which  
44  
45  
46 136 requires the material tested not to contain free calcium. It was therefore decided to characterise  
47  
48 137 the reactivity of these calcined materials by carrying out hydration tests.  
49

50  
51 138 For both MS1 and MS2, 1g of 800°C calcined material was manually mixed with water  
52  
53  
54 139 according to the chosen water to binder ratios (w/b = 0.8; 1; 2 and 4). The mixtures were left to  
55  
56 140 react in sealed conditions for 7, 14, 28 and 180 days. At the end of each time period, the  
57  
58  
59 141 hydration was stopped by freezing at -24°C during 24h and freeze-drying during 48h under  
60  
61  
62  
63  
64  
65

142 vacuum. The dried materials were crushed and analysed by X-ray diffraction (XRD) and solid  
143 state nuclear magnetic resonance (MAS NMR). As the result analysis did not reveal any  
144 significant differences between the different w/b, only the hydration results for w/b = 0.8 are  
145 reported.

#### 147 **2.4. X-ray diffraction analysis (XRD)**

148 Measurements were made with a Bruker D8 diffractometer using a Bragg-Brentano geometry  
149 with a copper anode tube X-ray source (40 kV/40 mA) emitting Cu K $\alpha$  radiation. The  
150 acquisitions of the diffractograms were made between 4° and 60° 2 $\theta$  with a step size of 0.017°  
151 2 $\theta$  and a measurement time of 1s per step. The Rietveld quantification of MS1 and MS2 was  
152 performed using the Profex Rietveld refinement program [33].

#### 154 **2.5. Solid state nuclear magnetic resonance (MAS NMR)**

155 <sup>27</sup>Al MAS NMR spectra were acquired in a 2.5 mm MAS probe using a Bruker Avance III 500  
156 MHz spectrometer with the following parameters : MAS frequency of 30 kHz, excitation pulse  
157 length of  $\pi/13$ , radio frequency field of 11 kHz and repetition time of 1s.

158 <sup>29</sup>Si MAS NMR spectra were acquired in a 7 mm MAS probe using a Bruker NEO 300 MHz  
159 spectrometer with the following parameters : MAS frequency of 5 kHz, excitation pulse length  
160 of  $\pi/2$  and repetition time of 10s. The chosen 10s repetition time is too short to obtain a  
161 quantitative signal from the quartz, but as quartz is unreactive shorter repetition time can be  
162 used to save spectrometer time.

163 All the acquisitions were performed with <sup>1</sup>H decoupling. An aqueous solution of Al(NO<sub>3</sub>)<sub>3</sub> was  
164 used to referenced <sup>27</sup>Al spectra while <sup>29</sup>Si spectra were referenced against TMS

165 (Tetramethylsilane). The Dmfit software [34] was used to perform the spectral decompositions  
166 (see supporting information).

## 167 **2.6. Calcined marlstone-cement blends and compressive strength measurements**

168 The compressive strength was assessed on mortar cubes (50 x 50 x 50 mm<sup>3</sup>) made with graded  
169 standard (supports ASTM C109) sand (sand to cement ratio = 2.75) and a constant water to  
170 binder ratio (w/b = 0.484). Blended cement was obtained by mixing 80 wt.% of general use  
171 Portland cement (GU) with 20 wt.% of 800°C calcined MS1 (for M-MS1 mortar) or MS2 (for  
172 M-MS2 mortar). The particle size distributions of the GU cement and MS1 and MS2 (before  
173 and after calcination) are shown in Table 3. The d-values indicate the maximal particle size  
174 diameter that includes 10% (d10), 50% (d50) and 90% (d90) of the particles (volume-weighted  
175 basis).

176 Table 3. Particle size distributions of GU cement and marlstones (MS1 and MS2) before and  
177 after calcination at 800°C.

Label	d10 (µm)	d50 (µm)	d90 (µm)
MS1	3.5	19.5	64.1
800°C-MS1	4.0	24.5	91.6
MS2	2.4	14.8	53.1
800°C-MS2	3.6	28.2	66.3
GU cement	3.5	20.5	59.7

178  
179 Both 800°C-MS1 and 800°C-MS2 have a particle size distribution close to that of GU cement,  
180 which ensures homogeneous blends.

181 Control mortars cubes (labelled M-Ref) were prepared using 100% GU cement. A  
182 polycarboxylate (PC) superplasticizer (0.6% by total weight of binder) was used to obtain a  
183 flow equivalent to that of the control mixture ( $\pm 5$  mm). Table 4 shows the proportions of the  
184 investigated mortars.

186 Table 4. Mix proportions of mortars

Label	Cement (g)	Pozzolan (g)	Sand (g)	Water (g)
M-Ref	500	0	1375	242
M-MS1	400	100	1375	242
M-MS2	400	100	1375	242

187  
188 Mortars were mixed and specimens were molded according to the standard procedure ASTM  
189 C109 [35]. After molding, the specimens were placed in plastic bags for 20-24h until  
190 demolding. The demolded mortar cubes were stored in saturated lime water until testing. At 7  
191 and 28 days the compressive strength was assessed according to the ASTM C109 loading  
192 procedure [35].

### 194 3. RESULTS AND DISCUSSION

#### 195 3.1. Calcination

196 Fig. 1. displays the evolution of MS1 (Fig. 1.A) and MS2 (Fig. 1.B) X-ray diffractograms as a  
197 function of the calcination temperature.

C2S = $\text{Ca}_2\text{SiO}_4$	Bio = <b>Biotite</b> $\text{K}(\text{Mg,Fe})_3(\text{OH,F})_2(\text{Si}_3\text{AlO}_{10})$
Dol = <b>Dolomite</b> $\text{CaMg}(\text{CO}_3)_2$	Pal = <b>Palygorskite</b> $(\text{Mg,Al})_2\text{Si}_4\text{O}_{10}(\text{OH}) \cdot 4\text{H}_2\text{O}$
Pe = <b>Periclase</b> $\text{MgO}$	Li = <b>Lime</b> $\text{CaO}$
Qz = <b>Quartz</b> $\text{SiO}_2$	Sm = <b>Smectite</b> $(\text{Ca})_{0.3}(\text{Al,Mg})_2\text{Si}_4\text{O}_{10}(\text{OH})_2 \cdot n\text{H}_2\text{O}$
Dehy Sm = <b>Dehydrated Smectite</b>	Hy = <b>Hydroxylapatite</b> $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$
Au = <b>Augite</b>	Ak = <b>Akermanite</b>

**Fig. 1.** Evolution of the X-ray diffractograms of MS1 (A) and MS2 (B) as a function of the calcination temperature.

202 At 600°C, for both MS1 and MS2 the 001 peak of smectite (Sm) is shifted from 6.2°(2θ) to  
1  
2 203 8.75°(2θ). This shift is explained by the dehydration of the smectite during the heat treatment  
3  
4 204 (the removal of the interlayer water leads to a decrease in d001 basal spacing) [36, 37].  
5  
6  
7 205 Concerning MS1, the characteristic peaks of palygorskite disappears at 600°C, reflecting its  
8  
9 206 loss of crystallinity.  
10

11 207  
12  
13  
14 208 At 800°C, for both MS1 and MS2 the dolomite ( $\text{CaMg}(\text{CO}_3)_2$ ) decarbonates into lime (CaO)  
15  
16 209 and periclase (MgO) and a peak associated with dicalcium silicate ( $\text{C}_2\text{S}$ ) appears. However, the  
17  
18 210 low intensity of the  $\text{C}_2\text{S}$  peaks (possibly due to low crystallinity of the phase) hinders the  
19  
20 211 determination of the type of polymorph. The fact that this  $\text{C}_2\text{S}$  is formed at the same temperature  
21  
22 212 as the lime supports the hypothesis that it results from a recombination phenomenon between  
23  
24 213 the calcium from the decarbonated dolomite and the silicon from calcined clay phases [38].  
25  
26  
27  
28  
29 214

30  
31 215 At 900°C, for both MS1 and MS2 the characteristic peaks of dehydrated smectite and biotite  
32  
33 216 disappear, indicating a complete loss of crystallinity of these two phyllosilicates. Quartz and  
34  
35 217 hydroxylapatite are not sensitive to heat treatment since their peaks remain detectable up to  
36  
37 218 900°C. Finally, there are recrystallisation phenomena in the form of augite and akermanite at  
38  
39 219 900°C.  
40  
41  
42  
43  
44 220

45  
46 221 Based on these XRD results, 800°C seems to be a suitable calcination temperature as it allows  
47  
48 222 the loss of crystallinity of the clay phases without causing recrystallisation phenomena (that  
49  
50 223 could reduce the reactivity) for both MS1 and MS2.  
51  
52  
53 224  
54  
55  
56 225  
57  
58 226  
59  
60  
61  
62  
63  
64  
65

227 Fig. 2. displays the evolution of the  $^{27}\text{Al}$  MAS NMR spectra of MS1 (Fig. 2.A) and MS2 (Fig.  
 228 2.B) as a function of the calcination temperature.

230 **Fig. 2.** Evolution of the  $^{27}\text{Al}$  MAS NMR spectra of MS1 (A) and MS2 (B) as function of the  
 231 calcination temperature.

233 Both spectra of raw MS1 and MS2 exhibit two main resonances at 3 and 70 ppm which  
 234 correspond to 6-fold and 4-fold aluminium, respectively [39]. The 6-fold aluminium resonance  
 235 (3 ppm) can be associated with aluminium in palygorskite, smectite and biotite for MS1 and  
 236 with aluminium in smectite and biotite for MS2 [40]. The 4-fold aluminium resonance (70 ppm)  
 237 can be associated with the isomorphic substitution of silicon by aluminium atoms into silicate  
 238 layers of palygorskite, smectite and biotite structures for MS1 and into smectite and biotite

239 structures for MS2 [40]. A weak resonance at 57 ppm is detected in both MS1 and MS2 spectra,  
1  
2 240 which corresponds to aluminium in q4(4Si) configuration [41] possibly associated with an  
3  
4  
5 241 additional phase occurring in low quantity and/or with low crystallinity, undetectable by XRD.  
6  
7  
8 242 With the increasing calcination temperature, the 6-fold aluminium resonance intensity  
9  
10 243 decreases while two new resonances appear at 27 and 59 ppm, which correspond to 5-fold and  
11  
12 244 4-fold aluminium, respectively [39]. During the calcination of MS1 and MS2, the calcination  
13  
14  
15 245 leads to a departure of hydroxyl groups from the clay phases (the dehydroxylation  
16  
17 246 phenomenon). The octahedral (6-fold) aluminium atoms to which these hydroxyl groups were  
18  
19  
20 247 bonded have changed their coordination to 5- and 4-fold aluminium atoms. The pozzolanic  
21  
22 248 activity of a calcined clay could be directly related to the relative proportion of 5- and 4-fold  
23  
24  
25 249 aluminium. These sites, in particular at the 5-fold one, are the starting point of the dissolution  
26  
27 250 and the initiation of the pozzolanic reaction [15]. For both MS1 and MS2, the highest relative  
28  
29  
30 251 proportion of aluminium 5 and 4 (without recrystallization) is reached at 800°C, which suggests  
31  
32 252 that this calcination temperature should allow the highest pozzolanic reactivity. By comparing  
33  
34  
35 253 the evolution of MS1 and MS2 it is clear that the dehydroxylation occurs more easily in MS1  
36  
37 254 (which contains smectite and palygorskite) than in MS2 (which contains only smectite). At  
38  
39  
40 255 800°C, a significantly higher relative proportion of 6-fold aluminium is still remaining in MS2  
41  
42 256 than in MS1. This difference can be explained by the occurrence of palygorskite in MS1, which  
43  
44 257 was found to dehydroxylate more efficiently (at lower temperature) than smectite and biotite.

262 Fig. 3. displays the evolution of the  $^{29}\text{Si}$  MAS NMR spectra of MS1 (Fig. 3.A) and MS2 (Fig.  
 263 3.B) as a function of the calcination temperature.

264  
 265 **Fig. 3.** Evolution of the  $^{29}\text{Si}$  MAS NMR spectra of MS1 (A) and MS2 (B) as function of the  
 266 calcination temperature.

267  
 268 Both spectra of raw MS1 and MS2 exhibit a resonance at -108 ppm which correspond to  $\text{Q}^4$   
 269 silicon atoms and which can be associated with silicon in the quartz structure [42]. For MS1,  
 270 the total signal between -84 and -100 ppm is composed of  $\text{Q}^3$  silicon atoms of smectite (-93  
 271 ppm) [12],  $\text{Q}^3(\text{1Al})$  silicon atoms of biotite (-86 ppm) [43],  $\text{Q}^2$  silicon atoms of palygorskite (-

1 272 84 ppm) [44] and two Q<sup>3</sup> silicon sites of palygorskite at -98 and -92 ppm which correspond to  
2 273 SiO<sub>4</sub> at the edges and at the centre of the ribbons of tetrahedra, respectively [45]. For MS2, the  
3  
4 274 total signal is only composed of Q<sup>3</sup> silicon atoms of smectite and Q<sup>3</sup>(1Al) silicon atoms of  
5  
6  
7 275 biotite and smectite. For both MS1 and MS2, the increase of the calcination temperature leads  
8  
9 276 to a broadening of the resonances associated with the Q<sup>3</sup> of the clay phases. This broadening is  
10  
11 277 explained by a distribution of the environments of the silicon atoms and indicate a structural  
12  
13 278 loss of the clay phases upon calcination [46]. At 800°C a new resonance appears at -71 ppm in  
14  
15  
16 279 MS1 and MS2 spectra. This new resonance corresponds to Q<sup>0</sup> silicon atoms and can be  
17  
18 280 associated with the silicon contained in the C<sub>2</sub>S structure [47], in accordance with XRD results.  
19  
20 281 With increasing the calcination temperature there is a low-frequency shift of the Q<sup>3</sup> resonances  
21  
22 282 for MS2, which is explained by the condensation of the Q<sup>3</sup> into Q<sup>4</sup> silica [17]. By comparing  
23  
24 283 MS1 and MS2 it is evident that the C<sub>2</sub>S formation is facilitated in MS1 compared to MS2 (a  
25  
26 284 higher relative proportion is observed). This could be explained by the occurrence of  
27  
28 285 palygorskite as it is the only main difference between both materials. However, this difference  
29  
30 286 of C<sub>2</sub>S formation between MS1 and MS2 is not observable by XRD, meaning that the main part  
31  
32 287 of this C<sub>2</sub>S is amorphous.  
33  
34  
35  
36  
37  
38

39 288 Overall, the results of XRD and MAS NMR indicates that 800°C is probably the best  
40  
41 289 calcination temperature for both MS1 and MS2. Moreover, MS1 seems to be more sensitive to  
42  
43 290 the calcination, which leads to higher dehydroxylation of the clay phases and to higher relative  
44  
45 291 amount of C<sub>2</sub>S. The major difference between MS1 and MS2 being the occurrence of  
46  
47 292 palygorskite in MS1, it seems clear that smectite and palygorskite have different responses to  
48  
49 293 calcination.

296 **3.2. Self-reactivity of calcined marlstones in water**

1  
2  
3 297 The calcination study of MS1 and MS2 revealed the formation of different reactive phases such  
4  
5 298 as lime, periclase and C<sub>2</sub>S as well as the loss of crystallinity of the clay phases. MS1 and MS2  
6  
7  
8 299 were thus hydrated in water in order to study their reactivity, the contribution of each phases,  
9  
10 300 their evolution and the possible presence of synergies.

11  
12  
13 301 Fig. 4. displays the evolution of the X-ray diffractograms of MS1 (Fig. 4.A) and MS2 (Fig. 4.B)  
14  
15  
16 302 calcined at 800°C and hydrated in water for 7, 14, 28 and 180 days.

Po = <b>Portlandite</b> $\text{Ca}(\text{OH})_2$	

**Fig. 4.** Evolution of the X-ray diffractograms of MS1 (A) and MS2 (B) calcined at 800°C and hydrated (w/b = 0.8) during 7, 14, 28 and 180 days.

306 After 7 days of hydration, for both MS1 and MS2, diffraction peaks characteristic of portlandite,  
307 calcite, hydrotalcite and brucite appear on the diffractograms. The formation of portlandite  
308 comes from the hydration of lime and calcite comes from its carbonation. The magnesium from  
309 the periclase is incorporated into two phases: brucite and hydrotalcite.

310 The formation of brucite can be problematic in cements. The hydration of periclase into brucite  
311 is a phenomenon that has relatively long kinetic compared to the hardening kinetic of cement.  
312 This post-hardening swelling can lead to cracking problems and therefore a loss of mechanical  
313 performance if there is not enough space available in the matrix [48]. Studies are currently  
314 underway to determine whether neoformed brucite leads to cracking in this system. However,  
315 there is no post-hardening swelling phenomenon associated with hydrotalcite (the second  
316 magnesian phase neoformed in our system) formation in the existing literature and the possible  
317 existence of synergies with the cement phases could enhance the formation of hydrotalcite  
318 instead of brucite in calcined marlstone-cement system.

319 The amount of neoformed brucite and portlandite is higher for MS2 than for MS1 (larger area  
320 under the peaks), therefore it is difficult to compare the evolution of these two phases between  
321 MS1 and MS2. With the increasing hydration time, the intensity of the peaks characteristic of  
322 portlandite decrease for MS1 and MS2. However, after 180 days of hydration the portlandite  
323 diffraction peaks are no longer detectable in MS1. This total consumption of portlandite in MS1  
324 could be a first indication of a possible stronger pozzolanic reactivity compared to MS2.  
325 However, this apparent consumption of portlandite may also be due to its carbonation into  
326 calcite as we observe an increase in the intensity of the peak associated with calcite with  
327 increasing hydration time.

328 Fig. 5. shows the evolution of the  $^{29}\text{Si}$  MAS NMR spectra of MS1 (Fig. 5.A) and MS2 (Fig.  
329 5.B) calcined at  $800^\circ\text{C}$  and hydrated in water during 7, 14, 28 and 180 days.

**Fig. 5.** Evolution of the  $^{29}\text{Si}$  MAS NMR spectra of MS1 (A) and MS2 (B) calcined at  $800^\circ\text{C}$  and hydrated ( $w/b = 0.8$ ) during 7, 14, 28 and 180 days.

After 7 days of hydration for both MS1 and MS2, a decrease is observed for the intensity of the broad  $\text{Q}^3$  resonances previously associated with the calcined clay phases. This decrease is correlated with the appearance of two new resonances at -78 and -85 ppm which correspond to  $\text{Q}^1$  and  $\text{Q}^2$  silicon atoms, respectively [49].  $\text{Q}^1$  silicon atoms can be associated with pairs of linked silicate tetrahedral (dimers) and/or terminal tetrahedral silicate groups of C-S-H.  $\text{Q}^2$  silicon atoms can be associated with C-S-H tetrahedral silicate groups in bridging ( $\text{Q}^2\text{-B}$ ) and/or intermediates ( $\text{Q}^2\text{-P}$ ) configurations [50].

The -71 ppm resonance corresponding to  $\text{Q}^0$  atoms (associated previously with  $\text{C}_2\text{S}$  neoformed during calcination) decreases considerably after 7 days of hydration and leaves a resonance at -73 ppm for both MS1 and MS2. This -73 ppm resonance can either be associated with the  $\text{Q}^1$  atoms of akermanite/gehlenite and/or  $\text{Q}^0$  of non-reactive  $\text{C}_2\text{S}$ . The fact that the  $\text{C}_2\text{S}$  XRD signal remains detectable even after 180 days of hydration supports the hypothesis that some of the  $\text{C}_2\text{S}$  is non-reactive (the crystallised one). However, during the calcination of MS1 and MS2, the formation of akermanite was observed at  $900^\circ\text{C}$  (Fig. 1.). The -73 ppm signal can thus also

348 be associated with akermanite which is not yet crystallised enough to be detectable by XRD at  
1  
2 349 800°C. Finally, several studies have highlighted the formation of gehlenite during the  
3  
4  
5 350 calcination of marlstones [51, 52] and this signal at -73 ppm could therefore be associated with  
6  
7 351 this phase.

8  
9  
10 352 After 14 days of hydration, for both MS1 and MS2, the intensity of the  $Q^3$  calcined clay phases  
11  
12 353 resonances continues to decrease while the intensity of the  $Q^1 + Q^2$  resonances associated with  
13  
14  
15 354 C-S-H increases. A new resonance at -81 ppm appears after 14 days for MS1 and 28 days for  
16  
17 355 MS2, which corresponds to silicon in  $Q^{2(1Al)}$  configuration and confirms the incorporation of  
18  
19  
20 356 aluminium into the C-A-S-H structure, which is characteristic of the pozzolanic reaction of  
21  
22 357 calcined clays. The trend will continue up to 180 days for MS1 and MS2, validating the intrinsic  
23  
24  
25 358 pozzolanic reactivity of these two calcined materials.

26  
27  
28 359 The comparison of the series of spectra indicates that the formation of C-A-S-H and the  
29  
30 360 consumption of calcined clay phases are significantly higher for MS1 than MS2. Spectral  
31  
32  
33 361 integration quantification was thus carried out to precisely compare the difference between  
34  
35 362 MS1 and MS2 in terms of the consumption of calcined clay phases and the formation of C-A-  
36  
37  
38 363 S-H.

39  
40  
41 364 Fig. 6. displays the evolution of the relative proportions (from the perspective of silicon content)  
42  
43 365 of the  $Q^n$  (C-A-S-H) and the  $Q^3$  (calcined clay phases) for hydrated 800°C-MS1 (Fig 6.A) and  
44  
45  
46 366 800°C-MS2 (Fig 6.B). Details of this quantification by spectral integration are given in the  
47  
48 367 supporting information. The  $Q^4$  signal associated with quartz is not quantitative and the  $Q^0$ - $Q^1$   
49  
50  
51 368 signal associated with  $C_2S$  and/or akermanite/gehlenite is constant from 7 days and onward.  
52  
53 369 Therefore, Fig 6. includes only the evolution of the  $Q^3$  (and  $Q^3$ - $Q^4$  for MS2) of the calcined clay  
54  
55  
56 370 phases and  $Q^n$  of the C-A-S-H.

**Fig. 6.** Relative proportions of silicon-containing phases of MS1 (A) and MS2 (B) calcined at 800°C (from the perspective of silicon content) as function of the hydration time obtained from  $^{29}\text{Si}$  MAS NMR spectra.

For MS1, after only 7 days of hydration, the relative proportion of silicon in  $Q^n$  configuration associated with C-A-S-H is already 30%. From 7 to 180 days of hydration, the relative proportion of silicon in  $Q^3$  configuration associated with the calcined clay phases decreases from 58% to 30%. In parallel, the relative proportion of  $Q^1$ ,  $Q^2(1Al)$  and  $Q^2$  silicon associated with the C-(A)-S-H increases from 30% to 58%.

For MS2, after 7 days of hydration, the relative proportion of silicon in  $Q^n$  configuration associated with C-A-S-H is only 14%, which is much lower than for MS1 (30%). From 7 to

180 days of hydration the relative proportion of silicon in Q<sup>3</sup>-Q<sup>4</sup> configuration associated with the calcined clay phases decreases from 67% to 39%. In parallel, the relative proportion Q<sup>1</sup>, Q<sup>2</sup>(1Al) and Q<sup>2</sup> silicon associated with the C-(A)-S-H increases from 14% to 43%. The consumption of the calcined clay phases, associated with the formation of C-A-S-H and the consumption of portlandite during hydration confirms the pozzolanic reactivity of MS1 and MS2 calcined at 800°C. However, this pozzolanic reactivity is more important for MS1 (which contains palygorskite) than for MS2 ( $\frac{Q^n(CASH)}{Q^3} = 1,93$  for MS1 and  $\frac{Q^n(CASH)}{Q^3+Q^4} = 1,13$  for MS2 after 180 days of hydration). Compressive strengths were measured on mortars incorporating the two marlstones calcined at 800°C to confirm their different reactivity.

### 3.3. Calcined marlstone-cement blends

Fig. 7. displays the compressive strength of M-Ref, M-MS1 and M-MS2 after 7 and 28 days of hydration. The error bars indicate the standard deviation for each set of 3 compression measurements.

Fig. 7. Compressive strengths at 7 and 28 days of M-Ref, M-MS1 and M-MS2

398 After 7 days M-MS1 shows a compressive strength slightly higher (31 MPa) to that of the  
399 reference (29 MPa for M-ref) whereas M-MS2 shows a significant lower strength (20 MPa). At  
400 28 days the trend continues for M-MS1 which shows an equivalent compressive strength (38  
401 MPa) to that of the reference (39 MPa) whereas M-MS2 still shows significant lower  
402 compressive strength (29 MPa).

403 The better mechanical performance of M-MS1 confirms the previous results assessed by <sup>27</sup>Al  
404 and <sup>29</sup>Si MAS NMR. The occurrence of palygorskite in MS1 leads to a higher degree of  
405 dehydroxylation at 800°C in comparison to MS2 (Fig. 2.). This enhances the pozzolanic  
406 reactivity of 800°C-MS1 in comparison to 800°C-MS2 (Fig. 6.) and results in higher  
407 compressive strengths at 7 and 28 days (Fig. 7.). These results suggest that the palygorskite has  
408 a higher pozzolanic activity after calcination at 800°C than smectite. To a lesser extent, the  
409 higher mechanical performance of M-MS1 compared to M-MS2 could also be attributed to the  
410 greater amount of C<sub>2</sub>S neofomed during the calcination (facilitated by the occurrence of  
411 palygorskite).

412

## 413 CONCLUSION

414 This paper compares the use of two calcined marlstones as SCMs in terms of calcination, self-  
415 reactivity in water and mechanical performance in cementitious blends. The two marlstones  
416 differ mainly by the presence of palygorskite (MS1) or not (MS2). Based on the results  
417 presented, the following conclusions can be drawn:

418 1. The calcination of MS1 and MS2 leads to the dehydroxylation of the clay phases associated  
419 with the formation of lime, periclase and C<sub>2</sub>S. A calcination temperature of 800°C resulted in  
420 the highest expected reactivity for both MS1 and MS2. The degree of dehydroxylation and the

421 amount of C<sub>2</sub>S neoformed are higher for MS1 than MS2, which was attributed to the occurrence  
1  
2 422 of palygorskite in MS1.  
3  
4

5 423 2. Both MS1 and MS2 calcined at 800°C exhibit significant self-reactivity in water, mainly  
6  
7 424 pozzolanic. The comparative study shows that MS1 calcined at 800°C exhibits a higher self-  
8  
9 425 reactivity than MS2 confirming the results of the calcination analysis.  
10  
11  
12

13 426 3. The comparative study shows that mortars made from cement blended with 20% of MS1  
14  
15 427 calcined at 800°C have much better compressive strength than those made with MS2 after 7  
16  
17 428 and 28 days. Once again, this confirms the results of the calcination (higher dehydroxylation of  
18  
19 429 MS1 than MS2) and self-reactivity in water analysis (higher reactivity of 800°C-MS1 than  
20  
21 430 800°C-MS2).  
22  
23  
24  
25

26 431 4. Calcination, self-reactivity in water and compressive strength results indicate that calcined  
27  
28 432 palygorskite-bearing marlstones have higher potential use as SCMs in cementitious systems  
29  
30 433 than calcined smectite-bearing marlstones. These results open up new applications for this type  
31  
32 434 of marlstones and suggest that palygorskite is a clay that could be used as SCM once calcined.
