Introduction: The Mars 2020 rover landed at Jezero crater on February 18, 2021 [1]. Since then, the rover has traveled around the “Séitah” region [2] and has collected data from the Mastcam-Z, Supercam, PIXL and SHERLOC instruments that has led to insights into the formation of the olivine-clay-carbonate bearing rocks that were identified from orbit [3,4]. Here we discuss three questions: 1) What have we learned about the olivine-clay-carbonate unit? 2) What terrestrial analogs exist for the unit? 3) Why do the rocks have a thinly layered morphology? We shall briefly mention instrumental measurements which provide important information regarding the olivine bearing rock at Seitah.

Mastcam-Z: The Mastcam-Z instrument obtains multispectral images extending to ~1020 nm. Images are being used to locate olivine via its absorption band centered near 1 μm . Infrequent ropey textures suggestive of lava flows have been imaged by Mastcam-Z (Fig 1) [5].

Supercam: Supercam has been used to identify cumulate olivine and characterize its Fo# using Raman and LIBS measurements [6]. The Supercam VISIR data set is being compared to spectral features seen from orbit by the CRISM instrument on MRO [7]. Fig 2 shows a olivine-rich rock with a cumulate texture imaged by the Supercam RMI at Cine in Seitah.

PIXL: PIXL provides the elemental composition of its target via x-ray fluorescence at a resolution of ~120 μm [7]. These data have now been used to identify at the millimeter scale cumulate olivine, high-Ca clinopyroxene and mesostasis (Figure 3) [8].

SHERLOC: SHERLOC UV Raman is being used for the identification of carbonates and olivine in a scanning mode and clays at a grid of points within the *in situ* FOV of the WATSON imager (Fig. 4) [9].

What have we learned about the Olivine-clay-carbonate lithology? The olivine-clay-carbonate lithology is among the best-documented rock types in Jezero crater and the surrounding watershed [3] and is potentially among the most astrobiologically compelling units in the region [10]. From orbital VNIR reflectance spectra, the unit contains abundant olivine (Fo#45-66) in large grains (>500 μm , based on band saturation) accompanied by clay and carbonate minerals [3], and its crater retention age is ~ 3.82 Ga [11]. Several potential origins of the olivine-rich unit are possible: 1) a density segregated melt associated with a lava flow or lake; 2) a pyroclastic density current (PDC) at low temperature [11]; 3) tephra fall [12]; or 4) some combination of all of the above, see also [13]. The transition from primary volcanic deposit to the olivine-carbonate-clay could have been from deuteric serpentinization and talc-carbonation [8] perhaps caused by late Noachian CO_2 outgassing [14]. It is also possible that the olivine was altered to carbonate when it was exposed to a thick CO_2 -rich Noachian atmosphere [15]. Discrimination between these formation and alteration histories is critical to advancing our understanding of Noachian mantle circulation [16].

Terrestrial analog of komatiite sequence: Here we consider a low viscosity lava flow or lake which density-segregated into a layered cumulate. Figure 5 shows two examples from the ultramafic Archean stromatolite-bearing Dresser Formation in Western Australia. Olivine replaced by serpentine and talc-carbonate are seen in a petrographic thin section in the image. Similarities with the olivine-clay-carbonate include the mm size cumulate textures and mineralogy, in this case the olivine is replaced by talc or serpentine.

Figure 5 - Outline of approach for differentiating alteration styles of the olivine-carbonate lithology using M2020 instrumentation suite.

Why such thin layering and polyhedral jointing? Terrestrial komatiite sequence lavas have extremely low viscosity, and provide a starting indication for what the lava emplacement mechanism must have been for the olivine-clay-carbonate layers at Seitah and beyond in Nili Fossae. The thin layering (Fig 6) probably also contributes to the draping appearance of the unit reported in [12]. In addition, polyhedral jointing is also present at the top of many komatiite successions, including Dundonald Sill and is regarded as unequivocal evidence of an extrusive origin [18].

We are using the elemental abundances of the Supercam LIBS instrument to calculate the viscosity of the olivine-clay-carbonate unit at Seitah and will compare with our analog.

Fig 7 - Fig 8 of McGetchin and Smythe 1978 [17] showing viscosity of their model Martian lava which we suggest is similar to the olivine-clay-carbonate.

Take away messages: 1) We have outlined how the instruments of the *Perseverance* rover are being used to increase our understanding of this unit and determine their variations around Jezero. **2)** We have outlined the case for a komatiitic succession of rocks as an information-rich analog for the olivine-bearing rocks at Seitah. **3)** We are calculating viscosities for the olivine-bearing rocks and these indicate a low viscosity that may help explain the thin cumulate layering of these rocks.
