The potential of the French overseas Convection-Permitting model AROME-OM to represent shallow cumulus and their main organisations for boreal winter conditions in the North Atlantic trades is investigated. The double-peak of the cloud fraction of shallow cumuli is well simulated and is primarily influenced by fluctuations of 2m-temperature and precipitable water. The different air mass characteristics leading to a discrimination of the different mesoscale patterns are identified both in observations collected during the EUREC4A field campaign and in AROME-OM.

Process Oriented evaluation of the oversea AROME configuration: focus on the representation of cloud organisation

Abstract

This study evaluates the ability of the French Convection-Permitting model AROME-OM to represent shallow cumulus and their main organisations for boreal winter conditions in the North Atlantic trades. It uses a set of three winter seasons (January-February 2018-2020) of high-resolution (1.3 and 2.5 km) simulations over the Caribbean domain (9.7-22.9°N, 75.3°W-51.7°W). The model is assessed against soundings at Grantley Adams Airport and remote-sensing observations at a site located on the east coast of Barbados which is representative of downwind trade regimes. The thermodynamic environment of the model fits the observations overall but the boundary layer is slightly too deep, resulting in a weak cold and dry bias. Both model and observations clearly exhibit i) a double peak of cloud fraction, a first peak near the cloud base and a second one near the cloud top and ii) a larger variance in cloudiness near the top of the deepest cumuli, at around 2 km, with a higher sensitivity to the environment. We then take advantage of the EUREC⁴A field campaign which took place in January-February 2020 to assess the ability of the model to reproduce the four main mesoscale patterns (Stevens et al., 2020) and to characterize the air-masses in which they develop. All the observations confirm the capacity of the model to predict the different mesoscale organizations and their associated environment.

1 Introduction

Subtropical oceanic fair-weather cumuli are ubiquitous across the downwind trade regions. There is a growing need to better understand the key mechanisms that regulate those clouds, which play a critical role in the boundary-layer dynamics and the global climate. Over the past two decades, parameterizations of shallow convection in general circulation models have improved greatly (Tiedtke 1989, Hourdin et al. 2002, Rio and Hourdin 2008, Pergaud et al 2009) but it is still a challenge to better represent the distribution of fair-weather cumuli and their organisation, especially over the subtropical oceans. The strong impact of trade wind cumuli on the radiation balance, even if they are small and short-lived, represents a source of uncertainty in climate projections with a wide variety of responses among climate models (Sherwood et al. 2014, Nuijens et al. 2015).

Trade wind regions are widespread and their thermodynamic large-scale environments show significant variability among tropical oceans. Fields of broken cumulus rather populate western sides of the oceans whilst over eastern sides the appearance of the clouds resemble open and closed cells. These variations of low-level cloudiness cloudiness can not be explained by a single strong predictor but are rather controlled by the combined effect of various parameters. A regime of downstream trades is dominated by relatively weak trade wind inversion, variable subsidence at 500 hPa, deep trade wind layer and warm sea surface temperature (SST) ranging between 26 and 28°C (Fig. 1a) (Bony et al. 2004, Medeiros and Nuijens 2016). Based on satellite observations, Stevens et al. (2020) have identified in this region four prominent mesoscale patterns known as – Sugar, Gravel, Flower and Fish – which distinguish themselves by their spatial organisation and their variation of the cloud top cloudiness. A significant dependence of these mesoscale cloud pattern on surface wind speed and trade wind inversion strength (measured by the lower-tropospheric stability, LTS, defined as $\theta_{700} - \theta_{1000}$, where θ is the potential temperature, Klein & Hartmann, 1993) has been found by Bony et al. (2020). These relationships have been

1 confirmed by Schulz et al. (2021) with the help of a neural network in order to classify the four
2 patterns (Rasp et al., 2020). Janssens et al. (2021) have shown that these organisations are
3 associated with the distribution extremes of organisations' metrics which explains why they are
4 easily distinguishable to the human eye but they do not allow the spanning of the large variety of
5 other organisations.

6 Simulations of the shallow convection remain a challenge since models must be able to
7 represent the subtle relationship between clouds and environment with typical cloud size
8 representing only a fraction of a model grid box. Recently, Heim et al. (2021) shed light on the
9 benefits of using kilometre-scale models - so-called convection-permitting models - (CPM) to
10 simulate shallow convection with an ability to partially resolve the interactions between clouds and
11 their environment. However, a large variability in the cloud simulation among the different models
12 could still be noted. The main goal of this work is to evaluate the ability of the overseas
13 configuration of the French CPM AROME (Seity et al., 2011), the so-called AROME-OM (Faure et
14 al., 2020), to represent the shallow convection at a kilometre resolution. Past studies have shown the
15 good capacity of AROME to reproduce the lifecycle of mesoscale convective systems during the
16 West African monsoon (Beucher et al. 2014, Beucher et al., 2019) but few focused on a maritime
17 tropical domain, in particular for the operational version (Faure et al., 2020).

18 The scarcity of the observations in the Caribbean domain (Fig. 1a) represents a major
19 hindrance for the evaluation of AROME-OM. The EUREC⁴A campaign which took place to the
20 east of Barbados in January-February 2020 (Stevens et al., 2021) represents an opportunity in that
21 regard since it provides a battery of supplementary observations (in addition to routine soundings).
22 Remote-sensing instruments installed since 2010 at the Barbados Cloud Observatory (BCO, Fig.
23 1b) (Stevens et al. 2016) provide insight into the vertical distribution of cloud fraction. Analysing
24 these data, Nuijens et al. (2014) found a double peak structure with a first peak at 1 km near the
25 cloud base and a second one slightly below 2 km with the development of a stratiform cloud layer
26 under the trade wind inversion. Unlike coarser global models (Nuijens et al., 2015), the double peak
27 of cloud fraction is rather well captured by the Large Eddy Simulation (LES) (Stevens et al. 2001,
28 Narenpitak et al. 2021), particularly when environment is characterized by a strong trade wind
29 inversion (Vogel et al., 2020).

30 Motivated by these past studies, this article addresses the following questions: to what
31 extent, under a regime of a weak trade wind inversion, is AROME-OM able to simulate this double
32 peak while the shallow convection is still parameterized? And in which environment is the vertical
33 distribution of the cloud fraction the most sensitive? We also investigate how AROME-OM is able
34 to capture the four main spatial mesoscale organisations (Stevens et al. 2020) and their associated
35 large-scale environment focusing on four typical case studies selected during the EUREC⁴A period.

36 In the following, we give a short description of the data used, along with the configuration
37 of AROME-OM (section 2). In section 3, we assess the ability of the model to capture the double
38 peak of cloud fraction and its dependence on the large-scale environment. This is followed in
39 section 4 by the evaluation of the model to reproduce the main mesoscale patterns of Stevens et al.
40 (2020) which is based on four case studies. Finally, the main results are outlined and perspectives
41 provided by such CPM for further investigations of the interplay of mechanisms leading to
42 mesoscale organisation changes are discussed.

43 2. Model configuration and observations for its evaluation

44 2.1 Configuration of AROME-OM

45 Since 2016, AROME-OM has been run across the French overseas territories at a 2.5 km
46 horizontal grid spacing four times a day with a 48h forecast range (Faure et al., 2020). This study
47 focuses on forecasts starting at 0000 UTC. We discard the first 6 hours in order to avoid the initial

1
2
3 1 spin-up phase and only use the 6h to 30h forecast ranges. AROME-OM system is basically a
4 2 downscale, without any additional data assimilation, of the deterministic global model Integrated
5 3 Forecasting System (IFS) of the European Centre for Medium-Range Weather Forecasts
6 4 (ECMWF). The model is forced on its lateral boundaries at an hourly frequency (Faure et al., 2020).
7 5 It uses 90 vertical levels with 41 levels below 700 hPa. The continental surface initial fields are
8 6 taken from the global model ARPEGE, which uses the same surface model as AROME-France,
9 7 known as SURFEX (Masson et al. 2013). The SST are initialized by the MERCATOR global model
10 8 PSY4 at 1/12 degree (Lellouche et al., 2018) and since 2017 AROME-OM has been coupled with a
11 9 1D vertical Mixed-Layer Ocean Model (CMO) (Lebeaupin et al., 2009). AROME-OM has no
12 10 specific tuning of its physical parameterizations compared to the AROME configuration (see
13 11 details in Seity et al. 2011). Note that at a 2.5 km grid spacing, the deep convection is permitted but
14 12 the shallow convection is parameterized by a mass-flux scheme based on a stationary bulk updraft
15 13 (Pergaud et al., 2009).

16 14 The assessment of AROME-OM is carried out over the French Caribbean domain (9.7-
17 15 22.9°N, 75.3°W-51.7°W, 1200 x 2000 km²) (Fig. 1a). The evaluation focuses on the south-eastern
18 16 part of this domain (Fig. 1a, black dashed box, 500 × 1000 km²) where the EUREC⁴A campaign
19 17 mainly took place. An additional forecasting setup of AROME-OM at a 1.3 km horizontal grid
20 18 spacing, the near-future operational configuration, was also performed specifically during
21 19 EUREC⁴A. This simulation was regridded at a 2.5 km resolution to ensure a fair comparison with
22 20 the operational configuration. Evaluation of this future configuration is focused in section 4.3.

23 21 24 22 2.2 Evaluation procedure

25 23
26 24 The evaluation of AROME-OM at a 2.5 km resolution spans across three winter seasons
27 25 (January-February) from 2018 to 2020 which ensures that a wide variety of large-scale
28 26 environments *isare* sampled. This evaluation is carried out against data collected at both the
29 27 Grantley Adams Airport (59.49°E, 13.07°N) and the BCO platform (Stevens et al., 2016) (Fig. 1b)
30 28 which is representative of a downwind trade regime where broken shallow cumuli prevail
31 29 (Medeiros and Nuijens, 2016). The dropsondes (George et al., 2021) that have been released along a
32 30 circle by the HALO aircraft during the EUREC⁴A campaign are also used for this evaluation.
33 31 Datasets used for the evaluation procedure are summarized in Table 1.

34 32 35 33 2.3 The BCO platform

36 34
37 35 In addition to standard surface meteorological measurements at 2 m above ground (wind,
38 36 temperature, humidity), the Max Planck Institute for Meteorology has installed at the BCO supersite
39 37 (<https://barbados.mpimet.mpg.de>) various advanced vertically-pointing remote-sensing devices.
40 38 Vertical profiles of hydrometeors (cloud and rain) are derived using the CORAL Ka-Band cloud
41 39 radar with a profile every 10 s and a vertical resolution of 30 m up to 18 km. The high sensitivity of
42 40 -55 dBZ at 5-km height for a 10-s averaging time, below which radar reflectivity is filtered, allows
43 41 to detect a wide spectrum of clouds in the entire troposphere (Görsdorf et al. 2015). For a fair
44 42 comparison with AROME-OM, the cloud radar profile (605 regular levels) is regridded on the
45 43 model vertical grid (90 levels). A roughly 30-min temporal averaging of the cloud radar profiles is
46 44 applied in order to match the horizontal scale resolved by the model (Hogan et al. 2001, Bouniol et
47 45 al. 2010). This averaging time is computed by estimating the required time for an air parcel to cross
48 46 the length of the effective horizontal resolution of the model advected by the horizontal wind. The
49 47 effective resolution is impacted by the implicit diffusion of the semi-implicit semi-lagrangian
50 48 scheme used in AROME (Malardel et al., 2015) and has been estimated as about nine times its
51 49 native grid spacing (Ricard et al 2012). To suppress echoes of rain below cloud base, cloud base
52 50 height and rain flag (rain-rate > 0.05 mm/hr) are derived using ceilometer and micro-rain radar (see

1
2
3 1 details in Nuijens et al. 2014). The occurrence of cloud is only considered when cloud fraction is
4 2 above 0.01.

5 3 Two different instruments are used for precipitable water (PW): a ground-based microwave
6 4 radiometer was installed in 2018 (Schnitt et al. 2020), followed by a Ground-based Global
7 5 Navigation Satellite System (GNSS) BCON station in 2020 (Bock et al., 2021). These datasets are
8 6 valuable for an evaluation of AROME-OM since they are not assimilated by its forcing IFS model,
9 7 with the caveat that the BCON GNSS shows a dry bias of 1.6 mm compared to the BCO sondes
10 8 (Bock et al., 2021).
11 9

12 13 14 10 2.4 Grantley Adams airport soundings 15 11

16 12 Within the Caribbean domain, five twice-daily (1100 UTC and 2300 UTC) radiosoundings
17 13 launched in Santo Domingo, San Juan, Le Raizet (Guadeloupe), Grantley Adams Airport
18 14 (Barbados), Trinidad and Tobago (Fig. 1a, blue stars) are assimilated into the IFS 4D system.
19 15 Within the domain targeted in this study, only the sounding of Barbados Airport (~ 5000 vertical
20 16 levels) remains for the assessment of the vertical thermodynamical profiles of AROME-OM. The
21 17 airport is located at an altitude of 52 metres in the southern part of the island, a few hundreds metres
22 18 away from the sea. It is located on the lee side of the trade winds which may differ slightly from
23 19 “pure” maritime conditions. The nearest grid point of the airport in AROME-OM is located 900 m
24 20 southwards at an altitude of 32 metres allowing an evaluation with a good accuracy. During
25 21 EUREC⁴A, soundings were also launched at the BCO but the period is not long enough for the
26 22 evaluation of AROME-OM thermodynamics.
27 23

28 23 29 24 2.5 EUREC⁴A dropsondes 30 25

31 26 During EUREC⁴A, additional vertical profiles are provided by the release of about twelve
32 27 dropsondes (George et al., 2021) along each HALO circle. The HALO circle path (Fig. 1a, blue
33 28 circle) extends between 12.3°N and 14.3°N (Konow et al., 2021), centred approximatively 1°
34 29 westwards of the BCO. To mimic the observations, the AROME-OM outputs have been averaged
35 30 along the circle. The evaluation of the parameters near the surface is carried out at 1000 hPa since
36 31 data from dropsondes are sometimes not available below this level. The dropsondes have also been
37 32 used to compute the vertical velocity from the divergence of the horizontal wind over the entire
38 33 circle (Bony and Stevens, 2019). For its evaluation, the simulated vertical velocity has also been
39 34 averaged over the entire circle in AROME-OM to ensure a fair comparison.
40 35

41 36 2.6 Satellite observations 42 37

43 38 In order to document the spatial variability, the dataset is complemented by observations
44 39 provided by spaceborne sensors, in particular from the visible channel 2 of the Advanced Baseline
45 40 Imager onboard the geostationary satellite GOES16. The satellite measures reflectance at a 0.5 km x
46 41 0.5 km resolution and a 10 minute temporal frequency. The combination of this reflectance and of a
47 42 2-km x 2-km cloud mask from the Nowcasting Satellite Application Facilities (SAFNWC) allows
48 43 us to construct a gridded field of cloud fraction at a 2-km x 2-km resolution. This gridded field
49 44 accounts for partial cloudiness inside a grid point instead of using a binary cloudiness flag. The
50 45 evaluation of the low and mid cloud cover (up to 450 hPa) of AROME-OM and IFS is carried out
51 46 against this reconstructed field.

52 47 To estimate PW, Advanced Microwave Scanning Radiometer 2 (AMSR2) measurements
53 48 (Imaoka, 2010) onboard Global Change Observation Mission–Water (GCOM–W1) satellite at a spatial
54 49 resolution of about 25 km x 25 km are also used. PW is retrieved from four AMSR2 channels
55 50
56 51
57 52
58 53
59 54
60 55

1
2
3 1 through a statistical algorithm. Errors on the PW retrieved from the AMSR2 family are expected to be
4 2 lower than 1 mm (Wentz and Meissner 2000).
5 3
6 4
7

8 5 **3. Ability of AROME-OM to represent the wintertime shallow convection**

9 6 10 7 3.1 Evaluation of the thermodynamical profiles

11 8
12 9
13 10 Figure 2 compares the wintertime composite soundings of 2300 UTC over the three
14 11 considered winters (January-February 2018-2020) with the vertical profiles of AROME-OM and of
15 12 the IFS model. The vertical profiles at 1100 UTC are not shown since they exhibit roughly the same
16 13 biases. Both potential temperature and specific humidity profiles show too deep a sub cloud layer
17 14 (SCL) in AROME-OM with a top located too high (~920 hPa) compared to the observations (~
18 15 940/950 hPa). This shortcoming also partly explains why AROME-OM is too dry (-1g/kg) in the
19 16 subcloud layer and too cold in the cloud layer (-0.5 K between 930-800 hPa). In contrast to
20 17 AROME-OM, the SCL is too thin in IFS compared to the observations, suggesting that the forcing
21 18 model does not control the thickness of the SCL in AROME-OM. It is hypothesized rather that the
22 19 shallow convection scheme (Pergaud et al., 2009) of AROME has to be tuned in order to reduce the
23 20 strength of the updraft or to adjust the entrainment/detrainment rates at the top of the SCL. The
24 21 overestimation of the wind speed (+1 to +2 m/s) in AROME-OM up to the trade wind inversion
25 22 (~800 hPa) could be partly driven by IFS as it roughly shows identical biases. This overestimation
26 23 of the trade winds in IFS has been recently confirmed by Savazzi et al. (2022) by using sondes that
27 24 have not been assimilated by IFS. Note that the 95% confidence interval of each environmental
28 25 profile (OBS and AROME) is rather weak which underlines the low intraseasonal variability of the
29 26 large-scale environment in which subtropical shallow convection form. Evaluation at the other
30 27 sounding sites in the Caribbean domain indicate similar biases. A simulation of AROME-OM
31 28 recently run over a vast domain from Barbados to Cape Verde during the period of EUREC⁴A
32 29 shows similar biases suggesting that the thermodynamics biases are rather linked to AROME
33 30 physical parameterizations than associated with the biases of the forcing model. In the following
34 31 sections, besides these existent biases, albeit weak, we analyse the ability of AROME-OM to
35 32 represent the shallow convection in terms of vertical and horizontal distributions.
36
37
38
39
40

41 33 3.2 Evaluation of the cloud fraction

42 34
43 35
44 36 Figure 3 shows an evaluation that spans the three considered winters (January-February
45 37 2018-2020) of the vertical distribution of the cloud fraction and of its occurrence frequency at the
46 38 BCO point. For a fair comparison with the AROME-OM hourly snapshots, cloud radar profiles are
47 39 averaged in time and vertically regridded (details in section 2.3). The AROME-OM vertical profile
48 40 of cloud occurrence (Fig. 3a) fits well the observed one with a peak of frequency of about 60-70%
49 41 near the cloud base, 900 hPa for AROME-OM and 920 hPa for the radar. As discussed in the
50 42 previous section, too thick and too cold a SCL explains why the cloud base is located too high in
51 43 the model. The radar profile shows a secondary peak of occurrence frequency at about 820 hPa
52 44 which is not simulated by the model (Fig. 3a). In contrast, when focusing on situations of cloud
53 45 occurrence (Fig. 3b), the cloud fraction of the secondary peak is well represented by AROME-OM
54 46 with values reaching 0.06. It demonstrates the ability of AROME-OM to mimic stratiform-like
55 47 clouds, although the occurrence of such clouds is significantly underestimated (Fig. 3a). The
56 48 temporal evolution of the cloud depth during EUREC⁴A shows that AROME-OM (Fig. 4a)
57 49 constructs two distinct modes of shallow convection: i) a first one, the most frequent, made of very
58 49 shallow convection (VSC) with a peak of cloud fraction of about 0.15 near the cloud base and ii) a

1
2
3 1 second one made of more vertically developed shallow convection (VDSC) with saturated cloud
4 2 fraction (magenta dot) near the cloud top. This latter feature illustrates that the updraft associated
5 3 with the cloud can cover the whole gridpoint. Indeed at a 2.5 km resolution the shallow convection,
6 4 in particular the stratiform one, is partially resolved (Honnert et al. 2016). As displayed in Figure
7 5 4b, the VSC mode is well observed in the cloud radar with a peak of occurrence of the maximum of
8 6 cloud fraction located near the cloud base, although values are slightly stronger (0.2-0.3) than in
9 7 AROME-OM. The VDSC mode exhibits divergent characteristics from AROME-OM with clouds
10 8 more vertically developed, the maximum of cloud fraction being instead located a few hundred
11 9 metres below the cloud top with a much more variable magnitude, from 0.3 to 1. For instance, from
12 10 22nd to 24th January 2020, the cloud top can exceed 4500 m in the observations and drops to 3000
13 11 m in AROME-OM. The distribution of the height of the base and the top of the cloud over the three
14 12 winter seasons (Fig. 5) confirms that AROME-OM shows a better ability to simulate the base than
15 13 the depth of the cloud. When small cloud fraction (<0.1) is filtered (Fig. 5b, right), the second peak
16 14 in the distribution of the cloud-top heights is well captured by AROME-OM. Overall, we may argue
17 15 that in spite of biases in the SCL, AROME-OM is able to simulate the double peak structure of the
18 16 shallow cumulus, with the caveat that the occurrence of the second peak is underestimated and
19 17 associated with an excessive cloud fraction when present.
20
21
22
23
24

19 3.3 Dependence of the cloud fraction on the large-scale environment

25
26
27 21 To gain further insight into how the large-scale environment affects trade wind cloudiness,
28 22 this section investigates the cloud fraction sensitivity to key controlling parameters such as 2m-
29 23 temperature (t_{2m}), 2m-zonal wind speed (u_{2m}), and PW. Figure 6 shows the mean profile of cloud
30 24 fraction associated with the 20 % lowest (resp. highest) parameter values as well as for 60% of
31 25 intermediate parameter values. These calculations are carried out only for common dates between
32 26 observations and AROME-OM in order to characterize similar environments. The spread between
33 27 the 20% lowest and 20% highest of each parameter is rather weak (see values in the figure legends),
34 28 highlighting the low variability of the environment over this maritime subtropical domain. 60 % of
35 29 values are within 1 K for the t_{2m} , 3 m/s for u_{2m} , and 9 mm for the PW.
36

37 30 The large cloud fractions near 800 hPa (Fig.6 upper panel) are associated with cold t_{2m} and
38 31 high PW in observations and AROME-OM but are not really sensitive to the surface wind speed.
39 32 To better investigate the role played by the large-scale environment, the high-frequency variability
40 33 of t_{2m} , u_{2m} and PW has been removed by a low-pass filter of 48h (Fig. 6 lower panel). The cloud
41 34 base in the observations is particularly sensitive to synoptic fluctuations in u_{2m} and PW (Fig. 6e-f).
42 35 An increase of u_{2m} leads to a moistening in the subcloud layer and an increase of cloudiness near
43 36 the level of free condensation. The failure of the model in reproducing this sensitivity could not be
44 37 linked with the biases identified in the SCL since near the surface, wind speed roughly fits the
45 38 observations (Fig. 7). More in-depth studies are necessary to disentangle the implied physical
46 39 mechanisms but mesoscale circulations associated with more vertically developed cumulus or
47 40 strength of the surface moisture flux could be misrepresented at a 2.5 km grid spacing. It is worth
48 41 mentioning that at the strongest u_{2m} the model shows rather a good ability to reproduce the
49 42 deepening of the cloud above 800 hPa (dotted lines, Fig. 6b,e), which confirms the findings of
50 43 Nuijens and Stevens (2012).
51

52 44 The second peak of cloudiness is the most influenced by large-scale environments, with
53 45 enhanced cloudiness on the days that are the coolest (Fig. 6d). This second peak is also influenced
54 46 by fluctuations of large-scale PW (Fig. 6f), suggesting that a drier environment favours stronger
55 47 trade wind inversion. In contrast, on the days that are the hottest, the cloudiness near 800 hPa
56 48 decrease. This is consistent with the findings of Schulz et al. (2021), showing that stratiform-like
57 49 structure rather originate from mid-latitudes (low t_{2m}) whilst variable vertically extensive structure
58 50 are consistent with a more tropical influence (high t_{2m}) (their Fig. 6 and 10). Note that when PW is
59
60

1
2
3 1 not filtered (Fig. 6c), PW and cloud depth are strongly correlated since PW corresponds to the local
4 2 footprint of the clouds.

5 3 Overall, it may be argued that the sensitivity of the large-scale environment is captured more
6 4 by the model at the cloud-top height than at the cloud base, suggesting that the subtle relationship
7 5 between clouds and environment are better represented at the level of the trade wind inversion than
8 6 in the subcloud layer or near the surface.

10 7 11 8 3.4 Evaluation of the environment variability on a daily to interannual scale 12 9

13 10 In the previous section, PW, u2m and t2m have been identified as large-scale parameters
14 11 that greatly control the cloud fraction of the shallow convection. To gain further insight into how
15 12 these parameters interplay, Figure 7 exhibits their 24h averaged time-evolution during three winter
16 13 seasons for both observations and AROME-OM at the BCO grid point. The evaluation of the
17 14 precipitation is carried out against precipitation forecasts averaged over a 0.25° square ahead of
18 15 BCO (Fig.1b, pink square), which is equivalent to the effective resolution of the clouds.
19 16 Precipitation is accumulated over a 0600-0600 UTC period.

20 17 AROME-OM captures fairly well the interannual variability of the environment at the BCO,
21 18 with a relatively wet, hot and windy season in 2018 followed by a relatively dry, cool and calm
22 19 season in 2019. The intraseasonal variability, with successive dry and wet events, is also well
23 20 reproduced. The day-to-day variability of PW is consistent with the estimates of the microwave
24 21 radiometer (HATPRO) and of the GNSS retrievals, except for the strongest events which are
25 22 underestimated down to -5 mm. Bock et al. (2021) highlighted the same shortcoming in the ERA5
26 23 reanalysis. The underestimation of precipitation in AROME-OM in intermediate range of intensity
27 24 (from 1 to 10 mm/day) found by Faure et al. (2020) could be related with this underestimation of
28 25 the peak of PW. In the absence of a strong peak of PW, as in 2019, the PW is in contrast
29 26 overestimated by AROME-OM by about 1 mm. The surface wind speed is also in good agreement
30 27 with the observations, except during the period of slackening of the winds (e.g. 15th-17th February
31 28 2019) where the overestimation in the model reaches 2 m/s. This bias could be partly accounted for
32 29 by the difference of land surface between the model and the BCO platform since the grid point in
33 30 AROME-OM is located a few hundreds metres away from the island. Although obviously less
34 31 pronounced near the surface, the overestimation of the wind is consistent with the bias observed in
35 32 radiosoundings (Fig. 2) at Grantley Adams Airport. The bias in surface temperature is not
36 33 significant (~ -0.2 K), except during marked rainy events (e.g. 23th January 2020) with a warm bias
37 34 ($\sim +1$ K) which may be related to the land surface difference between the grid point of AROME-OM
38 35 and the BCO.

39 36 It is not obvious to disentangle the interplay between PW, u2m, t2m and precipitation. The
40 37 relative dry season in 2019, dominated by low PW and scarce precipitation, appears to be correlated
41 38 with weak surface wind speed, which corroborates the literature (Nuijens and Stevens, 2012). In
42 39 2018 and 2020, except during the periods of sudden stilling in the trade wind regime (e.g. 1st-3th
43 40 February 2018), this relationship weakens. Indeed, the period of strengthening of the wind (e.g. 6th-
44 41 9th February 2020) is not necessarily associated with a moister environment (PW \sim 32mm). The
45 42 slow decrease of PW across the season 2018 is paired with that of t2m. However, this correlation is
46 43 not evident the two following years. The question of the link between precipitation occurrence and
47 44 PW was raised by Neelin et al. (2009). They found that precipitation may be triggered above a
48 45 critical value of PW which is driven by the mean layer-integrated tropospheric temperature. This
49 46 threshold is around 36 mm over the Sahel in summer (Parker, 2017, their Fig. 3.5) whereas it drops
50 47 to about 25-30 mm over the subtropical ocean in winter which explains the high occurrence of rainy
51 48 days since this threshold is often exceeded.

52 49 This discussion shows how it is difficult to shed light on the interplay of parameters that
53 50 control cloud fraction. Nevertheless, the good ability of the model to reproduce their temporal

1
2
3 1 variability allows to support the results of Fig. 6 concerning the sensitivity of the cloud fraction to
4 2 the large-scale environment.
5
6 3

4 4 **4. Ability of AROME-OM to represent the different shallow convection** 5 **mesoscale organisations during EUREC⁴A** 6 7

8 In this section, we investigate the ability of AROME-OM to reproduce the four main
9 mesoscale cloud spatial organisations (Stevens et al., 2020) and the environment in which they
10 form, with a particular focus on four different periods selected during the EUREC⁴A campaign.
11

11 4.1 Identification of four distinct large-scale environments during EUREC⁴A 12

13 Figure 8 shows the AROME-OM longitudinal Hovmöller diagrams for the EUREC⁴A field
14 campaign (16th January – 16th February 2020) averaged on the latitude band of the HALO circle for
15 various parameters which are likely to control the trade wind cumuli patterns: surface wind speed,
16 large-scale vertical velocity in the mid-troposphere ($\omega_{500-600}$ hPa), PW and estimated inversion
17 strength (EIS, Wood and Bretherton, 2006), defined as $EIS = LTS - \Gamma_{850}(z_{700} - LCL)$ where Γ_{850}
18 850 is the moist-adiabatic potential temperature gradient at 850 hPa, z_{700} is the height of the 700
19 hPa level, and LCL is the height of the lifting condensation level. In addition, the 6h accumulated
20 precipitation is shown. Focusing on the longitude of the HALO circle (in between the two vertical
21 dashed lines), several periods showing a distinct environment can be identified:
22

23 i) From 22nd to 25th January, the air mass is under the influence of an extra-tropical
24 intrusion in a form of a trailing cold front, associated with both a shear line in the trade winds (Fig.
25 8d, see the horizontal dashed-dotted line) and an increase of PW (Fig. 8a, see the tongue-like
26 structure). Schulz et al. (2021) and Aemisegger et al. (2021) suggested that the Fish pattern
27 frequently arises in association with this synoptic environment. The concomitant decrease of the
28 inversion strength (Fig. 8b) favours the deepening of the shallow cumulus leading to a significant
29 precipitation event (Fig. 8c). The large-scale environment of this period is called E1.
30

31 ii) This disturbed period is followed for about 4 days (27th-30th January) by fair weather with
32 very shallow cumulus (see the reports from the HALO <https://observations.ipsl.fr/aeris/eurec4a/#/>).
33 After the passage of the cold front, the depth of the trade wind layer decreases with calm winds at
34 the surface and above, at 700 hPa, a regime of light westerlies occurs. A decrease in wind speed
35 paired with a drop in surface temperature lead to a reduced latent heat flux and a relative decrease
36 of PW (Fig. 7c, see 27th January). The joint effects of weak subsiding motion in mid-troposphere
37 and the absence of strong inversion trades (+1 to +3 K), which prevents the spreading of the cloud
38 tops, favours the occurrence of a field of small ‘pop corn’ cumuli or even a regime of suppressed
39 clouds. This environment associated with a ‘pause’ in the trade wind regime is called E2.
40

41 iii) From 2nd February, the trade wind layer is largely modified with a sudden restoration of
42 strong easterlies at 700 hPa (Fig. 8e) associated with a deepening of the trade wind layer and an
43 increase of the inversion strength. However, surface easterlies remain weak for the season (Fig. 8d).
44 This ‘intermediate’ trade wind regime is so-called E3.
45

46 iv) From 5th to 11th February, the environment returns to its mean climatological features
47 with both an increase in the surface trade winds and stronger subsiding motion in mid-troposphere
48 coinciding with a westward extent of the subtropical North Atlantic high (not shown). This synoptic
49 regime results in both a moistening of the boundary layer (increase of PW) and weaker inversion
50 strength, leading to an increase in significant rainy events. This environment, more representative of
51 a climatological ‘trade wind regime’, is called E4.

4.2 Selection of four cases representative of the distinct large-scale environments

We hereby investigate whether the four distinct large-scale environments (E1, E2, E3, E4) identified in the previous section can be associated with different spatial mesoscale cloud organisations observed in geostationary images (Fig. 9, first line). The model shows a very good ability to reproduce the large variety of mesoscale pattern throughout the EUREC4A campaign (<https://observations.ipsl.fr/aeris/eurec4a/>) but in this study we focus on particular days for which a HALO flight has been conducted. The choice of the cases and their following description largely rely on both the HALO flight reports and the C³ONTEXT (Common Consensus on Convective OrgaNizaTion during the EUREC⁴A eXperiment) classification based on satellite observations (Schulz 2022):

i) The 24th January at 1200 UTC (Fig. 8 black dot) is characterized by an unusually deep (4 km) convection overshooting the trade wind inversion producing extensive stratiform clouds which are the remnants of the apparent fishbone-like skeleton. The presence of evident cold-pool to the north of the HALO circle is also mentioned in the flight report. According to the classification of Stevens et al. (2020), the appearance of this mesoscale cloud organisation can be associated with a Fish pattern (FI in the following). Following the C³ONTEXT classification of Schulz (2022), 22nd January would appear to be a better choice for the representation of the Fish environment (E1) nevertheless when HALO flew, the FI cloud patterns were much more prevalent on 24th February.

ii) To illustrate the environment E2, the 28th January at 1800 UTC (Fig. 8 blue dot) is selected. It is dominated by scattered shallow convection except in the very north with a remnant of a northwest-southeast oriented line of flower-like elements. This case is close to a Sugar cloud organisation (SU in the following).

iii) For the environment E3, the 2nd February at 1800 UTC (Fig.8 red dot) is chosen. It is characterized in the vicinity of the HALO circle by the occurrence of flowers-structure (FL in the following) associated with marked cold pools. The physical mechanisms implied in such a cloud pattern are fully documented by recent studies based on LES (Narenpitak et al. 2021, Dauhut et al., 2022).

iv) For the environment E4, the 9th February at 1200 UTC (Fig.8 yellow dot) is selected. The scene of the HALO circle was dominated by streets of cloud cumulus in development with occasionally larger stratiform cloud aggregation associated with precipitation. This variety of vertical extension (up to 3-4 km) with clouds organized along lines, sometimes resembling cold pools, may correspond to a Gravel cloud organisation (GR in the following).

4.3 Ability of AROME-OM to reproduce the four cases

The ability of AROME-OM to represent these four aforementioned cases is now assessed, both in its current configuration and in its future configuration at a 1.3 km resolution. This evaluation is also carried out against the analyses of IFS at a 12.5 km horizontal grid spacing.

Figures 9 and S1 (first row) present the cloud organisation as observed by geostationary satellite observations. Focusing on the scene of the HALO circle (Figure S1), the size of the cloud pattern depends widely on the organisations: SU is mostly populated by unorganized and very small cloud patterns, FI is dominated by large organisation of about 100 km wide, FL is more characterized by circular clumped structures of about 50-100 km whilst GR shows more linear patterns organized along lines of a few tens of km (yellow arrows). Both configurations of AROME-OM (second and third rows) show a good ability to reproduce the main features of these distinct organisations such as the mesoscale fish-bone like structure on the southern side of the HALO circle, the apparent gust front along which FL and GR clouds pattern form (Fig. S1, dashed yellow lines) as well as the large areas of clear air that surround FI and FL structures. Compared to the satellite images, the loss of accuracy in the structure of the clouds in both runs of AROME-OM is

1 partly linked with their effective resolution which is about 22-25 km for the current configuration
2 and 12 km for the future configuration. This is particularly evident for the finer structures as SU and
3 GR (Fig. S1). The benefit from an increase of resolution of AROME-OM is substantial on the
4 eastern boundary of the domain, where finer structures are better caught at a 1.3 km resolution (Fig.
5 9). The evaluation of AROME-OM is carried out in the vicinity of the HALO circle which is quite
6 far from the eastern side of the domain which may be strongly influenced by its forcing model. IFS
7 partly fails to mimic the main cloud organisations (Fig. 9), except for the extensive stratiform
8 clouds or flower-like structure, highlighting the need of a kilometre-scale model to reproduce the
9 four main mesoscale patterns described in Stevens et al. (2020).

10 In both the models and the satellite observations, the patches of cloud fraction greater than
11 80% (Fig. 10, blue contour) roughly coincide with PW greater than 36 mm (Fig. 10, in orange),
12 especially for GR and FL cases. PW exhibits strong mesoscale variability which suggests a major
13 role of the low-level convergence leading to a fast increase of PW, rather well captured by both
14 versions of AROME-OM. For instance, PW in the FI case ranges from 30 mm north of the HALO
15 circle to about 50 mm southeast. This mesoscale pattern is dominated by the most extensive patches
16 of the highest values of PW (> 50 mm) that are the footprint of the fishbone-like skeleton. The GR
17 type is rather populated by isolated strong peaks of PW (~ 50 mm) that do not exceed a horizontal
18 extension of about 10 km. FI and GR types are probably the two cases with the most extensive
19 cloud depth. The AROME-OM vertical-longitudinal cross section of the relative humidity (Fig. S2,
20 2nd line) indeed reveals that the cloud top height reaches 4 km (550/600 hPa) for FI and 5 km
21 (500/550 hPa) for GR. Although a little overestimated, this relative deep extension of the cumulus
22 was supported by the observations during the HALO flight. The joint examination of the spatial
23 distribution of the cloud fraction and the PW (Fig. S1 and Fig. 10) does not allow to determine a
24 PW threshold below which large-scale area of suppressed clouds occur. For instance, for the SU
25 case, the extensive area of clear sky in the region of the HALO exhibits PW ranging from 24 mm to
26 the north-east to 36 mm to the southwest. To better understand the relationship between PW and
27 cloud occurrence, further investigations must be undertaken. LES would be a suitable tool to
28 disentangle the mechanisms at play and their key spatio-temporal scales. In particular, the question
29 is open as to whether the positive anomalies in PW are due to enhanced boundary layer convective
30 activity, to shallow convection outflow (Narenpitak et al. 2021, Bretherton and Blossey 2017,
31 Dauhut et al. 2022), or former cloud clusters which dissipate.

4.4 Assessment of the large-scale environment during the four case studies against the dropsondes

35 The large-scale environment in which the four cases form is assessed against a unique
36 dataset of dropsondes launched along the HALO circle. The evaluation procedure is detailed in
37 section 2.3.

38 Figure 11 shows a comparison of the distribution of each parameter along the HALO circle
39 for the four cases. The distribution of both AROME-OM and IFS roughly agrees with that of
40 dropsondes, with a little benefit for AROME-OM, for the near surface temperature and relative
41 humidity, as well as PW in three out of four cases. The overestimation of the inversion strength in
42 AROME-OM ($\sim +2$ K) appears to be partly controlled by its forcing model ($\sim +1$ K). This may be
43 indicative of an overestimation of the large-scale-subsidence in free troposphere but the
44 examination of the vertical profile of the vertical velocities (Fig.12 for AROME-OM, not shown for
45 IFS) does not allow the confirmation of this hypothesis. Similarly, the large PW overestimation in
46 AROME-OM for FI and GR cases ($+4$ mm) is likely driven by that of IFS ($+5$ to $+6$ mm), even if
47 this bias is not observed for the two other cases. Both near surface wind speed and near surface
48 temperature exhibit weak biases (resp. < 1 m/s and < 0.5 K) which are in good agreement with the
49 biases found at the BCO during the three winter seasons (Figure 7).

50 Figure 12 compares the thermodynamical profile of AROME-OM against the mean

1 profile of about twelve dropsondes. Overall, the biases of the four cases are consistent with those
2 previously identified in the radiosoundings at Grantley Adams Airport during the three winter
3 seasons (2018-2020), namely a cold bias in the cloud layer (~ -1 K 930-800 hPa), a dry bias (~ -1
4 g/kg) in the subcloud layer as well as an overestimation of the trade winds (~ 1 m/s) below 850 hPa.
5 The AROME-OM vertical velocity profiles roughly coincide with those of the dropsondes, even if
6 the magnitude of the upward motion in the cloud and subcloud layers of the GR case is
7 underestimated.

8 To summarize, in spite of weak biases, AROME-OM is able to represent the variety of
9 large-scale environments in which the main mesoscale organisations form.

11 4. 5. Documentation of the air masses of the four case studies

12
13 Recent investigations (Bony et al. 2020, Schulz et al. 2021) have shown that the near-
14 surface wind speed and the strength of the lower-tropospheric stability play a discriminating role on
15 the occurrence of the mesoscale patterns in the western North Atlantic trade wind region. This
16 following section hereby investigates to what extent the variety of large-scale environment
17 identified among the 4 case studies adheres these findings.

18 The examination of the thermodynamical profiles (Fig. 12) allows us to discriminate the
19 four cases into two thermodynamically distinct environments : a first including the FI and SU cases
20 (so-called 'FISU') with a shallow trade wind layer (1st line) and a second one including FL and GR
21 cases (so-called 'FLGR') with a deep trade wind layer penetrating up to 600 hPa (2nd line). This
22 difference of environment occurs throughout the Caribbean domain (Fig. S2, 1st line) and is rather
23 consistent with the findings of Bony et al. (2020) who have shown that FL and GR tend to form
24 when the trade wind are strong.

25 The FI and SU environments differ greatly in their estimated inversion strength. As
26 discussed in section 4.1, this FI case is driven by an extratropical wind shear line leading to an
27 increase of low-level convergence and moistening (PW ~ 40 mm, Fig. 11) which in turn favours
28 instability (EIS ~ 0 K, Fig. 11). The strong upward motion in the SCL (Fig.12) supports the vertical
29 development of cumulus up to 600 hPa as exhibited on the vertical profile of specific humidity (Fig.
30 12). In contrast to the FI case, the SU case is characterized by a somewhat stronger inversion
31 strength (EIS $\sim +2-3$ K, Fig.11). Disentangling mechanisms responsible for such differences between
32 FI and SU is rather complex, but a finer exploration of the causes of the sudden stilling in the trade
33 wind regime provides a hint. Here, the light winds are associated with a loose horizontal pressure
34 gradient in relation with a westward shift of the subtropical highs over Southern Europe (not
35 shown). In agreement with the findings of Nuijens et al. (2012), a slackening in the trade wind
36 regime is correlated with low PW (Fig. 7, see between the blue vertical line and the two days
37 before). In turn, low PW favours both stability and subsiding motion in the SCL, as exhibited in the
38 vertical profile. This case is consistent with the works of Bony et al. 2020 where during the winter
39 2009-2010 (their Fig. 4e) SU pattern can occur in such a stable environment.

40 The FL and GR case environments also significantly differ by their inversion strength. The
41 GR case arises in an unstable environment with an estimated inversion strength close to 0 (Fig. 11).
42 Examination of the vertical profile of potential temperature (Fig. 12) confirms that this case is the
43 most unstable among the four cases even if the signature of the clouds is not visible on the vertical
44 profile of the specific humidity since no deep cumulus crosses the HALO circle but rather lies
45 inside. The vertical extension of cumulus up to 4 km (Fig. S2 ~ 600 hPa) is probably fuelled by the
46 occurrence of strong upward motions in the subcloud layer (Fig. 12). The ability of the strong
47 subsidence in mid-troposphere in patterning the mesoscale shallow convection need more in depth-
48 studies. In contrast to the GR case, the FL case is associated with a strong inversion strength
49 (EIS $\sim +4-5$ K, Fig. 11). In agreement with Schulz et al. (2021), the cloud top is much lower than in
50 the GR case (Fig. S2, 2nd line) and spread below a 700-750 hPa layer of strong stability (Fig. 12, see

1
2
3 1 potential temperature). This case exhibits significant subsiding motions in the SCL (Fig.12, red
4 2 lines) which probably represent the footprint of a cold pool covering the major area of the HALO
5 3 circle. In agreement with Bock et al. (2021), it could be hypothesized that in a windy environment
6 4 the difference of organisation between FL and GR is not driven by the PW since the same amounts
7 5 of PW are observed for both cases (Fig. 11), which differs greatly from the environment of the
8 6 FISU family where PW plays a discriminating role.

9 7 To conclude, it may be argued that AROME-OM captures the large variety of environment
10 8 in which the four main organisations identified by Stevens et al. (2020) form. The four illustrated
11 9 cases are in agreement with the past studies, except for the FI case which is characterized by a much
12 10 stronger inversion strength than usually observed (Bony et al. 2020, their Fig. 4e).

13 11

14 12 **6. Conclusions**

15 13
16 14 The major aim of this study was to investigate the potential of the French operational
17 15 convection-permitting model AROME-OM in order to represent the shallow convection in the
18 16 downwind trade regime. The principal findings are based on a set of three wintertime (January-
19 17 February 2018-2020) 2.5 km resolution simulations performed across a very large domain (2000 x
20 18 1200 km²) with lateral boundary conditions provided by IFS. A subdomain is defined (1000 x 500
21 19 km²) in order to take advantage of the international EUREC⁴A field campaign which took place to
22 20 the east of Barbados in January-February 2020. In terms of observations, this study also benefits
23 21 from in-situ measurements which have been collected at the Grantley Adams Airport and at the
24 22 BCO platform which are both representative of the environment in which trade wind cumuli
25 23 develop.

26 24 The evaluation of the model against the soundings of Grantley Adams Airport revealed an
27 25 excessive deepening of the boundary layer leading to a cold and dry bias, along with trade winds
28 26 which were too strong. One objective of this study was to investigate the ability of AROME-OM to
29 27 capture the double peak of cloud fraction (Nuijens et al. 2014), with a first peak near the cloud base
30 28 (~920 hPa) and a second peak near the top (~820 hPa) of the deepest cumuli. Even though the
31 29 shallow convection is parametrized as in most kilometric-scale horizontal resolution models, the
32 30 model shows a good ability to simulate a larger variance in cloudiness near cloud top rather than
33 31 near cloud base, in agreement with observations (Schulz et al., 2021). Cloud depth is overall a little
34 32 underestimated in AROME-OM and the cloud fraction near the top of the deepest cumuli is too
35 33 strong. This suggests that additional calibration of the vertical mixing of the shallow convection
36 34 scheme which strongly affects the depth of the boundary layer (Heim et al., 2021) is required. The
37 35 analysis of the cloudiness sensitivity to the large-scale environment indicates a significant increase
38 36 at the cloud top for colder surface temperature and low PW, which probably corresponds to FL or
39 37 FI cloud organisations. In agreement with Nuijens and Stevens (2012), it has also been found that
40 38 the cloud deepens in conditions of stronger winds, with the caveat that the increase of cloudiness
41 39 near the cloud base is poorly represented in AROME-OM.

42 40 One may also wonder if air mass characteristics are indicative of the different mesoscale
43 41 cloud organisations. Earlier studies (Schulz et al. 2021, Bony et al. 2020, Aemisegger et al. 2021,
44 42 Medeiros and Stevens 2011) suggested that organisation is the result of combined effect of various
45 43 parameters such as surface wind speed, lower-tropospheric stability and vertical velocity in mid
46 44 and/or low troposphere. The EUREC⁴A field campaign allowed us to show the good ability of
47 45 AROME-OM at a 2.5 km resolution to represent the large variety of organisations that occur in
48 46 boreal winter conditions in the North Atlantic trades (Stevens et al. 2020). This study focuses on
49 47 four case studies that were selected during this campaign on the basis of the HALO flight reports
50 48 and of the C³ONTEXT classification (Schulz 2022). Our analysis reveals that AROME-OM gives a
51 49 much better description of the cloud organisation than a model at lower resolution such as IFS for
52 50 those cases. The model shows a good ability to describe the different environments in which the

1
2
3 1 four cases form, in line with the EUREC⁴A observations, with weak biases consistent with the
4 2 biases found when comparing to the long-term observations at the BCO. In agreement with past
5 3 studies (Bony et al. 2020, Schulz et al. 2021), the FI and SU cases occur in a calm environment
6 4 associated with a shallow trade wind layer whilst the GR and FL cases arise under the influence of a
7 5 windy environment characterized by a deep trade wind layer. This study is also in phase with the
8 6 work of Bock et al. (2021) which revealed that the amount of PW does not allow to distinguish the
9 7 patterns, except for FI. The main point of divergence with earlier studies (Bony et al., 2020) is
10 8 related to the FI case since it is characterised by stability much lower than usually observed. A
11 9 closely related question is how vertical velocities matters for the organisation of mesocale shallow
12 10 convection. In agreement with Dauhut et al. (2022), the four case studies highlight that mesocale
13 11 vertical motions represent the imprint of the cloud systems, but the role of vertical velocities at
14 12 larger scale (hundreds of km) on the cloud organisation remains an open question.

15 13 In this study, we have focused on the sensitivity of the organisation to the environment but
16 14 further work is necessary in order to explore which processes are involved in the aggregation of the
17 15 shallow convection into mesoscale organisations. In particular the role of cold pools (Touzé-Peiffer
18 16 et al., 2021) or diabatic heating (Bretherton et al., 2017) merit further investigation. The changes in
19 17 organisation that occur across the subtropical Atlantic Ocean could also be explored in virtue of the
20 18 use of such kilometric convection-permitting model in order to conduct simulations over vast
21 19 domains for several weeks.

22 21 **Acknowledgements**

23 22 The authors are grateful to the reviewers and Marie Lothon for their thoughtful and useful
24 23 comments that have greatly improved the original manuscript and Yohan Brunet for his
25 24 contribution to this work. We also kindly thank all contributors to the datasets used in this study,
26 25 which were produced as part of the EUREC⁴A campaign, and in particular Geet George for his
27 26 JOANNE dropsonde products. Special thanks to Olivier Bock and Sabrina Schnitt for providing
28 27 data from the gps and the radiometer installed at BCO and for their useful advice. The BCO
29 28 infrastructure is maintained by Ilya Serikov, Lutz Hirsch, Friedhelm Jansen, Bjoern Bruegmann,
30 29 Monika Pfeiffer, and Holger Linne: without them this work would not have been possible. We
31 30 would like to thank Vincent Douet from AERIS and the AERIS team for their support in publishing
32 31 on the website <https://observations.ipsl.fr/aeris/eurec4a/#/> the datasets, the AROME outputs at both
33 32 resolutions (2.5 km and 1.3 km), and the HALO flight reports associated with this paper.

Figure 1: (a) Map of the Caribbean domain (1200 x 2000 km²) of AROME-OM with blue stars indicating available radiosoundings (DOMI for ‘Santo Domingo’, JUAN for ‘San Juan’, GUAD for ‘Guadeloupe’, ‘BARB’ for Grantley Adams Airport, TRID for ‘Trinidad and Tobago’). The black dashed box indicates the focus domain (500 x 1000 km²) for the evaluation of AROME-OM. The blue circle represents the HALO circle path along which dropsondes are released during the EUREC⁴A campaign. The thin black rectangle is the zoom shown in (b). In the background the mean AROME-OM SST averaged over the EUREC⁴A period (January-February 2020) is displayed. (b) Zoom over the Barbados Island with radiosounding launched at Grantley Adams Airport and the Barbados Cloud Observatory (BCO) equipped with various remote-sensor instruments such as the cloud radar. The 81 pink mesh grids represent the size of the effective resolution of AROME-OM which is about 9 times its native grid (2.5 km) (see details in section 2.3).

Figure 2: Mean vertical profiles (January-February 2018-2020) at 2300UTC at the Grantley Adams Airport of the (a) potential temperature, (b) specific humidity, and (c) wind speed for the radiosoundings (full dark line), AROME-OM (grey full line) and IFS (grey dashed line) models. The 95% interval confidence is displayed with black horizontal lines for the radiosoundings and with grey shading for AROME-OM.

Figure 3: Mean vertical profiles (January-February 2018-2020) at the BCO of (a) the cloud occurrence frequency, and (b) the cloud fraction when there is occurrence. The Coral cloud radar is displayed in black and AROME-OM in grey.

Figure 4: Temporal evolution at the BCO of the cloud during EUREC⁴A at an hourly frequency. The vertical lines represent the vertical extension of the cloud. The dots represent the location of the maximum of the cloud fraction with colour indicating its value ranging between 0 and 1. Coloured dots (black, blue, red, yellow) represent the four case studies (Fish, Sugar, Flower, Gravel) detailed in section 4.

Figure 5 : Occurrence distribution over three winter periods (January-February 2018-2020) at the BCO for AROME-OM (in blue) and the cloud radar (in brown) of the cloud base height (left figure) and the cloud top height (right figure) for two different thresholds (0.01 and 0.1) below which cloud fraction is masked. The two dotted lines represent the first and last quartile and the dashed line the median of each distribution.

Figure 6: Mean vertical profiles (January-February 2018-2020) at the BCO of the sensitivity of the cloud fraction to the (a) surface temperature (t_{2m}), (b) surface zonal wind speed u_{2m} (c) precipitable water (PW). For PW, estimates come from HATPRO. (d-e-f) same as (a-b-c) but for 48h low-pass filtered t_{2m}, u_{2m}, PW. The mean cloud fraction associated with the 20% lowest values (first quintile) of the distribution of each parameter is plotted on a dotted line, the 60% intermediate values on a dashed line, and the 20% highest values (last quintile) on a solid line. Note that the first quintile (20% lowest values) of u_{2m} represents the strongest trade winds (on a dotted line).

Figure 7: Daily averaged time-evolution at the BCO over three winter periods (January-February 2018-2020) for the observations (dashed line) and AROME-OM (solid line) of the precipitable water (in blue), the surface zonal wind (in grey) and the surface temperature (in green). In all panels, PW estimates derived from the HATPRO radiometer are displayed with a dashed blue line. For 2020, in the lowest panel, PW estimates derived from the BCON GNSS are displayed with blue diamonds. Blue bars represent the 24h-accumulated precipitation (0600-0600 UTC) of the raingauge (blue solid bar) and of AROME-OM (white bar with blue edge) that have been averaged over a $0^{\circ}25$ square ahead of BCO (see Fig. 1b). Vertical coloured (black, blue, red, orange) solid lines represent the four case studies (Fish, Sugar, Flower, Gravel) detailed in section 4.

Figure 8: Longitude-time diagrams over the EUREC⁴A's period (16th January-16th February) for the AROME-OM 6h-30h forecasts range initiated every day at 0000 UTC of the (a) precipitable water (PW, in mm), (b) estimated inversion strength (EIS, in K), (c) 6h-accumulated precipitation (mm), (d) surface zonal wind speed (u_{10} , in m/s), (e) zonal wind at 700 hPa (U_{700} , in m/s), and (f) vertical velocity averaged in the layer 500-600 hPa ($w_{500-600}$, in Pa/s). Fields are averaged in the latitude band of the HALO circle extending between 12.3°N - 14.3°N . (a-f) The two vertical dashed lines denote the longitudinal extension of the HALO circle. (a-c) The tongue-like structure (black solid line) outlines a period of large PW, low EIS and high precipitation. (d) The dashed-dotted line highlights the occurrence of a shear line in the zonal wind. (d-e) The dashed lines represent periods of (d-e) strong winds and (f) strong subsiding motions. Coloured dots and vertical bars mark the four case studies and their associated environment (E1, E2, E3, E4) which are detailed in section 4.

Figure 9: Cloud fraction (%) for (1st column) the FI case on 24th January 1200 UTC, (2nd column) the SU case on 28th January 1800 UTC, (3rd column) the FL case on 2nd February 1800 UTC, and (4th column) the GR case on 9th February 1200 UTC. The 1st line shows the 2 km gridded field of cloud fraction (up to 450 hPa) constructed with a combination of the visible channel of GOES16 and a cloud mask from SAFNWC. The 2nd-4th lines represent the cloud fraction (up to 450 hPa) of AROME-OM at a 2.5 km resolution, AROME-OM at a 1.3 km gridded at a 2.5 km resolution, and IFS at a 12.5 km resolution, respectively. The BCO is represented by a yellow star and the HALO path by a yellow circle.

Figure 10: As in Figure 9 but for the PW and focused on the HALO circle. The 1st row for the PW as measured by AMSR2 for the 24th January 1512 UTC (FI), 28th January 1635 UTC (SU), 2nd February 1657 UTC (FL) and 9th February 1703 UTC (GR). The cloud fraction greater than 80% is superimposed with a blue isoline. The BCO and the HALO path are represented by the black star and the black circle, respectively.

Figure 11: Distribution along the HALO path circle for the four case studies of the (a) PW, (b) 1000 hPa zonal wind speed, (c) zonal wind speed at 700 hPa (U_{700}), (d) EIS, (e) 1000 hPa temperature, (f) 1000 hPa relative humidity from the JOANNE dropsonde products (obs), AROME-OM (Aro) and IFS. The FI case is displayed in black, the SU in blue, the FL in red and the GR in yellow. Orange lines represent median values and coloured box the interquartile range. Upper whiskers extend up to 1.5 times the last interquartile and lower whiskers down to 1.5 times the first interquartile.

Figure 12 Vertical profiles for the FI and SU cases (1st line) and the FL and GR cases (2nd line) of the (1st column) zonal wind (U), (2nd column) potential temperature, (3rd column) specific humidity (q_v), and (4th column) vertical velocity (VV). Averaged over the HALO path, solid lines represent JOANNE dropsonde product and dotted lines AROME-OM.

Figure S1: As in Figure 9 but zoom on the HALO circle for OBS, AROME-OM at a 2.5 km resolution, AROME-OM at a 1.3 km resolution gridded at a 2.5 km resolution. Examples of cold pools are identified in FL and GR with yellow dashed lines.

Figure S2: Vertical-longitudinal cross section along the AROME-OM domain at a 2.5 km resolution for the (1st column) FI case, (2nd column) SU case, (3rd column) FL case, (4th column) GR case of the (1st line) zonal wind, with easterlies in brown and westerlies in green, and (2nd line) relative humidity. Fields are averaged in the latitude band extending between 13°N-13.5°N. The two vertical dotted lines indicate the longitudinal extension of the HALO circle.

Table 1: Set of data used for the evaluation of AROME-OM.

Parameter	Instrument	Period	Resolution OBS	Figure Number (* with low- pass filter)
			<i>AROME-OM</i>	
Cloud fraction (z profile)	Cloud radar and Ceilometer	Jan/Feb 2018-2020	BCO	Fig.3-4-5-6
			2.5 km	
Cloud fraction (x,y)	GOES16+SAFNWC	4 case studies	2 km x 2 km	Fig.9, Fig. S1
			2.5 km and 1.3 km	
Accumulated rainfall	raingauge	Jan-Feb 2018-2020	BCO	Fig.7
			Square ahead of BCO (22.5 x 22.5 km ²)	
PW (x,y)	AMSR2	4 case studies	25 km x 25 km	Fig.10
			2.5 km and 1.3 km	
PW	GNSS radiometer HATPRO	Jan/Feb 2020	BCO	Fig.6*, Fig.7
		Jan/Feb 2018-2020	BCO 2.5 km	
u2m	Anemometer	Jan/Feb 2018-2020	BCO	Fig.6*, Fig.7
			2.5 km	
t2m	thermometer	Jan/Feb 2018-2020	BCO	Fig.6*, Fig.7
			2.5 km	
Wind speed, T, qv	sounding	Jan/Feb 2018-2020	Airport	Fig.2
			2.5 km	
T, U, qv, VV	dropsonde	4 case studies	mean over Halo Circle (12 dropsondes)	Fig.11-12
			mean over Halo Circle
