HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Cell size scaling laws: a unified theory

The dimensions and compositions of cells are tightly regulated by active processes. This exquisite control is embodied in the robust scaling laws relating cell size, dry mass, and nuclear size. Despite accumulating experimental evidence, a unified theoretical framework is still lacking. Here, we show that these laws and their breakdown can be explained quantitatively by three simple, yet generic, physical constraints defining altogether the Pump and Leak model (PLM). Based on estimations, we clearly map the PLM coarse-grained parameters with the dominant cellular events they stem from. We propose that dry mass density homeostasis arises from the scaling between proteins and small osmolytes, mainly amino-acids and ions. Our theory predicts this scaling to naturally fail, both at senescence when DNA and RNAs are saturated by RNA polymerases and ribosomes respectively, and at mitotic entry due to the counterion release following histone tail modifications. We further show that nuclear scaling results from osmotic balance at the nuclear envelope (NE) and a large pool of metabolites, which dilutes chromatin counterions that do not scale during growth.

I. INTRODUCTION

1 Although cell size varies dramatically between cell types, during the cell cycle and depends on various external
2 stresses [1], each cell type often shows small volumetric variance. This tight control reflects the importance of size in
3 monitoring cell function. It is often associated to generic linear scaling relations between cell volume, cell dry mass
4 and the volume of the nucleus ([2], [3], [4]). These scaling laws have fascinated biologists for more than a century
5 [5] [6], because of the inherent biological complexity and their ubiquity both in yeasts, bacteria and mammals, hence
6 raising the question of the underlying physical laws.

7 Although robust, these scaling relations do break down in a host of pathologies. The nuclear-to-cytoplasmic (NC)
8 ratio (also called karyoplasmic ratio) has long been used by pathologists to diagnose and stage cancers ([7],[8],[9]).
9 Similarly, senescent cells such as fibroblasts are known to be swollen and their dry mass diluted [10], a feature suspected
10 to be of fundamental biological importance since it could represent a determinant of stem cell potential during ageing
11 [11].

12 Paradoxically, there is still no unified understanding of these scaling laws and of the reasons of their breakdown
13 in diseases. This is in part due to the experimental difficulty to perform accurate volume and dry mass measure-
14 ments ([12],[13],[14]). Many methods were developed in the past decades but they sometimes lead to contradictory
15 observations highlighting the need of comparing and benchmarking each method ([15],[16]).

16 Moreover, extensive experimental investigations have identified a plethora of biological features influencing these
17 scalings but comparatively fewer theoretical studies have precisely addressed them, leaving many experimental data
18 unrelated and unexplained. Several phenomenological theories have emerged to understand individual observations,
19 but they are still debated among biologists. The “nucleoskeletal theory” emphasizes the role of the DNA content in
20 controlling the NC ratio, based on the idea that ploidy dictates cell and nuclear sizes since tetraploid cells tend to
21 be larger than their diploid homologs [4]. Other experiments suggest that genome size is not the only determining
22 factor: indeed it would not explain why cells from different tissues, having the same amount of DNA, have different
23 sizes. Instead, it has been shown that nuclear size depends on cytoplasmic content, nucleo-cytoplasmic transport,
24 transcription, RNA processing and mechanics of nuclear envelope structural elements such as Lamina [3].

25 In parallel, theoretical models, based on non-equilibrium thermodynamics, were developed ([17],[18],[19]), often
26 based on the “Pump-and-Leak” principle ([1],[16],[20]). Charged impermeant molecules in cells create an imbalance
27 of osmotic pressure at the origin of the so-called Donnan effect [21]. Cells have two main ways to counteract the
28 osmotic imbalance. They can adapt to sustain a high hydrostatic pressure difference as plants do by building cellulose
29 walls. Or, as done by mammalian cells, they can use ion pumps to actively decrease the number of ions inside
30 the cells, thus decreasing the osmotic pressure difference across the cell membrane and therefore impeding water
31 penetration. However, due to the large number of parameters of these models, we still have a poor understanding of
32 the correspondence between biological factors and physical parameters of the model.

33 In this paper, we bridge the gap between phenomenological and physical approaches by building a minimal frame-
34 work based on a nested PLM to understand the cell size scaling laws as well as their breakdown. Performing order of
35 magnitude estimates, we precisely map the coarse-grained parameter of a simplified version of the PLM to the main
36 microscopic biological events. We find that the dry mass of the cell is dominated by the contribution of the proteins,
37 while the cell volume is mostly fixed by the contribution to the osmotic pressure of small osmolytes, such as amino-
38 acids and ions. The maintenance of a homeostatic cell density during growth is then due to a linear scaling relation
39 between protein and small osmolyte numbers. Combining simplified models of gene transcription and translation and
40 of amino-acid biosynthesis to the PLM, we show that the linear scaling relation between protein and small osmolyte
41 numbers is obtained in the exponential growth regime of the cell by virtue of the enzymatic control of amino-acid
42 production.

43 On the other hand, the absence of linear scaling relation between protein and small osmolyte numbers is at the
44 root of the breakdown of density homeostasis. We show that this is the case both at senescence and at mitotic entry
45 due to two distinct physical phenomena. At senescence, cells cannot divide properly. Our theory then predicts that
46 DNA and RNAs become saturated by RNA polymerases (RNAPs) and ribosomes respectively, leading to a change of
47 the growth regime: the protein number saturates while the amino-acid number increases linearly with time, resulting
48 in the experimentally observed dry mass dilution. This prediction is quantitatively tested using published data of
49 growing yeast cells prevented from dividing [10]. At mitotic entry, chromatin rearrangements, such as histone tail
50 modifications, induce a counterion release inside the cell, resulting in an influx of water and dry mass dilution in order
51 to maintain the osmotic balance at the cell membrane.

52 Finally, to further illustrate the generality of our model, we show that the linear scaling of nucleus size with
53 cell size originates from the same physical effects. Using a nested PLM for the cell and the nucleus, we show that
54 nuclear scaling requires osmotic balance at the nuclear envelope. The osmotic balance is explained by the nonlinear
55 osmotic response of mammalian nuclei, that we attribute to the presence of folds at the surface of many nuclei [22],
56 which in turn buffer the NE tension and enforce scaling. Nonetheless, the condition on osmotic balance appears to
57 be insufficient to explain the robustness of the NC ratio during growth. Counter-intuitively, metabolites, though
58 permeable to the NE, are predicted to play an essential role in the NC ratio. Their high concentrations in cells, a
59 conserved feature throughout living cells, is shown to dilute the chromatin counterions which do not scale during
60 growth; thereby allowing the scaling of nuclear size with cell size both at the population level and during individual
61 cell growth.

II. RESULTS

A. Pump and leak model.

Our theoretical approach to understand the various scaling laws associated to cell size is based on the the Pump and Leak model (PLM) ([23] and Figure 1.A). The PLM is a coarse grained model emphasizing the role of mechanical and osmotic balance. The osmotic balance involves two types of osmolytes, impermeant molecules such as proteins and metabolites, which cannot diffuse through the cell membrane, and ions, which cross the cell membrane and for which at steady state, the incoming flux into the cell must equal the outgoing flux. For simplicity, we restrict ourselves to a two-ions PLM where only cations are pumped outward of the cell. We justify in the Discussion why this minimal choice is appropriate for the purpose of this paper. Within this framework, three fundamental equations determine the cell volume. (1) Electroneutrality: the laws of electrostatic ensure that in any aqueous solution such as the cytoplasm, the solution is neutral at length scales larger than the Debye screening length i.e. the electrostatic charge of any volume larger than the screening length vanishes. In physiological conditions, the screening length is typically on the nanometric scale. Therefore, the mean charge density of the cell vanishes in our coarse-grained description (Eq.S.19) (2) Osmotic balance: balance of the chemical potential of water inside and outside the cell; the timescale to reach the equilibrium of water is of the order of tens to hundreds of milliseconds after a perturbation [16],[24]. (3) Balance of ionic fluxes: the typical timescales of ion relaxation observed during a cell regulatory volume response after an osmotic shock are of the order of a few minutes [16], [25]. Together, this means that our quasi-static theory is designed to study cell size variations on timescales larger than a few minutes. Mathematically, the three equations read (see Appendix V A for the full derivations of these equations) :

$$n^+ - n^- - z \cdot x = 0 \quad (1)$$

$$\Delta P = \Delta \Pi = kT \cdot (n^+ + n^- + x - 2n_0) \quad (2)$$

$$n^+ \cdot n^- = \alpha_0 \cdot n_0^2 \quad (3)$$

where, n^+ , n^- , n_0 are respectively the cationic and anionic concentrations inside and outside the cell. The external ionic concentrations are assumed to be identical for cations and anions in order to enforce electroneutrality since the concentrations of non-permeant molecules in the external medium are typically much lower than their ionic counterparts [24]. The cell is modelled as a compartment of total volume V divided between an excluded volume occupied by the dry mass R and a wet volume. The cell contains ions and impermeant molecules such as proteins, RNA, free amino-acids and other metabolites. The number X , respectively the concentration $x = \frac{X}{V-R}$, of these impermeant molecules may vary with time due to several complex biochemical processes such as transcription, translation, plasma membrane transport, and degradation pathways. The average negative charge $-z$ of these trapped molecules induces a Donnan potential difference U_c across the cell membrane. The Donnan equilibrium contributes to the creation of a positive difference of osmotic pressure $\Delta \Pi$ that inflates the cell. Cells have two main ways to counteract this inward water flux. They can either build a cortex stiff enough to prevent the associated volume increase, as done by plant cells. This results in the appearance of a hydrostatic pressure difference ΔP between the cell and the external medium. Or they can pump ions outside the cell to decrease the internal osmotic pressure, a strategy used by mammalian cells. We introduce a pumping flux of cations p . Cations can also passively diffuse through the plasma membrane via ion channels with a conductivity g^+ . In Eq.3, the pumping efficiency is measured by the dimensionless number $\alpha_0 = e^{-\frac{p}{k_B T g^+}}$ where T is the temperature and k_B the Boltzmann constant. The pumping efficiency varies between 0 in the limit of "infinite pumping" and 1 when no pumping occurs (see Appendix V A for an explanation on the origin of this parameter).

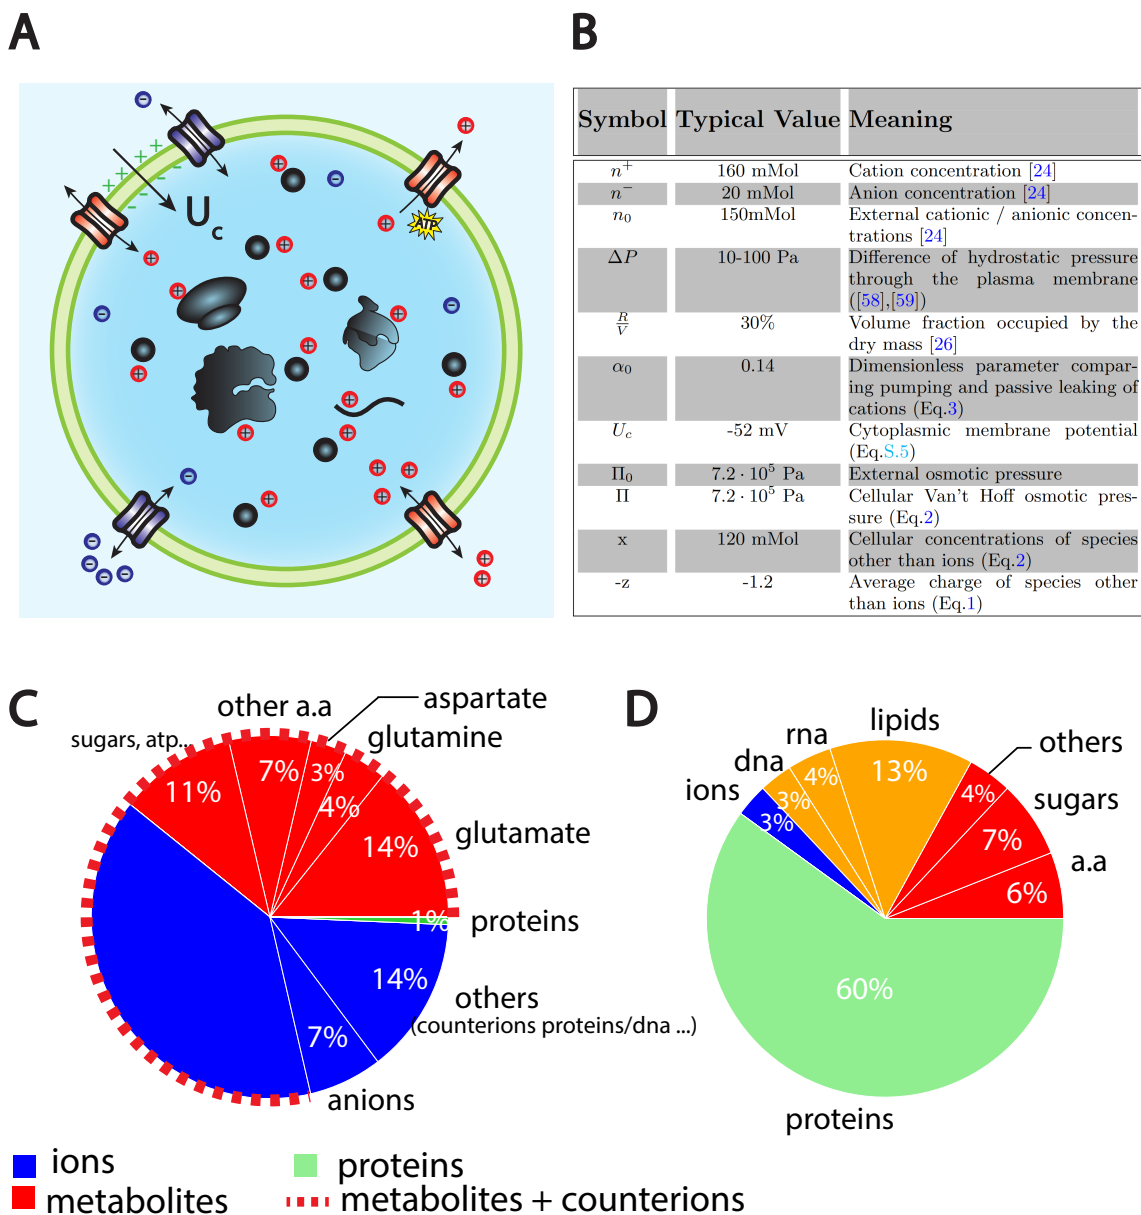

FIG. 1. **The PLM.** (A) Schematic of the PLM. Species in black are impermeant molecules such as proteins, mRNAs and metabolites (black circles). In average, those molecules are negatively charged and thus carry positive counterions (red species) to ensure electroneutrality. Ions can freely cross the plasma membrane through channels. Their concentrations in the cell result from the balance of three fluxes: the electrical conduction, the entropic diffusion, and pumping. In the model, only cations are pumped out of the cell to model the Na/K pump but this assumption is not critical (see Discussion III C and Appendix V B 3) (B) Estimation of the coarse grained PLM parameters for a typical Mammalian cell. (C) Fraction of volume and (D) of the dry mass occupied by the constituents of a mammalian cell (see Appendix V C and [26]). Note that most of the number of impermeant molecules (X) are accounted for by metabolites (mainly amino-acids and glutamate).

B. Volume and dry mass scaling

Although proposed more than 60 years ago [23] and studied in depth by mathematicians [18], and physicists [27], little effort has been done to precisely map the coarse-grained parameters of the PLM to microscopic parameters. We adopt here the complementary strategy and calculate orders of magnitude in order to simplify the model as much as possible, only keeping the leading order terms. We summarize in Figure.1.B the values of the PLM parameters that we estimated for a "typical" mammalian cell. Three main conclusions can be drawn: (1) Pumping is important, as indicated by the low value of the pumping efficiency $\alpha_0 \sim 0.14$. Analytical solutions presented in the main text will thus be given in the "infinite pumping" limit, i.e., $\alpha_0 \sim 0$, corresponding to the scenario where the only ions present in the cell are the counterions of the impermeant molecules. Though not strictly correct, this approximation gives a reasonable error of the order 10% on the determination of the volume, due to the typical small concentration of free anions in cells Fig.1.B. This error is comparable to the typical volumetric measurement errors found in the literature. (2) Osmotic pressure is balanced at the plasma membrane of a mammalian cell, since hydrostatic and osmotic pressures differ by at least three orders of magnitude. This result implies that even though the pressure difference ΔP plays a significant role in shaping the cell, it plays a negligible role in fixing the volume (see Eq.S.30 for justification). (3) The cellular density of impermeant species is high, $x \sim 120\text{mMol}$, comparable with the external ionic density n_0 . In this limit, the volume of the cell hence reads (the complete expression is given in Appendix VB) :

$$V = R + \frac{(z+1) \cdot X}{2n_0} \quad (4)$$

The wet volume of the cell is thus slaved to the number of impermeant molecules that the cell contains. While this conclusion is widely acknowledged, the question is to precisely decipher which molecules are accounted for by the number X. We first estimate the relative contributions of the cellular free osmolytes to the volume of the cell and then, compute their relative contributions to the dry mass of the cell. We provide a graphical summary of our orders of magnitudes in Fig.1.C and D as well as the full detail of their derivations in Appendix.VC. The conclusion is twofold. Metabolites and their counterions account for most of the wet volume of the cell, 78% of the wet volume against 1% for proteins. On the other hand, proteins account for most of the dry mass of mammalian cells, accounting for 60% of the cellular dry mass against 17% for metabolites.

We further note that metabolites are mainly amino-acids and in particular three of them, glutamate, glutamine and aspartate accounting for 73% of the metabolites [28]. It is important to note that the relative proportion of free amino-acids in the cell does not follow their relative proportion in the composition of proteins. For instance, glutamate represents 50% of the free amino-acid pool while its relative appearance in proteins is only 6% [29]. This is evidence that some amino-acids have other roles than building up proteins. In particular, we demonstrate throughout this paper their crucial role on cell size and its related scaling laws.

These conclusions may appear surprising due to the broadly reported linear scaling between volume (metabolites) and dry mass (proteins), hence enforcing a constant dry mass density ρ during growth. Many theoretical papers have assumed a priori a linear phenomenological relation between volume and protein number in order to study cell size [30],[31],[32]. Our results instead emphasize that the proportionality is indirect, only arising from the scaling between amino-acid and protein numbers. The dry mass density reads (to lowest order):

$$\rho = \frac{M}{V} \approx \frac{\mathcal{M}_A \cdot l_p \cdot P_{tot}}{v_p \cdot P_{tot} + \frac{(z_{A^f}+1) \cdot A^f}{2n_0}} \quad (5)$$

where, \mathcal{M}_a , z_{A^f} and A^f are respectively the average mass, charge and number of amino-acids; l_p , v_p and P_{tot} , the average length, excluded volume and number of proteins. Note that density homeostasis is naturally achieved in the growth regime where A^f is proportional to P_{tot} .

C. Model of stochastic gene expression and translation

To further understand the link between amino-acid and protein numbers we build upon a recent model of stochastic gene expression and translation ([30] and Fig.2.A). The key feature of this model is that it considers different regimes of mRNA production rate \dot{M}_j and protein production rate \dot{P}_j according to the state of saturation of respectively the DNA by RNA polymerases (RNAPs) and mRNAs by ribosomes. For the sake of readability, we call enzymes both ribosomes and RNAPs, their substrates are respectively mRNAs and DNA and their products proteins and mRNAs. The scenario of the model is the following. Initially, the majority of enzymes are bound to their substrates and occupy

145 a small fraction of all possible substrate sites. In this non saturated regime, i.e when the number of enzymes is smaller
 146 than a threshold value P_p^* and P_r^* Eq.S.52, the production rates of the products of type j read [30]:

$$\dot{M}_j = k_0 \cdot \phi_j \cdot P_p - \frac{M_j}{\tau_m}, \quad \text{if } P_p \leq P_p^* \quad (6)$$

$$\dot{P}_j = k_t \cdot \frac{M_j}{\sum M_j} \cdot P_r - \frac{P_j}{\tau_p}, \quad \text{if } P_r \leq P_r^* \quad (7)$$

147 Both production rates have two contributions. (1) a source term characterized by the rates k_0 and k_t at which the
 148 enzyme produces the product once it is bound to its substrate, times the average number of enzymes per substrate
 149 coding for the product of type j. This number is the fraction of substrates coding for product of type j - that can
 150 be identified as a probability of attachment ($\phi_j = \frac{g_j}{\sum g_j}$ and $\frac{M_j}{\sum M_j}$, where g_j , M_j accounts for the number of genes
 151 and mRNAs coding for the product of type j) - multiplied by the total number of enzymes (P_p and P_r). (2) A
 152 degradation term characterized by the average degradation times τ_m and τ_p of mRNAs and proteins. Note that we
 153 added a degradation term for proteins not present in [30], which turns out to be of fundamental importance below.
 154 Although these timescales vary significantly between species their ratio remains constant, τ_m being at least one order
 155 of magnitude smaller than τ_p in yeast, bacteria and mammalian cells [24]. This justifies a quasistatic approximation,
 156 $\dot{M}_j \sim 0$ during growth such that the number of mRNAs of type j adjusts instantaneously to the number of RNAPs,
 157 in the non saturated regime :

$$M_j = k_0 \cdot \tau_m \cdot \phi_j \cdot P_p \quad (8)$$

158 During interphase, the number of enzymes grows, increasingly more enzymes attach to the substrates up to the
 159 saturation value due to their finite size. In this regime, we use the same functional form for the production rates
 160 only replacing the average number of enzymes per substrate by their saturating values : $g_j \cdot \mathcal{N}_p^{max}$ for RNAPs and
 161 $M_j \cdot \mathcal{N}_r^{max}$ for ribosomes (see Appendix VD and Eq.S.50,S.51); where, \mathcal{N}_p^{max} and \mathcal{N}_r^{max} are the average maximal
 162 number of RNAPs and ribosomes per mRNAs and genes. Note that the model predicts that the saturation of DNA
 163 precedes that of mRNAs, whose number initially increases with the number of RNAPs Eq.8 while the number of genes
 164 remains constant. Once DNA is saturated, the number of mRNAs plateaus, leading to their saturation by ribosomes
 165 (see Appendix VD and Eq.S.56).

166 Our previous analysis has highlighted the fundamental importance of free amino-acids on cell volume regulation
 167 Fig.1.C. The production rate of free amino-acids can be related to the number of enzymes catalyzing their biosynthesis,
 168 using a linear process by assuming that the nutrients necessary for the synthesis are in excess:

$$\dot{A}^f = k_{cat} \cdot P_e - l_p \cdot \dot{P}_{tot} \quad (9)$$

169 where k_{cat} is the rate of catalysis and P_e the number of enzymes. The second term represent the consumption of
 170 amino-acids to form proteins, with $P_{tot} = \sum P_j$. Although Eq.9 is coarse-grained we highlight that, since glutamate
 171 and glutamine are the most abundant amino acids in the cell, it could in particular model the production of these
 172 specific amino-acids from the Krebs cycle [26]. Note that we also ignored amino-acid transport through the plasma
 173 membrane. The rationale behind this choice is twofold. (1) We do not expect any qualitative change when adding this
 174 pathway to our model since amino-acid transport is also controlled by proteins. (2) We realized that the amino-acids
 175 that actually play a role in controlling the volume, mainly glutamate, glutamine and aspartate, are non-essential
 176 amino-acids, hence that can be produced by the cell.

177 D. Dry mass scaling and dilution during cell growth

178 We now combine the PLM, the growth model and the amino-acid biosynthesis model to make predictions on the
 179 variation of the dry mass density during interphase. A crucial prediction of the growth model is that as long as mRNAs
 180 are not saturated, i.e., $P_r < P_r^*$, all the protein numbers scale with the number of ribosomes, $P_j \sim \frac{\phi_j}{\phi_r} \cdot P_r$. Moreover,
 181 the autocatalytic nature of ribosome formation makes their number grow exponentially Eq.7, i.e $P_r = P_{r,0} \cdot e^{k_r \cdot t}$;
 182 where, $k_r = k_t \cdot \phi_r - \frac{1}{\tau_p}$ is the effective rate of ribosome formation (and also the rate of volume growth in this regime

Eq.S.54). The most important consequence of this exponential growth coupled to the equation modeling amino-acid biosynthesis Eq.9 is that it implies that both amino-acids and total protein content scale with the number of ribosomes ultimately leading to a homeostatic dry mass density independent of time (see Appendix VD):

$$\rho^H = \frac{\mathcal{M}_a}{\frac{v_p}{l_p} + \frac{(z_{Af}+1)}{2n_0} \cdot \left(\frac{\phi_e}{l_p} \cdot \frac{k_{cat}}{k_r} - 1 \right)} \quad (10)$$

We emphasize that Eq.10 only applies far from its singularity since it was obtained assuming that the volume of the cell is determined by free amino-acids, i.e, $\frac{\phi_e}{l_p} \cdot \frac{k_{cat}}{k_r} \gg 1$.

Not only does our model explain the homeostasis of the dry mass, but it also makes the salient prediction that this homeostasis naturally breaks down if the time spent in the G1 phase is too long. Indeed, after a time $t^{**} = \frac{1}{k_r} \cdot \ln \left(\frac{\mathcal{N}_r^{max} \cdot \mathcal{N}_p^{max} \cdot k_0 \cdot \tau_m \cdot \sum g_j}{P_{r,0}} \right)$ (see Appendix VD), mRNAs become saturated by ribosomes, drastically changing the growth of proteins from an exponential growth to a plateau regime where the number of proteins remains constant. After the time $t^{**} + \tau_p$, all protein numbers reach their stationary values $P_j^{stat} = k_t k_0 \tau_p \tau_m \mathcal{N}_R^{max} \mathcal{N}_p^{max} g_j$. In particular, the enzymes coding for amino-acids also plateau implying the loss of the scaling between free amino-acids and proteins as predicted by Eq.9. The number of amino-acids then increases linearly with time whereas the number of proteins saturates. In this regime, the volume thus grows linearly with time but the dry mass remains constant leading to its dilution and the decrease of the dry mass density (see Appendix VD and Eq.S.60) :

$$\rho^{lin}(t) = \frac{\mathcal{M}_a}{\frac{v_p}{l_p} + \frac{(z_{Af}+1)}{2n_0} \cdot \left(\frac{\phi_e \cdot k_{cat}}{\phi_r \cdot k_r \cdot k_t \cdot l_p \cdot \tau_p} - 1 + \frac{k_{cat} \cdot \phi_e}{l_p} \cdot t \right)} \quad (11)$$

Finally, our model makes other important predictions related to the cell ploidy that we briefly enumerate. First, the cut-off P_r^* Eq.S.56 at which dilution is predicted to occur depends linearly on the genome copy number $\sum g_j$. Intuitively, mRNAs are saturated only if DNA has previously saturated. At saturation the RNA number is proportional to the genome size. As a consequence, the volume $V^* \propto P_r^*$ at which dilution occurs scales with the ploidy of the cell, a tetraploid cell is predicted to be diluted at twice the volume of its haploid homolog. On the other hand, by virtue of the exponential growth, the time t^{**} Eq.S.57 at which the saturation occurs only depends logarithmically on the number of gene copies making the ploidy dependence much less pronounced timewise. Second, the growth rate in the linear regime scales with the ploidy of the cell, as opposed to the growth rate in the exponential regime. Indeed, in the saturated regime, the growth rate scales as $k_{cat} \cdot P_e^{stat}$ (see Appendix VD and Eq.S.58), where P_e^{stat} is the number of enzymes catalyzing the reaction of amino-acids biosynthesis after their numbers have reached their stationary values, while in the exponential regime, the growth rate $k_r = \phi_r \cdot k_t - \frac{1}{\tau_p}$ scales with the fraction of genes coding for ribosomes ϕ_r , which is independent of the ploidy.

E. Comparison to existing data

Our main prediction, namely that the cell is diluted after the end of the exponential growth, is reminiscent of the intracellular dilution at senescence recently reported in fibroblasts, yeast cells and more recently suspected in aged hematopoietic stem cells [10],[11]. Here we quantitatively confront our theory to the data of [10], where the volume, the dry mass and the protein number were recorded during the growth of yeast cells that were prevented from both dividing and replicating their genome. Though our theory was originally designed for mammalian cells, it can easily be translated to cells with a cell wall provided that the hydrostatic pressure difference across the wall ΔP is maintained during growth by progressive incorporation of cell wall components (see Appendix VB). Indeed, our conclusions rely on the fact that the cell volume is primarily controlled by small osmolytes whose concentration in the cell dominates the osmotic pressure, a feature observed to be valid across cell types [28].

We first check the qualitative agreement between our predictions and the experiments. Two clear and very distinct growth regimes are evident in non-dividing yeast cells; an initial exponential growth followed by a linear growth Fig.2.C. The occurrence of linear or exponential growth has been the object of intense debate. We think that the ambiguity comes from the fact that cells often divide too fast for the exponential regime to be properly identified. Our results suggest that the fact that cell division occurs in the exponential regime is essential to prevent cells from being diluted. Our theory also predicts that as long as protein number is constant the volume must grow linearly Eq.9,S.60. This is precisely what is observed in the experiments: cells treated with rapamycin exhibits both a constant protein content and a linear volume increase during the whole growth (see Fig.S6.F in [10]). Finally, our predictions

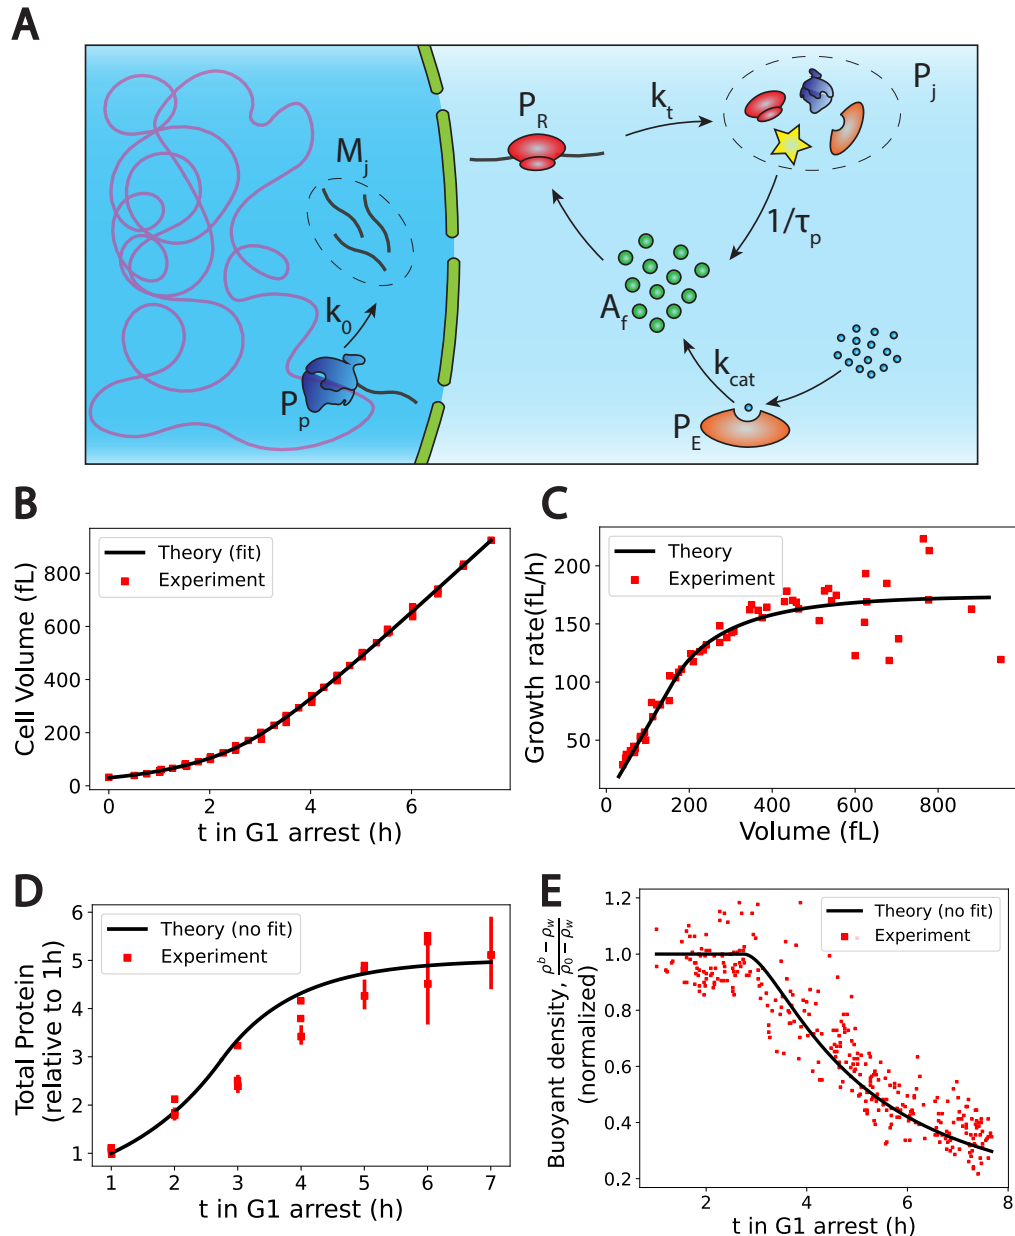

FIG. 2. The PLM coupled to a growth model predicts quantitatively dry mass homeostasis and its subsequent dilution at senescence. (A) Schematic of the growth model. RNAPs (P_p) transcribe DNA and form mRNAs (M_j) at an average rate k_0 . mRNAs are then read by ribosomes (P_r) to produce proteins (P_j) at an average rate k_t . Proteins are degraded at an average rate $\frac{1}{\tau_p}$ into free amino-acids (A_f). Free amino-acids are also synthesized from nutrients (blue circles) at a rate k_{cat} . This reaction is catalyzed by enzymes (P_e). (B) to (E) Comparison between theory (black) and experiment (red). Data adapted from [10]. (D) and (E) model predictions without any fitting parameters. The buoyant mass ρ_b density is defined as the total mass of the cell (water and dry mass) over the total volume of the cell.

227 on the relationship between ploidy and dilution are in very good agreement with experiments as well. Indeed, while
 228 the typical time to reach the linear growth regime - of the order of 3 hours - seems independent of the ploidy of the
 229 cell, the volume at which dilution occurs is doubled (see Fig.S7.A in [10]). Moreover, the growth rate during the
 230 linear regime scales with ploidy, as the haploid cells growth rate is of order 129 fL/h against 270 fL/h for their diploid
 231 counterparts [10].

232 Encouraged by these qualitative correlations, we further designed a scheme to test our theory more quantitatively.
 233 Although our theory has a number of adjustable parameters, many of them can be combined or determined self-

consistently as shown in Appendix VD4). We end up fitting four parameters, namely τ_p , t^{**} , k_r and the initial cell volume v_1 , using the cell volume data Fig.2.B. We detail in the Appendix VD5 the fitting procedure and the values of the optimal parameters. Interestingly, we find a protein degradation time $\tau_p = 1\text{h}9\text{min}$, corresponding to an average protein half-life time: $\tau_{1/2} \sim 48\text{min}$ which is very close to the value 43min, measured in [33]. Moreover, we obtain a saturation time $t^{**} = 2\text{h}44\text{min}$ which remarkably corresponds to the time at which the dry mass density starts to be diluted Fig.2.E, thus confirming the most critical prediction of our model. We can then test our predictions on the two other independent datasets at our disposal, i.e., the dry mass density, obtained from suspended microchannel resonator (SMR) experiments, and the normalized protein number, from fluorescent intensity measurements. We emphasize that the subsequent comparisons with experiments are done without any adjustable parameters. The agreement between theory and experiment is striking Fig.2.D,E, and gives credit to our model. We underline that the value of the density of water that we used is 4 % higher than the expected value, $\rho_w = 1.04\text{ kg/L}$ to plot Fig.2.E. This slight difference originates from the fact that our simplified theory assumes that the dry mass is entirely due to proteins whereas proteins represent only 60% of the dry mass. This hypothesis is equivalent to renormalizing the density of water as shown in Appendix VD4.

In summary, our theoretical framework combining the PLM with a growth model and a model of amino-acid biosynthesis provides a consistent quantitative description of the dry mass density homeostasis and its subsequent dilution at senescence without invoking any genetic response of the cell; the dilution is due to the physical crowding of mRNAs by ribosomes. It also solves a seemingly apparent paradox stating that the volume is proportional to the number of proteins although their concentrations are low in the cell without invoking any non-linear term in the osmotic pressure (see Discussion and Appendix VC12).

F. Mitotic swelling

Our previous results explain well the origin of the dilution of the cellular dry mass at senescence. But can the same framework be used to understand the systematic dry mass dilution experienced by mammalian cells at mitotic entry? Although this so called mitotic swelling or mitotic overshoot is believed to play a key role in the change of the physio-chemical properties of mitotic cells, its origin remains unclear [34],[35].

We first highlight five defining features of the mitotic overshoot. (1) It originates from an influx of water happening between prophase and metaphase, resulting in a typical 10% volume increase of the cells. (2) The swelling is reversible and cells shrink back to their initial volume between anaphase and telophase. (3) This phenomenon appears to be universal to mammalian cells, larger cells displaying larger swellings. (4) Cortical actin was shown not to be involved in the process, discarding a possible involvement of the mechanosensitivity of ion channels, contrary to the density increase observed during cell spreading [16] (5) Nuclear envelope breakdown (NEB) alone cannot explain the mitotic overshoot since most of the swelling is observed before the prometaphase where NEB occurs [34],[35].

The dry mass dilution at mitotic overshoot is thus different from the cases studied in the previous section. First, it happens during mitosis when the dry mass is constant [35]. Second, the 10% volume increase implies that we need to improve the simplified model used above, which considers only metabolites and proteins (and their counterions). Having in mind that ions play a key role in the determination of the cell volume Fig.1C, we show how every feature of the mitotic overshoot can be qualitatively explained by our theory, based on a well-known electrostatic property of charged polymer called counterion condensation first studied by Manning [36]. Many counterions are strongly bound to charged polymers (such as chromatin) because the electrostatic potential at their surface creates an attractive energy for the counterions much larger than the thermal energy $k_B T$. The condensed counterions partially neutralize the charge of the object and reduce the electrostatic potential. Condensation occurs up to the point where the attractive energy for the free counterions is of the order $k_B T$. The condensed counterions then do not contribute to the osmotic pressure given by Eq.2 which determines the cell volume. These condensed counterions act as an effective "internal" reservoir of osmolytes. A release of condensed counterions increases the number of free cellular osmolytes and thus the osmotic pressure inside the cell. Therefore, it would lead to an influx of water in order to restore osmotic balance at the plasma membrane Fig.3.

But how to explain such a counterion release at mitotic overshoot? For linear polymers such as DNA, the condensation only depends on a single Manning parameter $u = \frac{l_b}{A}$; where, l_b is the Bjerrum length Tab.I which measures the strength of the coulombic interaction and A the average distance between two charges along the polymer. The crucial feature of Manning condensation is the increase of the distance between charges A by condensing counterions and thus effectively decreasing u down to its critical value equal to 1 (see Appendix VE for a more precise derivation). Hence, the number of elementary charges carried by a polymer of length L_{tot} is $Q_{tot} = \frac{L_{tot}}{A}$ before condensation. After condensation, the effective distance between charges increases to $A^{eff} = A \cdot u$ such that the effective number of charges on the polymer is reduced to $Q^{eff} = \frac{Q_{tot}}{u}$. The number of counterions condensed on the polymer is $Q^{cond} = Q_{tot} \cdot (1 - \frac{1}{u})$. The most important consequence of these equations is that they suggest that a structural mod-

FIG. 3. **Dry mass dilution at mitosis is explained with the PLM by the decondensation of chromatin counterions following histone tail modifications.** (A) and (B) Microscopic working model. An enzyme gives its positive charge to a histone, resulting in the release of a condensed counterions. Ions depicted within the chromatin (dark blue cylinder) are condensed and those outside are freely diffusing and participate in the nuclear osmotic pressure. (C) and (D) The subsequent increase in the number of osmolytes lead to a water influx in order to sustain osmotic balance at the plasma membrane of mammalian cells. For readability, other osmolytes are not displayed.

289 ification of the chromatin could lead to a counterion release. Indeed, making the chromatin less negatively charged,
 290 i.e., increasing A , is predicted to decrease u and thus to lead to the decrease of Q^{cond} . Detailed numerical simulations
 291 of chromatin electrostatics show that this description is qualitatively correct [37].

292 Biologists have shown that chromatin undergoes large conformational changes at mitotic entry. One of them
 293 attracted our attention in light of the mechanism that we propose. It is widely accepted that the affinity between
 294 DNA and histones is enhanced during chromatin compaction by stronger electrostatic interactions thanks to specific
 295 covalent modifications of histone tails by enzymes. Some of these modifications such as the deacetylation of lysines
 296 add a positive charge to the histone tails, hence making the chromatin less negatively charged [26]. Moreover, histone
 297 tails are massively deacetylated during chromatin compaction [38], potentially meaning that this specific reaction

298 plays an important role in counterion release and thus on the observed mitotic swelling. However, we underline that
 299 the idea that we propose is much more general and that any reaction modifying chromatin electrostatics is expected
 300 to impact the swelling. The question whether deacetylation of lysines is the dominant effect is left open here.

301 Is the proposed mechanism sufficient to explain the observed 10% volume increase? We estimate the effective
 302 charge of chromatin for a diploid mammalian cell to be $Q^{eff} = 2 \cdot 10^9 e^-$ and the number of condensed monovalent
 303 counterions to be $Q^{cond} = 8 \cdot 10^9$ (see Appendix VC). The PLM framework predicts the subsequent volume increase
 304 induced by the hypothetical release of all the condensed counterions of the chromatin. We find an increase of
 305 order $\Delta V \sim 100 - 150 \mu\text{m}^3$ which typically represents 10% of a mammalian cell size (see Appendix VC and Eq.S.44).
 306 Admittedly crude, this estimate suggest that chromatin counterion release can indeed explain the amplitude of mitotic
 307 swelling.

308 In summary, the combination of the PLM framework with a well-known polymer physics phenomenon allows us
 309 to closely recapitulate the features displayed during mitotic swelling. In brief, the decondensation of the chromatin
 310 condensed counterions, hypothetically due to histone tail modifications, is sufficient to induce a 10% swelling. This
 311 implies that, all mammalian cells swell during prophase and shrink during chromatin decondensation after anaphase;
 312 again, consistent with the dynamics of the mitotic overshoot observed on many cell types. Another salient implication
 313 is that the amplitude of the swelling is positively correlated with the genome content of the cells: cells having
 314 more chromatin are also expected to possess a larger "internal reservoir" of osmolytes, which can participate in
 315 decondensation. This provides a natural explanation for the observed larger swelling of larger cells. For instance,
 316 Hela cells were shown to swell on average by 20%, in agreement with the fact that many of them are tetraploid.
 317 Admittedly, many other parameters enter into account and may disrupt this correlation such as the degree of histone
 318 tail modifications or the initial state of chromatin; The existence of a larger osmolyte reservoir does not necessarily
 319 mean that more ions are released.

320 Finally, we point out that the ideas detailed in this section can be tested experimentally using existing in vivo or in
 321 vitro methods. For example, we propose to massively deacetylate lysines during interphase, by either inhibiting lysine
 322 acetyltransferases (KATs) or overexpressing lysine deacetylases (HDACS), in order to simulate the mitotic swelling
 323 outside mitosis. We also suggest to induce mitotic slippage or cytokinesis failure for several cell cycles, to increase
 324 the genome content, while recording the amplitude of swelling at each entry in mitosis [39].

325 G. Nuclear scaling

326 Another widely documented scaling law related to cell volume states that the volume of cell organelles is proportional
 327 to cell volume ([40],[3]). As an example, we discuss here the nuclear volume. We develop a generalised "nested" PLM
 328 that explicitly accounts for the nuclear and plasma membranes (see Fig.4.A). Instead of writing one set of equation
 329 (Eq.1,2,3) between the interior and the exterior of the cell, we write the same equations both inside the cytoplasm
 330 and inside the nucleus (see Eq.S.70). Before solving this nonlinear system of equations using combined numerical
 331 and analytical approaches, we draw general conclusions imposed by their structure. As a thought experiment, we
 332 first discuss the regime where the nuclear envelope is not under tension so that the pressure jump at the nuclear
 333 envelope ΔP_n is much smaller than the osmotic pressure inside the cell $\Delta P_n \ll \Pi_0$. The osmotic balance in each
 334 compartment implies that the two volumes have the same functional form as in the PLM, with two contributions: an
 335 excluded volume due to dry mass and a wet volume equal to the total number of particles inside the compartment
 336 divided by the external ion concentration (see Eq.S.71). It is noteworthy that the total cell volume, the sum of the
 337 nuclear and cytoplasmic volumes, is still given by Eq.4 as derived in the simple PLM. This result highlights the fact
 338 that the PLM strictly applies in the specific condition where the nuclear envelope is under weak tension. In addition,
 339 a crucial consequence of the osmotic balance condition at the NE is that it leads to a linear scaling relation between
 340 the volumes of the two compartments:

$$V_n = \frac{N_n^{tot}}{N_c^{tot}} \cdot V_c + \left(R_n - \frac{N_n^{tot}}{N_c^{tot}} \cdot R_c \right) \quad (12)$$

341 where V_i , R_i and N_i^{tot} denote, respectively, the total volume, the dry volume and the total number of osmolytes of
 342 compartment i , the index $i = n, c$ denoting either the nucleus n , or the cytoplasm c . Importantly, this linear scaling
 343 between the nucleus and the cytoplasm was reported repeatedly over the last century and is known as nuclear scaling
 344 [4], [3]. While this conclusion is emphasized in some recent papers [32], [41], we point out that Eq.12 is only a partial
 345 explanation of the nuclear scaling. Indeed, we still need to understand what cellular and nuclear properties makes
 346 the ratio $\frac{N_n^{tot}}{N_c^{tot}}$ insensitive to external perturbations or to growth.

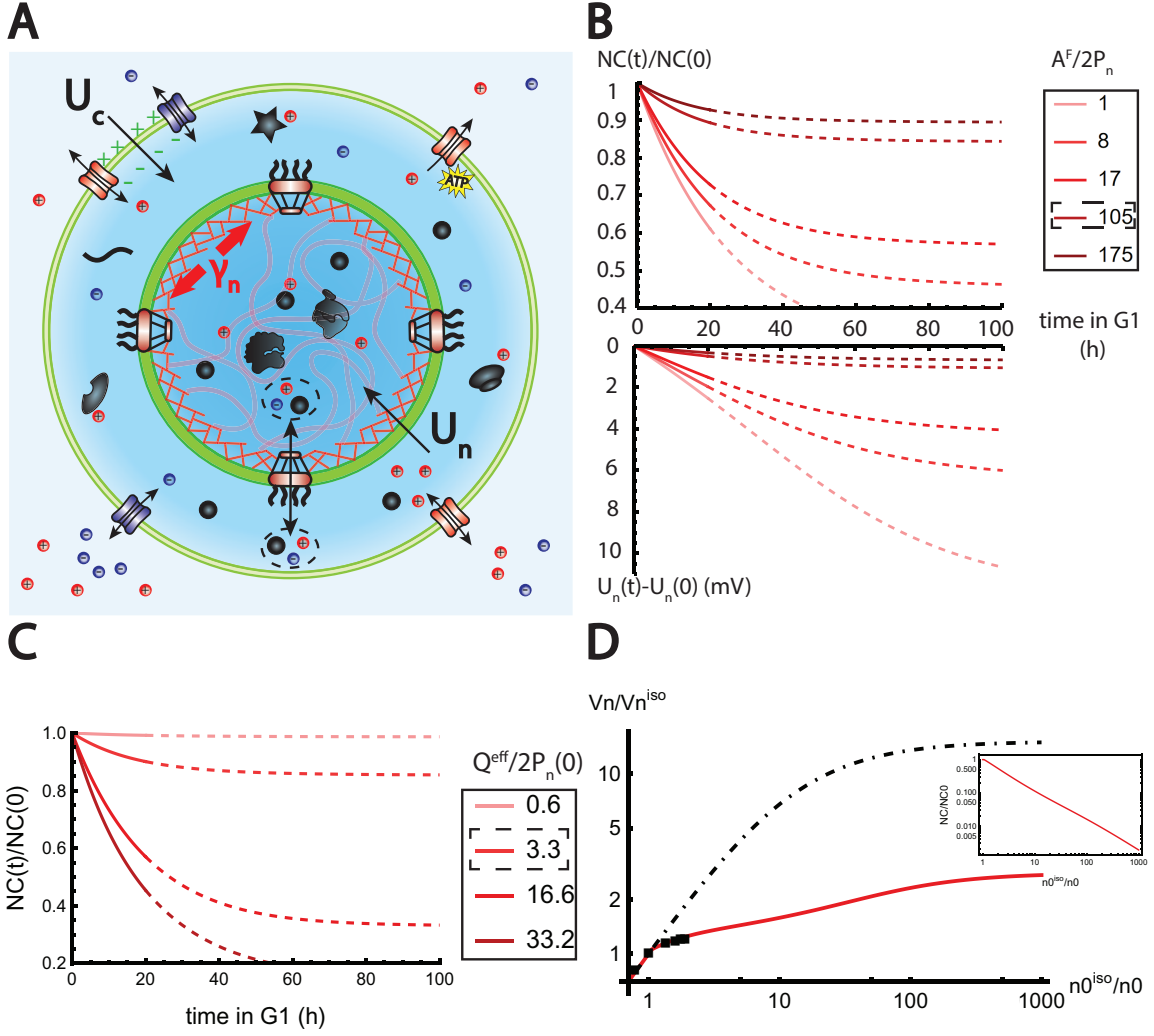

FIG. 4. **The nested PLM explains nuclear scaling.**(A) Schematic of the nested PLM. Species in black are impermeant molecules (X) and are now partitioned between the cytoplasm and the nucleus. Among those, only metabolites (black circles) can cross the NE. The NE is composed of the membrane (green) and the lamina (red) can be stretched when the nuclear folds are flattened. (B) and (C) Simulations of the nested PLM Eq.S.70 during growth when the osmotic pressure is balanced at the NE. The growth rate was adjusted to data in [35] (B) Though permeable to the NE, Metabolites play a role in the homeostasis of the NC ratio by diluting chromatin (free) counterions which do not scale during growth (top plot). Higher variations of the NC ratio correlate with higher variations of the NE potential (bottom plot). (C) Variations of the NC ratio during growth for different chromatin charges. (D) Normalized nuclear volume after a hypo-osmotic shock. Nuclear volume saturates because of the tension at the NE, leading to the decrease of the NC ratio (inset: log-log plot). The dash-dotted line represents the nuclear volume if the number of osmolytes in the nucleus were assumed constant throughout the shock. Thus, showing that Metabolites leave the nucleus during the shock which strongly decreases nucleus swelling. The value at the saturations are given by Eq.17. The square black dots are data extracted from [42]. We used $K = 50\text{mN/m}^a$ and $s = 4\%$ folds to fit the data. Additional results of the nested PLM are plotted in the supplementary figure: Fig.5

^a The value of K used to fit the data [42] is twice the measured value in [43]. The rationale is threefold. (1) Nuclei used in [42] are chondrocyte nuclei originating from articular cartilage. They possess a high Lamina A to Lamina B ratio and are thus likely to be stiffer [44] (2) We could lower the value of the fitted K by increasing the pumping efficiency α_0 . A more detailed characterisation of the PLM parameters for chondrocytes would be required to precisely infer the elastic properties of the NE. (3) Considering the chromatin mechanical contribution would increase K by a factor $E_{DNA} \cdot R_{nucleus}$; with E_{DNA} the elastic modulus of the chromatin and $R_{nucleus}$ the radius of the nucleus.

H. NC ratio in the low tension regime

We now examine the influence of the various cell osmolytes on the NC ratio. For the sake of readability, we assume that the volume fraction occupied by the dry mass is the same in the nucleus and the cytoplasm (see Appendix V F 1). The NC ratio is then the ratio between the wet volumes. Following the lines of our previous discussion, four different components play a role in volume regulation: chromatin (indirectly through its non-condensed counterions), proteins (mainly contributing to the dry volume), metabolites and ions (mainly contributing to the wet volume). These components do not play symmetric roles in the determination of the NC ratio. This originates from the fact that metabolites are permeable to the nuclear membrane and that chromatin, considered here as a gel, does not contribute directly to the ideal gas osmotic pressure because its translational entropy is vanishingly small [45]. The nested PLM leads to highly nonlinear equations that cannot be solved analytically in the general case (see Eq.S.70). Nevertheless, in the particular regime of monovalent osmolytes and high pumping $z_a = 1$, $z_p = 1$ and $\alpha_0 = 0$ corresponding to the case where there is no free anions in the cell, the equations simplify and are amenable to analytical results. This regime is physically relevant since it corresponds to values of the parameters close to the ones that we estimated (Fig.1). For clarity, we first restrict our discussion to this particular limit. We will also discuss both qualitatively and numerically the influence of a change of the parameters later. In this scenario, the nested PLM equations reduce to:

$$\begin{cases} p_c + a_c^f + n_c = 2n_0 \\ p_n + a_n^f + n_n = 2n_0 \\ n_c - a_c^f - p_c = 0 \\ n_n - a_n^f - p_n - q = 0 \\ n_c \cdot a_c^f = n_n \cdot a_n^f \end{cases} \quad (13)$$

where the first and second equations correspond to osmotic pressure balance in the two compartments; the third and fourth equation correspond to macroscopic electroneutrality in each compartment; and the fifth equation is the balance of the chemical potential of the cations and metabolites on each side of the NE. p_i , n_i , a_i respectively accounts for the concentrations of proteins, cations and metabolites either in the cytoplasm - subscript c - or in the nucleus, subscript n. q accounts for the effective chromatin charge density. From these equations, we express the concentrations of cations in each compartment as functions of the extracellular concentration n_0 and the chromatin charge density q (Eq.S.75), leading to the following expression of the NE potential:

$$U_n = -\ln \left(1 + \frac{q}{2n_0} \right) = -\ln \left(1 + \frac{Q^{eff}}{Q^{eff} + 2A_n^f + 2P_n} \right) \quad (14)$$

A salient observation from Eq.14 is that the NE potential difference U_n is a proxy of the chromatin charge density. At low q , $U_n = 0$, i.e., the respective concentrations of metabolites and cations are equal on each side of the membrane. Eq.13, also shows that the protein concentrations are equal in the two compartments. This implies that when the charge of chromatin is diluted, the volumes of the nucleus and of the cytoplasm adjust such that the NC ratio equals the ratio of protein numbers in the two compartments $NC_1 = \frac{P_n}{P_c}$. In the PLM, which considers a single compartment, a membrane potential appears as soon as there exist trapped particles in the compartment (see Appendix V F 2 and Eq.S.73). In contrast, our extended nested PLM predicts that in the case of two compartments, the system has enough degrees of freedom to adjust the volumes as long as q is small, thereby allowing the potential to be insensitive to the trapped charged proteins. At high values of the chromatin charge Q^{eff} , U_n saturates to the value $-\ln(2)$ which in physical units is equivalent to -17mV at 300K . Note that this lower bound for the potential is sensitive to the average charge of the proteins z_p and can be lowered by decreasing this parameter. We also highlight that Eq.14 makes another testable prediction, namely, that the NE potential is independent of the external ion concentration. In the literature, NE potentials were recorded for several cell types [46]. They can vary substantially between cell types ranging from $\sim 0\text{mV}$ for *Xenopus* oocytes to -33mV for *Hela* Cells. This result is in line with our predictions. The *Xenopus* oocyte nucleus has a diameter roughly twenty times larger than typical somatic nuclei, but its chromatin content is similar [43], resulting in a very diluted chromatin and a vanishing NE potential. On the other hand, *Hela* cells are known to exhibit an abnormal polyploidy which may lead to a large chromatin charge density and a large nuclear membrane potential.

This last prediction allows to understand the influence of the metabolites on the NC ratio. An increase of the number of metabolites in the cell A_{tot}^f , induces growth of the total volume (Eq.S.71), leading to the dilution of the chromatin charge and a strong decrease of the nuclear membrane potential (Eq.14). In the limit where A_{tot}^f is

dominant, we thus expect the NC ratio to be set to the value NC_1 . On the other hand, at low A_{tot}^f , metabolites do not play any role on the NC ratio, which is then given by $NC_2 > NC_1$, with:

$$NC_1 = \frac{P_n}{P_c} \quad , \quad NC_2 = \frac{P_n + Q^{eff}/2}{P_c} \quad (15)$$

(see Eq.S.74 for the general formula). The actual NC ratio is intermediate between the two limiting behaviors (see Fig.5B and Eq.S.80).

During cell growth, the ratio NC_1 is constant, while the ratio NC_2 varies with time. Indeed, if nucleo-cytoplasmic transport is faster than growth, the protein numbers P_n and P_c are both proportional to the number of ribosomes in the exponential growth regime and the ratio NC_1 does not vary with time (see Appendix VF 5). On the other hand, the DNA charge Q^{eff} is constant during G1 phase while P_n grows with time, so NC_2 decreases with time. The fact that the NC ratio remains almost constant during growth ([47], [48]) suggest that cells are closer to the NC_1 regime, and point at the crucial role of metabolites in setting the NC ratio (Fig.4 and 5.B). Importantly, these conclusions are overlooked in a large part of the existing literature ([31],[32],[41]) which often assumes that metabolites do not play any role on the NC ratio due to their permeability at the NE. We end this qualitative discussion by predicting the effect of a variation of the parameters z_p , z_a and α_0 that were so far assumed to be fixed. Our main point is that, any parameter change that tends to dilute the chromatin charge, also tends to increase the (negative) NE potential and make the NC ratio closer to the regime NC_1 and further from the regime NC_2 . Consequently, increasing both z_p and z_a , the number of counterions carried by each protein or metabolite increases, resulting in a global growth of the volume, hence to the dilution of the chromatin charge and to the increase of the NE potential. Any increase of the pumping parameter α_0 (decrease of pumping efficiency) has a similar effect. It increases the number of ions in the cell resulting again in the dilution of the chromatin charge. Note that in the absence of pumping, ($\alpha_0 = 1$), the PLM predicts a diverging volume because this is the only way to enforce the balance of osmotic pressures at the plasma membrane (if there is no pressure difference at the membrane due to a cell wall).

Five crucial parameters have emerged from our analytical study: (1) $\frac{P_n}{P_c}$ (2) $\frac{A^f}{2P_n}$ (3) $\frac{Q^{eff}}{2P_n}$ (4) α_0 and (5) z_p/z_a . But what are the biological values of these parameters? We summarize our estimates in Appendix VC. Importantly, the ratio between chromatin (free) counterions and the number of nuclear trapped proteins (and their counterions) is estimated to be of order one (see Appendix VC and Fig.4.C). As a key consequence, we find that the NC ratio would be four times larger in the absence of metabolites Fig.5.B. This non intuitive conclusion sheds light on the indirect, yet fundamental, role of metabolites on the NC ratio, which have been overlooked in the literature.

We now turn to a numerical solution to obtain the normalized variations of the NC ratio during growth in the G1 phase for different parameters Fig.4. Interestingly, variations of the NC ratio and variations of the NE potential are strongly correlated, a feature that can be tested experimentally Fig.4.B. Moreover, we deduce from our numerical results that, in order to maintain a constant NC ratio during the cell cycle, cells must contain a large pool of metabolites, see Fig.4.C. Our estimates point out that this regime is genuinely the biological regime, thus providing a natural explanation on the origin of the nuclear scaling, which is a robust feature throughout biology.

In summary, many of the predictions of our analysis can be tested experimentally. Experiments tailored to specifically modify the highlighted parameters are expected to change the NC ratio. For example, we predict that depleting the pool of metabolites, by modifying amino-acid biosynthesis pathways, i.e., lowering $\frac{A^f}{2P_n}$, would lead to an increase of the NC ratio. Importantly, good metabolic targets in these experiments could be glutamate or glutamine because they account for a large proportion of the metabolites in the cell [28]. We also point out that cells with a smaller metabolic pool are expected to experience higher variations of the NC ratio during growth and thus larger fluctuations of this ratio at the population level Fig.4.B. These predictions could shed light on understanding the wide range of abnormal karyoplasmic ratio among cancer cells. Indeed, metabolic reprogramming is being recognized as a hallmark of cancer [49]; some cancer cells increase their consumption of the pool of glutamate and glutamine to fuel the TCA cycle and enhance their proliferation and invasiveness [50].

Moreover, disruption of either nuclear export or import is expected to change $\frac{P_n}{P_c}$ and thus the NC ratio. Numerical solutions of the equations displayed in Fig.5 show a natural decrease of the NC ratio due to the disruption of nuclear import. On the other hand, if nuclear export is disrupted, we expect an increase of the NC ratio. This is in agreement with experiments done very recently in yeast cells [32]. The authors reported a transient decrease followed by an increase of the diffusivities in the nucleus. This is precisely what our theory predicts. The initial decay is due to the accumulation of proteins in the nucleus, resulting in an associated crowding. While, the following increase, is due to the impingement of ribosome synthesis. As this step requires nuclear export, it leads to the loss of the exponential growth and a decoupling between protein and amino acid numbers that drives the dilution of the nuclear content.

Finally, our framework also predicts that experiments that would maintain the 5 essential parameters unchanged, would preserve the nuclear scaling. We thus expect that, as long as the NE is not under strong tension, changing the

external ion concentration does not influence the scaling directly. Experiments already published in the literature [15] shows precisely this feature.

I. Mechanical role of the Lamina on the NC ratio

So far we have assumed that the osmotic pressure is balanced at the NE, which is a key condition for the linear relationship between nuclear and cytoplasmic volume. But why should this regime be so overly observed in biology? We first address this question qualitatively. For simplicity in the present discussion, we assume that DNA is diluted so that the NE potential is negligible. This implies that metabolites are partitioned so that their concentrations are equal in the nucleoplasm and the cytoplasm, hence cancelling their contribution to the osmotic pressure difference at the NE Eq.13. In the limit $\alpha_0 \sim 0$, this allows to express the volume of the nucleus as:

$$V_n = \frac{kT \cdot (z_p + 1) \cdot P_n}{\Delta P_n + (z_p + 1) \cdot p_c} \quad (16)$$

While the previous expression does not represent the exact solution of the equations, it qualitatively allows to realise that the NE hydrostatic pressure difference plays a role in the volume of the nucleus if it is comparable to the osmotic pressure exerted by proteins and their counterions. This pressure is in the 1000Pa range since protein concentration are estimated to be in the millimolar range (Appendix V C). We further estimated an upper bound for the nuclear pressure difference to be in the 10^4 Pa range (Eq.S.48). Admittedly crude, these estimates allow us to draw a three-fold conclusion. (1) The nuclear pressure difference can be higher than the cytoplasmic pressure difference, in part due to the fact that Lamina has very different properties compared to cortical actin: it is much stiffer and its turnover rate is lower. This points out the possible role of nuclear mechanics in the determination of the nuclear volume contrary to the cortical actin of mammalian cells that does not play any direct role for the cell volume, (2) The typical hydrostatic pressure difference at which mechanical effects become relevant is at least two orders of magnitude lower for the nucleus than for the cytoplasm, for which it is of order π_0 , (3) Assuming linear elasticity, small NE extensions of 10% would be sufficient to impact nuclear volume. These conclusions stand in stark contrast to the observed robustness of the nuclear scaling, thus pointing out that the constitutive equation for the tension in the lamina is nonlinear. Biologically, we postulate that this non-linearity originates from the folds and wrinkles that many nuclei exhibit [22]. These folds could indeed play the effective role of membrane reservoirs, preventing the NE tension to grow with the nuclear volume, and setting the nuclear pressure difference to a small constant value, thereby maintaining cells in the scaling regime discussed in the previous sections. This conclusion is consistent with the results of Ref. [42], which observed that the nucleus exhibits non-linear osmotic properties.

To further confirm our conclusions quantitatively, we consider the thought experiment of non-adhered cells experiencing hypoosmotic shock. This experiment is well adapted to study the mechanical role of nuclear components on nuclear volume because it tends to dilute the protein content while increasing the hydrostatic pressure by putting the NE under tension. For simplicity, we ignore the mechanical contribution of chromatin that was shown to play a negligible role on nuclear mechanics for moderate extensions [51]. To gain insight into the non-linear set of equations, we split the problem into two parts. First, we identify analytically the different limiting regimes of nuclear volume upon variation of the number of impermeant molecules X_n present in the nucleus and the NE tension γ_n . We summarize our results in a phase portrait (see Appendix V F 6 and Fig.5). Two sets of regimes emerge: those, studied above, where nuclear and cytoplasmic osmotic pressures are balanced, and those where the nuclear hydrostatic pressure matters. In the latter situations, the nuclear volume does not depend on the external concentration and saturates to the value (see Appendix V F 7) :

$$\frac{V_n^{max}}{V_n^{iso}} = \frac{(1+s)^{3/2}}{2\sqrt{2}} \cdot \left(1 + \sqrt{1 + \frac{1}{(1+s) \cdot K^{eff}}} \right)^{3/2} \quad \text{with,} \quad K^{eff} = \frac{K}{kT \cdot \frac{N_n^{tot}}{V_n^{iso}} \cdot \left(\frac{6}{\pi} \cdot V_n^{iso}\right)^{1/3}} \quad (17)$$

where, s and V_n^{iso} are respectively the fraction of membrane stored in the folds and the volume of the nucleus at the isotonic external osmolarity $2 \cdot n_0^{iso}$. K^{eff} is an effective adimensional modulus comparing the stretching modulus of the nuclear envelope K with an osmotic tension that depends on the total number of free osmolytes contained by the nucleus N_n^{tot} . The saturation of the nuclear volume under strong hypoosmotic shock originating from the pressure build up in the nucleus after the unfolding of the folds, implies a significant decrease of the NC ratio and a loss of nuclear scaling Fig.4.D.

As a second step, we investigate the variations of $X_n = A_n^f + P_n$ after the shock. Our numerical solution again highlight the primary importance of considering the metabolites A_n^f for the modelling of nuclear volume. Indeed,

disregarding their contribution would lead to an overestimation of the number of trapped proteins. Additionally, X_n would remain constant during the osmotic shock, resulting in the reduction of the effective modulus of the envelope Eq.17. We would thereby overestimate the nuclear volume (Fig.4.D dashed line). In reality, since free osmolytes are mainly accounted for by metabolites which are permeable to the NE, the number of free osmolytes in the nucleus decreases strongly during the shock. This decrease can easily be captured in the limit where metabolites are uncharged $z_a = 0$. The balance of concentrations of metabolites Eq.13 implies that the number of free metabolites in the nucleus, A_n^f , passively adjusts to the NC ratio:

$$A_n^f = \frac{1}{1 + \frac{1}{NC}} \cdot A^f \quad (18)$$

As mentioned earlier, the tension of the envelope is responsible for the decrease of the NC ratio. This in turn decreases the number of metabolites inside the nucleus, reinforcing the effect and thus leading to a smaller nuclear volume at saturation Fig.4.D. We find the analytical value of the real saturation by using Eq.17 with $N_n^{tot} = (zp + 1) \cdot P_n + Q^{eff}$, i.e., no metabolites remaining in the nucleus.

Our investigations on the influence of the hydrostatic pressure term in the nested PLM, lead us to identify another key condition to the nuclear scaling, i.e., the presence of folds at the NE. Moreover, although not the purpose of the present article, using our model to analyse hypoosmotic shock experiments could allow a precise characterisation of the nucleus mechanics.

III. DISCUSSION

In this study, we have investigated the emergence of the cell size scaling laws, which are the linear relations between dry mass, nuclear size and cell size, and which seem ubiquitous in living systems. Using a combination of physical arguments ranging from thermodynamics, statistical physics, polymer physics, mechanics and electrostatics, we have provided evidence that the robustness of these scaling laws arises from three physical properties : electroneutrality, balance of water chemical potential, and balance of ionic fluxes. The set of associated equations defines a model developed 60 years ago named the PLM. The major challenge in probing the origin of the scaling laws using the PLM, which we have addressed in this study, is to link a wide range of cell constituents and microscopic biological factors, such as ion transport, translation, transcription, chromatin condensation, nuclear mechanics, to the mesoscopic parameters of the PLM, Fig.1.B. A host of experimental papers has gathered evidence on these scaling laws and their breakdown over the past century [2],[3],[4], but no theoretical analyses have unified these observations within a single theoretical framework.

In order to go in this direction, we have simplified the PLM to its utmost based on the determination of precise orders of magnitude of the relevant parameters. The use of a simplified model focusing on the leading order effects, such as the homeostasis between amino-acids and proteins, is a powerful way to isolate and better study the origin of the scaling laws. This is embodied in the accurate predictions, without any adjustable parameters, for the dry mass dilution and the protein dynamics of yeast cells, which are prevented from dividing. A phenomenon that was so far unexplained [10] despite the fact that it is believed to be of fundamental biological importance [11] by establishing a functional relationship between cell size (and density) and cell senescence, potentially providing a novel mechanism driving this important aging process.

The key ingredient of our model is the consideration of small osmolytes and in particular metabolites and small ions. Their high number fractions among cell free osmolytes implies that they dominate the control of cell volume. We make three quantitative predictions from this finding (1) The homeostasis between amino-acids and proteins, originating from the enzymatic control of the amino-acid pool, explains the dry mass density homeostasis. The disruption of homeostasis, due to mRNA crowding by ribosomes or pharmacological treatment such as rapamycin, is predicted to lead to dry mass dilution upon cell growth, due to the saturation of the protein content while the number of amino-acids and thus the volume keeps increasing with time, (2) The dry mass dilution observed at mitotic entry for mammalian cells can naturally be explained by the release of counterions condensed on the chromatin, leading to the increase of the number of osmolytes inside the cell and to the subsequent influx of water to ensure osmotic pressure balance at the plasma membrane, (3) The robustness of the NC ratio to the predicted value $\frac{P_n}{P_c}$ is due to the high pool of metabolites within cells, resulting in the dilution of the chromatin (free) counterions which do not scale during growth.

Interestingly, only few amino-acids represent most of the pool of the metabolites possessed by the cell, i.e., glutamate, glutamine and aspartate. Emphasizing their crucial role on cell size. Our investigations thus link two seemingly distinct hallmark of cancers : the disruption of the cell size scaling laws such as the abnormal karyoplasmic ratio, historically used to diagnose cancer, and metabolic reprogramming, some cancer cells showing an increased consumption of their

pool of glutamate and glutamine to fuel the TCA cycle and enhance their proliferation and invasiveness [50]. This may thus represent possible avenues for future research related to the variability of nucleus size in cancer cells [52]. Moreover, the large pool of metabolites is a robust feature throughout biology [28], making it one of the main causes of the universality of the cell size scaling laws observed in yeasts, bacteria and mammalian cells. We believe that the more systematic consideration of such small osmolytes will allow to understand non-trivial observations. For instance, the recent observation of the increase of diffusivities in the nucleus after blocking nuclear export, is explained in our model by the decoupling between protein and amino-acid homeostasis after the impingement of ribosome synthesis, a step that requires nuclear export [32].

A. The nucleoskeletal theory

To study the nuclear scaling law, we developed a model for nuclear volume, by generalizing the PLM, that includes both nuclear mechanics, electrostatics and four different classes of osmolytes. The clear distinction between these classes of components is crucial according to our analysis and is new. (1) Chromatin, considered as a gel, does not play a direct role in the osmotic pressure balance because its translational entropy is vanishingly small. Yet, it plays an indirect role on nuclear volume through its counterions. This creates an asymmetry in our system of equations, leading to the unbalance of ionic concentrations across the NE and to the appearance of a NE potential related to the density of chromatin. (2) Proteins, are considered as trapped in the nucleus, their number being actively regulated by nucleo-cytoplasmic transport. (3) Metabolites, are considered as freely diffusible osmolytes through the NE but not through the plasma membrane. Note that only half of the proteins are trapped in the nucleus because about half of them have a mass smaller than the critical value 30-60kDa [24], which corresponds to the typical cut-off at which they cannot freely cross nuclear pore complexes. This represents more a semantic issue than a physical one, and permeant proteins are rigorously taken into account as metabolites in the model, but are negligible in practice due to the larger pool of metabolites. (4) Free ions, are able to diffuse through the plasma membrane and the NE.

As a consequence, we show that the nuclear scaling originates from two features. The first one is the balance of osmotic pressures at the NE, that we interpret as the result of the non-linear elastic properties of the nucleus likely due to the presence of folds in the nuclear membrane of mammalian cells. Interestingly, yeast cells do not possess lamina such that the presence of nuclear folds may not be required for the scaling. In this regard, our model adds to a recently growing body of evidence suggesting that the osmotic pressure is balanced at the NE in isotonic conditions [41],[32],[42]. The second feature is the presence of the large pool of metabolites accounting for most of the volume of the nucleus. This explains why nuclear scaling happens during growth while the number of chromatin counterions does not grow with cell size.

Interestingly, although not the direct purpose of this article, our model offers a natural theoretical framework to shed light on the debated nucleoskeletal theory [4], [3]. Our results indicate that the genome size directly impacts the nuclear volume only if the number of (free) counterions of chromatin dominates the number of trapped proteins and the number of metabolites inside the nucleus. We estimate that this number is comparable to the number of trapped proteins while it is about 60 times smaller than the number of metabolites, in agreement with recent observations that genome content does not directly determine nuclear volume [3]. Although not directly, chromatin content still influences nuclear volume. Indeed, nuclear volume (Eq.S.76) is mainly accounted by the number of metabolites, which passively adjusts according to Eq.S.70(7). In the simple case, of diluted chromatin and no NE potential, metabolite concentration is balanced and $NC = \frac{P_n}{P_c}$, such that the metabolite number depends on two factors (Eq.18). The first one, is the partitioning of proteins $\frac{P_n}{P_c}$, that is biologically ruled by nucleo-cytoplasmic transport in agreement with experiments that suggest that the nucleo-cytoplasmic transport is essential to the homeostasis of the NC ratio [3]. The second one is the total number of metabolites, ruled by the metabolism Eq.9, which ultimately depends upon gene expression (Appendix V D), as shown by genetic screen experiments done on fission yeast mutants [3]. However, when the chromatin charge is not diluted, which is likely to occur for cells exhibiting high NE potential such as some cancer cells, our theory predicts that the number of metabolites in the nucleus also directly depends on the chromatin content due to electrostatic effects. This highlights the likely importance of chromatin charge in the nuclear scaling breakdown in cancer.

B. Role of NE breakdown in cell volume variations

The nested PLM predicts that the cell swells upon NE breakdown if the NE is under tension. NE breakdown occurs at prometaphase, and does not explain most of the mitotic swelling observed in [34, 35], which occurs at prophase. Within our model based on counterion release, mitotic swelling is either associated with cytoplasm swelling if the released counterions leave the nucleus, or with nuclear swelling if they remain inside. In the latter case, swelling at

592 prophase would be hindered by an increase of NE tension, and additional swelling would occur at NE breakdown.
 593 This prediction can be tested by artificially increasing the NE tension through strong uniaxial cell confinement [53],
 594 which would synchronise mitotic swelling with NE breakdown.

595 C. Physical grounds of the model

596 Physically, why can such a wide range of biological phenomena be explained such a simple theory? A first ap-
 597 proximation is that we calculated the osmotic pressure considering that both the cytoplasm and the nucleus are ideal
 598 solutions. However, it is known that the cytoplasm and the nucleoplasm are crowded ([54],[55]). The qualitative
 599 answer again comes from the fact that small osmolytes constitute the major part of the free osmolytes in a cell so
 600 that steric and short range attractive interactions are only a small correction to the osmotic pressure. We confirm this
 601 point by estimating the second virial coefficient that gives a contribution to the osmotic pressure only of order 2kPa
 602 (see Appendix V C), typically 2 orders of magnitude smaller than the ideal solution terms Fig.1.B. However, note that
 603 we still effectively take into account excluded volume interactions in our theory through the dry volume R . Moreover,
 604 we show in appendix V G) that although we use an ideal gas law for the osmotic pressure, the Donnan equilibrium
 605 effectively accounts for the electrostatic interactions. Finally, our theory can be generalized to take into account any
 606 ions species and ion transport law while keeping the same functional form for the expressions of the volume Eq.S.36,
 607 as long as only monovalent ions are considered. This is a very robust approximation, because multivalent ions such as
 608 calcium are in the micromolar range. Together, these observations confirm that the minimal formulation of the PLM
 609 that we purposely designed is well adapted to study cell size.

610 D. Future extensions of the theory

611 As a logical extension of our results, we suggest that our framework be used to explain the scaling of other membrane
 612 bound organelles such as vacuoles and mitochondria [40]. We show in appendix (Eq.S.98) that the incorporation of
 613 other organelles into our framework lead to the same equations as for the nucleus, thus pointing out that the origin of
 614 the scaling of other organelles may also arise from the balance of osmotic pressures. We also propose that our theory
 615 be used to explain the scaling of membraneless organelles such as nucleoids [56]. Indeed, the Donnan picture that we
 616 are using does not require membranes [57]. However, we would have to add other physical effects in order to explain
 617 the partitioning of proteins between the nucleoid and the bacterioplasm.

618 Taken as a whole, our study demonstrates that cell size scaling laws can be understood and predicted quantitatively
 619 on the basis of a remarkably simple set of physical laws ruling cell size as well as a simple set of universal biological
 620 features. The multiple unexplained biological phenomena that our approach allows to understand indicates that this
 621 theoretical framework is fundamental to cell biology and will likely benefit the large community of biologists working
 622 on cell size and growth.

623 IV. ACKNOWLEDGMENTS

624 We thank Matthieu Piel and the members of his team, in particular Damien Cuvelier, Alice Williart, Guilherme
 625 Nader and Nishit Srivastava, for insightful discussions and for showing us data that originally motivated the theory
 626 on nuclear volume; Thomas Lecuit for introducing us to the cell size scaling laws with his 2020 course at College
 627 de France entitled “Volume cellulaire determinants Physico-chimiques et regulation”; Pierre Recho for showing us
 628 his seminal work on nuclear volume; the members of the UMR 168, Amit Singh Vishen, Ander Movilla, Sam Bell,
 629 Mathieu Dedenon and Joanna Podkalicka as well as Dan Deviri for fruitful discussions. The Sens laboratory is a
 630 member of the Cell(n)Scale Labex.

V. SUPPLEMENTARY INFORMATION

A. PLM fundamental equations

In this section we derive and discuss the three physical constraints we used throughout our paper to study cell volume regulation. These results are classical and can be found in a reference textbook such as [21].

1. Electroneutrality

The intrinsic length scale associated to the Poisson equation is the Debye length. It appears explicitly in the linearized version of the Poisson equation also called the Debye-Huckel equation. It reads:

$$\lambda_D = \left(\frac{1}{4\pi \cdot l_b \cdot (n^+ + n^-)} \right)^{\frac{1}{2}} \quad (\text{S.19})$$

Where: $l_B = \frac{e^2}{4\pi kT \epsilon_r \epsilon_0}$ is the Bjerrum length - which qualitatively corresponds to the distance between two elementary charges at which the electrostatic energy will be comparable to the thermal energy. $l_B \approx 0.7\text{nm}$ in water at 300K. In the unit used in this paper (concentrations in mMol) the Debye length can be estimated using the following formula:

$$\lambda_D \approx \frac{9.7}{\sqrt{n^+(mM) + n^-(mM)}} \cdot nm \quad (\text{S.20})$$

For a typical mammalian cell $n^+(\text{mM}) + n^-(\text{mM}) \approx 180\text{mM}$ (Fig.1) which leads to a Debye length $\lambda_D \approx 0.7\text{nm}$. Thus, the Debye length is at least 3 orders of magnitude smaller than the typical radius of a cell or of a nucleus. This justifies the approximation of electroneutrality used throughout the main paper for length scales much larger than the Debye length.

2. Balance of water chemical potential

We define the osmotic pressure as:

$$\Pi = -\frac{1}{v_w} \cdot (\mu_w - \mu_w^*) \quad (\text{S.21})$$

where : v_w is the molecular volume of water, μ_w , μ_w^* are the chemical potential of water respectively in the real solution and in a pure water volume. Assuming that water is incompressible, $\mu_w^* = \mu_0(T) + v_w \cdot P$, where P is the hydrostatic pressure. When water is equilibrated, thermodynamics imposes that the chemical potential of water is equal on both sides of the membrane. From the previous equations it is straightforward to derive Eq.2 in the main text.

3. Balance of ionic fluxes

The total flux J of cations - respectively anions - is decomposed between 3 main contributions: active pumping, electrical conduction and entropic diffusion. For simplicity we assumed that only cations are pumped out of the cell. This simplifying choice was made to model the Na/K pump which is one of the most relevant cationic pumps. Though, we show in subsection.VB that this assumption is not critical since the equations keep the same functional form if it is relaxed. As a convention, we choose J to be positive when ions are entering the cell. At steady-state, the fluxes vanish:

$$\begin{cases} J_{+,tot} = g^+ \cdot \left[-e \cdot U_c - kT \cdot \ln \left(\frac{n^+}{n_0} \right) \right] - p = 0 \\ J_{-,tot} = g^- \cdot \left[e \cdot U_c - kT \cdot \ln \left(\frac{n^-}{n_0} \right) \right] = 0 \end{cases} \quad (\text{S.22})$$

where p is the pumping flux, g^\pm are the membrane conductivities for cations and anions, and U_c is the cell transmembrane potential, which can be expressed as:

$$U_c = -\frac{kT}{e} \cdot \ln\left(\frac{n^+}{n_0}\right) - \frac{p}{g_+} = \frac{kT}{e} \cdot \ln\left(\frac{n^-}{n_0}\right) \quad (\text{S.23})$$

For Eq.S.23 to be verified, the following relationship between n^+ and n^- must be imposed :

$$\begin{cases} n^+ \cdot n^- = \alpha_0 \cdot n_0^2 \\ \alpha_0 = e^{-\frac{p}{g^+}} \end{cases} \quad (\text{S.24})$$

The latter equation takes the form of a generalized Donnan ratio that includes the active pumping of cations. The usual Donnan ratio [21] is recovered when $p = 0$. The generalized Donnan ratio Eq.3 together with the electroneutrality condition Eq.1 yield analytic expressions for the ionic densities n^+ and n^- (the notations are defined in the main text):

$$\begin{cases} n^+ = \frac{zx + \sqrt{(zx)^2 + 4\alpha_0 n_0^2}}{2} \\ n^- = \frac{-zx + \sqrt{(zx)^2 + 4\alpha_0 n_0^2}}{2} \end{cases} \quad (\text{S.25})$$

The cell osmotic pressure can thus be expressed as:

$$\frac{\pi}{kT} = \sqrt{(zx)^2 + 4\alpha_0 n_0^2} + x \quad (\text{S.26})$$

B. General expressions of the volume in the PLM model

The system of equation formed by Eq.1,2,3 is nonlinear and cannot be solved analytically in its full generality. One complexity arises from the difference of hydrostatic pressure ΔP . Intuitively, if the volume increases, the surface increases which may in some situations increase the tension of the envelope and in turn impede the volume growth. Mathematically, Laplace law relates the difference of hydrostatic pressure to the tension γ and the mean curvature of the interface - which simplifies to the radius of the cell R in a spherical geometry. The difference of hydrostatic pressure then reads:

$$\Delta P = \frac{2\gamma}{R} \quad (\text{S.27})$$

In the case where the interface exhibits a constitutive law which is elastic $\gamma = K \cdot \frac{S-S_0}{S_0}$, it is easy to see that ΔP exhibits power of V which makes the problem non analytical. However, we can get around this limitation in two biologically relevant situations :

- When ΔP is negligible. As shown in Fig1.B this happens for mammalian cells that do not possess cellular walls.
- When ΔP is buffered by biological processes. We argue that this situation applies for yeasts and bacteria during growth. Indeed, if the volume increase is sufficiently slow, one can hypothesize that cells have time to add materials to their cellular walls such that the tension does not increase during growth.

We give the corresponding analytical expressions under these two hypotheses in the next two paragraphs.

1. Analytical expression of the volume when hydrostatic pressure difference is negligible

The balance of water chemical potential Eq.2, neglecting the difference of pressure and injecting the expressions for the ionic densities Eq.S.25 leads to the following equation for the density of impermeant molecules x :

$$(z^2 - 1) \cdot x^2 + 4n_0 \cdot x - 4 \cdot (1 - \alpha_0) \cdot n_0^2 = 0 \quad (\text{S.28})$$

685 Solving this equation and using the definition of the density of impermeant molecules $x = \frac{X}{V-R}$ yield the expression
686 for the volume of the cytoplasm :

$$\begin{cases} V - R = \frac{kT \cdot N^{tot}}{\Pi_0} \\ N^{tot} = X \cdot \frac{(z^2 - 1)}{-1 + \sqrt{1 + (1 - \alpha_0)(z^2 - 1)}} \end{cases} \quad (\text{S.29})$$

687 The volume can thus be written as an ideal gas law with a total number of free osmolytes N^{tot} . This number takes
688 into account the different ions and is thus larger than the actual number of impermeant molecules X . In the limit of
689 very fast pumping - $\alpha_0 \rightarrow 0$ - Eq.S.29 reduces to the expression given in the main text Eq.4

690 2. Analytical expression of the volume when ΔP is buffered

691 The same procedure can be used when ΔP is buffered (independent of the volume). The final expression reads:

$$\begin{cases} V - R = \frac{kT \cdot N^{tot}(\Delta P)}{(\pi_0 + \Delta P)} \\ N^{tot}(\Delta P) = X \cdot \frac{z^2 - 1}{-1 + \sqrt{1 + (z^2 - 1) \cdot \left(1 - \frac{\alpha_0}{\left(1 + \frac{\Delta P}{kT \cdot 2n_0}\right)^2}\right)}} \end{cases} \quad (\text{S.30})$$

692 Interestingly, the wet volume $V - R$ remains proportional to the number of impermeant molecules X in this limit.

693 3. Analytical expression of the volume for an arbitrary number of ions and active transports

694 In this subsection, we generalize the PLM to any type of ions and any ionic transport. Each ion can be actively
695 transported throughout the membrane. Importantly, we show that - as long as ions are monovalent - the PLM
696 equations and solutions take the same functional form as the two-ions model used in the main text. We use the same
697 notations as in the main text (Section II A and Fig.1), except that we now add subscript i to refer to the ion of type
698 i . For instance, z_i^- - respectively n_i^- - refers to the valency - respectively the concentration - of the anion i . The
699 densities of positive / negative charges in the cell read:

$$\begin{cases} d^+ = \sum_j z_j^+ \cdot n_j^+ \\ d^- = \sum_j z_j^- \cdot n_j^- \end{cases} \quad (\text{S.31})$$

700 Electroneutrality thus simply reads:

$$d^+ - d^- - z \cdot x = 0 \quad (\text{S.32})$$

701 Balancing ionic fluxes for each ion types, as in Eq.S.22, leads to :

$$\begin{cases} n_j^{+/-} = n_j^0 \cdot \alpha_j \cdot e^{(-/+)\cdot z_j \cdot \frac{e \cdot U_c}{kT}} \\ \alpha_j = e^{-\frac{p_j}{q_j}} \end{cases} \quad (\text{S.33})$$

702 Using Eqs.S.31,S.32, S.33 and assuming that all ions are monovalent, the product of the cationic and anionic densities
703 can be expressed as :

$$d^+ \cdot d^- = \underbrace{\left(\sum_j n_j^{+,0} \cdot \alpha_j \right) \cdot \left(\sum_i n_i^{-,0} \cdot \alpha_i \right)}_{\equiv \tilde{\alpha}(n_i^0)} \quad (\text{S.34})$$

704 and the analytical solution of the full problem reads:

$$\begin{cases} d^+ = \frac{zx + \sqrt{(zx)^2 + 4\tilde{\alpha}(n_i^0)}}{2} \\ d^- = \frac{-zx + \sqrt{(zx)^2 + 4\tilde{\alpha}(n_i^0)}}{2} \end{cases} \quad (\text{S.35})$$

$$\begin{cases} V - R = \frac{kT \cdot N^{tot}(\Delta P)}{(\pi_0 + \Delta P)} \\ N^{tot}(\Delta P) = X \cdot \frac{z^2 - 1}{-1 + \sqrt{1 + (z^2 - 1) \cdot \left(1 - \frac{4\tilde{\alpha}(n_i^0)}{\left(\frac{1}{kT} \cdot \pi_0 + \frac{1}{kT} \cdot \Delta P \right)^2} \right)^2}} \end{cases} \quad (\text{S.36})$$

705 which shows a similar form as the two-ion model, Eqs.S.25,S.30.

706 C. Order of magnitudes

707 Throughout the main text, we used order of magnitudes to guide our investigations and justify our approximations.
708 For the sake of readability we gather all the parameter significations, values, and origins in Table I.

709 1. Protein concentration

710 We use data published in [35] to estimate the typical concentration of proteins in mammalian cell p_{tot} as :

$$p_{tot} = \%_p^{mass} \cdot \frac{\rho}{\mathcal{M}_a \cdot l_p \cdot \left(1 - \frac{R}{V}\right)} \sim 2mMol \quad (\text{S.37})$$

711 where, $\%_p^{mass}$ is the fraction of dry mass occupied by proteins Fig.1.D.

712 2. mRNA to protein fraction

713 In figure 1.C we neglected the contribution of mRNAs to the wet volume of the cell. The rationale behind this
714 choice is twofold. (1) Proteins represent less than 1% of the wet volume (2) The mRNA to protein number fraction is
715 estimated to be small, due to the fact that the mass of one mRNA is 9 times greater than the one of a protein while
716 the measured fraction of mRNA to dry mass is of the order 1% [24] :

$$\frac{M_{tot}}{P_{tot}} = \frac{\mathcal{M}_p}{\mathcal{M}_{mRNA}} \cdot \frac{\%_{mRNA}^{mass}}{\%_p^{mass}} \sim \frac{1}{500} \quad (\text{S.38})$$

717 Thus, mRNAs contribute even less than proteins to the wet volume.

TABLE I. Description and values of the parameters used for the order of magnitudes.

| Symbol | Typical Value | Meaning |
|----------------------|----------------------------------|--|
| ρ | $0.1\text{kg}\cdot\text{L}^{-1}$ | Typical dry mass density in a mammalian cell [35] |
| \mathcal{M}_a | 100Da | Average mass of an amino-acid [24] |
| l_p | 400a.a | Average length of an eukaryotic protein [24] |
| \mathcal{M}_{mRNA} | $3 \cdot \mathcal{M}_a$ | Average mass of a mRNA [24] |
| l_{mRNA} | $3 \cdot l_p$ | Average length of a mRNA [24] |
| l_{bp} | 1/3nm | Average length of one base pair |
| Q_{bp} | 2 | Average number of negative charge per base pair |
| $L_{nucleosome}$ | 200bp | Average length of DNA per nucleosome |
| L_{link} | 53bp | Length of the DNA linking two histones |
| L_{wrap} | 147bp | Length of the DNA wrapped around one histone |
| u_{DNA} | 4 | Manning parameter for pure DNA, i.e., 75% of the charges will be screened by manning condensation. |
| L_{tot} | $6 \cdot 10^9\text{bp}$ | Total length of the DNA within a diploid human cell |
| Q_{hist} | 76 | Average number of positive charges per histone at less than 1nm from the wrapped DNA backbone [37] |
| Q_{wrap} | 174 | Average number of condensed counterions around the wrapped DNA [37] |
| l_b | 0.7nm | Bjerrum length in water at 300k |
| K | 25mN/m | Stretching modulus of Lamina [43] |

718

3. Metabolite concentration

719 We find the metabolite concentration self-consistently by enforcing balance of osmotic pressure at the plasma
720 membrane Eq.2 :

$$a^f = 2n_0 - p_{tot} - n^+ - n^- \sim 118mMol \quad (\text{S.39})$$

721 where the concentrations of ions were reported in [24] (see Fig.1). This high value of metabolite concentration is
722 coherent with reported measurements [28].

723

4. Contribution of osmolytes to the wet volume of the cell Fig.1.C

724 The contribution of osmolytes to the wet volume fraction is simply equal to the ratio of the osmolyte concentration
725 to the external osmotic pressure, here equal to $2n_0$ Eq.4. The concentration of specific amino-acids and metabolites
726 were estimated using their measured proportion in the metabolite pool [28] times the total concentration of metabolites
727 a^f (Eq.S.39).

728

5. Amino-acids contribution to the dry mass

729 One of the main conclusions from our order of magnitude estimates is that amino-acids play an essential role in
730 controlling the volume but have a negligible contribution to the cell's dry mass. This originates from the large average
731 size of proteins $l_p \sim 400\text{a.a}$. The contribution of amino-acids to the dry mass reads:

$$\%_{a.a}^{mass} = \%_{a.a}^{number} \cdot \frac{a^f}{p_{tot}} \cdot \frac{\%_p^{mass}}{l_p} \sim 6\% \quad (\text{S.40})$$

732 where, $\%_{a.a}^{number} \sim 73\%$ is the number fraction of amino-acids among metabolites.

733 6. Effective charge of chromatin

734 The average effective charge per nucleosome is estimated to be:

$$Q_{pernucleosome}^{eff} = L_{Link} \cdot \frac{Q_{bp}}{u_{DNA}} + L_{wrap} \cdot Q_{bp} - Q_{hist} - Q_{wrap} = 71 \quad (\text{S.41})$$

735 where, the right hand side can be understood as the total negative charge of pure DNA, screened in part by histone
736 positive charges and by the manning condensed counterions. Note that the number of condensed counterions Q_{wrap}
737 around the wrapped DNA simulated in [37] is similar to the value expected by the manning theory which we estimate
738 to be 164 elementary charges.

739 The number of nucleosomes is simply $N_{hist} = \frac{L_{tot}}{L_{nucleosomes}} = 3 \cdot 10^7$ such that the effective charge of chromatin is
740 estimated to be :

$$Q^{eff} = 2 \cdot 10^9 \quad (\text{S.42})$$

741 7. Condensed counterions on chromatin

742 The condensed counterions on chromatin can simply be found from the effective charge of the chromatin, the total
743 charge of pure DNA and the charge of histones. We obtain:

$$Q^{cond} = Q_{bp} \cdot L_{tot} - Q^{eff} - Q_{hist} \cdot N_{hist} \sim 8 \cdot 10^9 \quad (\text{S.43})$$

744 8. Estimation of the amplitude of the Mitotic Swelling

745 At mitosis cells have doubled their genome content such that we double the number of condensed counterions
746 estimated earlier for a diploid mammalian cell. Using the PLM, we compute the amplitude of swelling if all the
747 chromatin condensed counterions were released at the same time, assuming an external osmolarity of $n_0 = 100 -$
748 150mM .

$$\Delta V = \frac{2 \cdot Q^{cond}}{2n_0} \sim 100\mu\text{m}^3 \quad (\text{S.44})$$

749 Note that ΔV must scale with the number of genome duplications. For instance, for tetraploid cells, the previous
750 amplitude must be doubled.

751 9. Average charge of proteins and metabolites

752 The average charge of proteins used in the paper, $z_p \sim 0.8$, was estimated from [58] assuming that Histidines are
753 neutral. This is reasonable because their Pka is of order 6 while typical physiological pH is of order 7.4, so that only
754 4% of histidines are charged in the cell.

755 The average charge of metabolites is assumed to be $z_a \sim 1$ since glutamate is the most abundant [28]. We have
756 checked that changing this parameter does not alter our conclusions.

10. Absolute number of osmolytes

757

758 To obtain the Figure.4, we had to estimate the parameter $NC_1 = \frac{P_n}{P_c}$ and thus, the number of protein trapped
 759 inside the nucleus P_n at the beginning of interphase. The total number of proteins and metabolites at the beginning of
 760 interphase is simply obtained by multiplying the concentration of proteins p_{tot} , m_{tot} estimated earlier by the volume
 761 at the beginning of interphase, measured to be equal to $1250\mu\text{m}^3$, minus the dry volume which roughly represent 30%
 762 of the total volume [35] and Fig.1.B.

$$P_{tot} = p_{tot} \cdot (V - R) \sim 10^9 \quad (\text{S.45})$$

$$A^f = \frac{a^f}{p_{tot}} \cdot P_{tot} \sim 60 \cdot 10^9 \quad (\text{S.46})$$

763 In the regime where the chromatin is diluted (large amount of metabolites), the NC ratio can be well approximated by
 764 $NC_1 = \frac{P_n}{P_c}$. Usual values of NC reported in the literature typically range from 0.3 to 0.6 [15], [31]. We thus estimate
 765 reasonable values of P_n as:

$$P_n = \frac{NC}{1 + NC} \cdot P_{tot} \sim 3 \cdot 10^8 \quad (\text{S.47})$$

766 Note that we also used the numerical solutions of Eq.S.70 in Section VF to infer NC_1 from NC exactly. This method
 767 made no qualitative difference to the results plotted in Fig.4.

768

11. Estimation of an upper bound for the hydrostatic pressure difference of the nucleus

769 Even though the stiffness of the lamina layer is susceptible to vary according to the tissue the cell is belonging to
 770 [44], its stretching modulus was reported to range from 1 to 25mN/m [43], [51]. Also, Lamina turnover rate is much
 771 slower than the actin turnover rate. Together, this suggests that Lamina - at the difference to the cortical actin -
 772 can sustain bigger pressure difference on longer timescales. This solid-like behavior of Lamina was observed during
 773 micropipette aspiration of Oocyte nuclei through the formation of membrane wrinkles at the pipette entrance [43].
 774 We thus chose to mathematically model lamina with an elastic constitutive equation when it is tensed Eq.S.89. Using
 775 Laplace law, we estimate an upper bound for ΔP_n , assuming a typical nuclear radius of $5\mu\text{m}$, to be:

$$\Delta P_n \sim \frac{2K}{R} \sim 10^4 Pa \quad (\text{S.48})$$

776

12. Estimation of the second virial term in the osmotic pressure

777 We estimate the steric term in the osmotic pressure to be:

$$\pi_{steric} \sim kT \cdot v_p \cdot p_{tot}^2 \sim 2kPa \quad (\text{S.49})$$

778 where, v_p is the excluded volume per protein, estimated to be $v_p \sim \frac{R}{P_{tot}} \sim 375\text{nm}^3$. This corresponds to a protein
 779 radius of 4.5nm, a value coherent with observations [24]. This steric contribution in the osmotic pressure may thus
 780 safely be neglected, as $\pi_{steric} \ll \pi_0$.

781

D. A cell growth model

782 We summarize here the equations derived and discussed in the main text (Eqs.6,7). The rates of production of
 783 mRNAs and proteins in the non-saturated and saturated regimes read:

$$\dot{M}_j = \begin{cases} k_0 \cdot \phi_j \cdot P_p - \frac{M_j}{\tau_m}, & \text{if } P_p \leq P_p^* \\ k_0 \cdot g_j \cdot \mathcal{N}_p^{max} - \frac{M_j}{\tau_m}, & \text{if } P_p \geq P_p^* \end{cases} \quad (\text{S.50})$$

$$\dot{P}_j = \begin{cases} k_t \cdot \frac{M_j}{\sum M_j} \cdot P_r - \frac{P_j}{\tau_p}, & \text{if } P_r \leq P_r^* \\ k_t \cdot M_j \cdot \mathcal{N}_r^{max} - \frac{P_j}{\tau_p}, & \text{if } P_r \geq P_r^* \end{cases} \quad (\text{S.51})$$

784 The cut-off values - P_p^* , P_r^* - above which the substrates become saturated are obtained by imposing continuities of
785 the production rates at the transition:

$$\begin{cases} P_p^* = \mathcal{N}_p^{max} \cdot \sum g_j \\ P_r^* = \mathcal{N}_r^{max} \cdot \sum M_j \end{cases} \quad (\text{S.52})$$

786 *1. Neither DNA nor mRNAs are saturated: $P_p \leq P_p^*$ and $P_r \leq P_r^*$*

787 The fast degradation rate of mRNAs ensures that their number reach steady-state during growth (Eq.8 which with
788 Eq.7 yield an exponential growth for the number of ribosomes $P_r = P_{r,0} \cdot e^{k_r \cdot t}$ (with $k_r = k_t \cdot \phi_r - 1/\tau_p$) and of any
789 other protein, $P_j = \frac{\phi_j}{\phi_r} \cdot P_r$; where we neglected the initial conditions on proteins other than ribosomes due to the
790 exponential nature of the growth. Incorporating the dynamics of growth of the enzyme catalyzing the amino-acid
791 biosynthesis P_e into Eq.9, we obtain the number of free amino-acids in the cell:

$$A^f = \left(\phi_e \cdot \frac{k_{cat}}{k_r} - l_p \right) \cdot \frac{P_r}{\phi_r} \quad (\text{S.53})$$

792 Using the expression of the volume Eq.4 derived from the PLM coupled to our quantitative order of magnitudes, it is
793 straightforward to show that the volume grows exponentially :

$$V = \left(v_p + \frac{(z_{A,f} + 1) \cdot \left(\phi_e \cdot \frac{k_{cat}}{k_r} - l_p \right)}{2n_0} \right) \cdot \frac{P_r}{\phi_r} \quad (\text{S.54})$$

794 where we assumed the dry volume to be mainly accounted by proteins. Incorporating the previous expressions in
795 the equation for the dry mass density Eq.5, we obtain the homeostatic dry mass density written in the main text
796 Eq.10. These expressions were obtained assuming that neither the DNA nor the mRNA were saturated. Importantly,
797 mRNAs cannot be saturated if DNA is not saturated because the cut-off value P_r^* for which ribosomes saturates
798 mRNAs grows at the same speed as the number of ribosomes : $P_r^* = \mathcal{N}_r^{max} \cdot k_0 \cdot \tau_m \cdot \frac{\phi_p}{\phi_r} \cdot P_r$. Hence, DNA will saturate
799 before mRNAs during interphase, at a time t^* given by:

$$t^* = \frac{1}{k_r} \cdot \ln \left(\frac{g_r}{g_p} \cdot \frac{\mathcal{N}_p^{max} \cdot \sum g_j}{P_{r,0}} \right) \quad (\text{S.55})$$

800 *2. DNA is saturated but not mRNAs: $P_p \geq P_p^*$ and $P_r \leq P_r^*$*

801 The only difference with the previous regime is that mRNA number saturates to the value $M_j = k_0 \cdot g_j \cdot \tau_m \cdot \mathcal{N}_p^{max}$.
802 Hence, the threshold P_r^* will saturate to the value:

$$P_r^* = \mathcal{N}_r^{max} \cdot \mathcal{N}_p^{max} \cdot k_0 \cdot \tau_m \cdot \sum g_j \quad (\text{S.56})$$

803 This allows for the subsequent saturation of mRNAs by ribosomes after a time t^{**} ; whose expression can be derived
804 after simple algebra as :

$$t^{**} = t^* + \frac{1}{k_r} \cdot \ln \left(\frac{g_p}{g_r} \cdot \mathcal{N}_r^{max} \cdot k_0 \cdot \tau_m \right) \quad (\text{S.57})$$

805 However, before reaching this time, there won't be any consequence on the proteomic dynamics, which still scales
 806 with the number of ribosomes $P_j = \frac{\phi_j}{\phi_r} \cdot P_r$. This regime thus still corresponds to an exponential growth and the dry
 807 mass density remains at its homeostatic value Eq.10.

3. Both DNA and mRNAs are saturated: $P_p \geq P_p^*$ and $P_r \geq P_r^*$

809 The dynamics of growth is profoundly impacted by mRNA saturation. The protein number no longer grows
 810 exponentially, but saturates to the stationary value $P_j^{stat} = k_t \cdot k_0 \cdot \tau_p \cdot \tau_m \cdot \mathcal{N}_r^{max} \cdot \mathcal{N}_p^{max} \cdot g_j$ after a typical time
 811 $t^{**} + \tau_p$ according to:

$$P_j = P_j^{stat} + (P_j(t^{**}) - P_j^{stat}) \cdot e^{-\frac{t-t^{**}}{\tau_p}} \quad (\text{S.58})$$

812 The loss of the exponential scaling of proteins implies a breakdown of the proportionality between amino-acid and
 813 protein numbers as predicted by the amino-acid biosynthesis equation Eq.9. The total amino-acid pool in the cell
 814 $A_{tot} = A_f + l_p \cdot P_{tot}$ now scales as:

$$A_{tot} = A_{tot}(t^{**}) + k_{cat} \cdot \left(P_e^{stat} \cdot (t - t^{**}) - \tau_p \cdot (P_e(t^{**}) - P_e^{stat}) \cdot e^{-(t-t^{**})/\tau_p} \right) \quad (\text{S.59})$$

815 with, $A_{tot}(t^{**}) = \frac{\phi_e}{\phi_r} \cdot \frac{k_{cat}}{k_r} \cdot \mathcal{N}_r^{max} \cdot \mathcal{N}_p^{max} \cdot k_0 \cdot \tau_m \cdot \sum g_j$. Although, expressions still remain analytical in the transient
 816 regime and were implemented in Fig.2 in order to quantitatively test our theory, we avoid analytical complications
 817 here, by writing expressions after saturation has been reached, i.e., after a typical time $t^{**} + \tau_p$. The volume thus
 818 increases linearly with time:

$$V^{lin} = v_p \cdot P_{tot}^{stat} + \frac{(z_{Af} + 1) \cdot (A_{tot}(t^{**}) + k_{cat} \cdot P_e^{stat} \cdot (t - t^{**}) - l_p \cdot P_{tot}^{stat})}{2n_0} \quad (\text{S.60})$$

819 As emphasized in the main text, the fundamental property of this regime is that the dry mass density is predicted to
 820 decrease with time with no other mechanism than a simple crowding effect on mRNAs (see Eq.11 in the main text).

4. Quantification of the model of growth with published data

822 Many of the parameters involved in the growth model can be obtained independently, so that four parameters suffice
 823 to fully determine the volume, the amount of protein and the dry mass density during interphase growth. Here, we
 824 summarize the equations used to fit the data displayed in Fig.2. The volume can be expressed as:

$$V = \begin{cases} v_1 \cdot e^{k_r \cdot t}, & \text{if } t \leq t^{**} \\ v_2 \cdot (t - t^{**}) + v_3 \cdot e^{-(t-t^{**})/\tau_p} + v_4, & \text{if } t \geq t^{**} \end{cases} \quad (\text{S.61})$$

825 in which (v_1, v_2, v_3, v_4) are volumes that can be, if needed, expressed function of the previously defined parameters.
 826 We obtain (v_2, v_3, v_4) as a function of v_1, τ_p and t^{**} by imposing regularity constraints on the volume and growth
 827 rate:

$$\begin{cases} v_3 = \tau_p^2 \cdot k_r^2 \cdot v_1 \cdot e^{k_r \cdot t^{**}} \\ v_2 = \frac{v_3}{\tau_p} + k_r \cdot v_1 \cdot e^{k_r \cdot t^{**}} \\ v_4 = v_1 \cdot e^{k_r \cdot t^{**}} - v_3 \end{cases} \quad (\text{S.62})$$

828 Similarly, the normalized total number of protein can be expressed as:

$$\frac{P_{tot}}{P_{tot}(1h)} = \begin{cases} e^{k_r \cdot (t-1)}, & \text{if } t \leq t^{**} \\ p_1 + p_2 \cdot e^{-(t-t^{**})/\tau_p}, & \text{if } t \geq t^{**} \end{cases} \quad (\text{S.63})$$

829 Again imposing regularity constraints at the mRNA saturating transition, allows us to relate p_1 and p_2 to k_r , τ_p and
830 t^{**} .

$$\begin{cases} p_2 = -\tau_p \cdot k_r \cdot e^{k_r \cdot (t^{**}-1)} \\ p_1 = e^{k_r \cdot (t^{**}-1)} - p_2 \end{cases} \quad (\text{S.64})$$

831 Finally, we can express the buoyant mass density ρ^b of the cell (see Fig.2 for a definition) using the expressions of
832 total protein number and volume Eq.S.63,S.61 :

$$\frac{\rho^b - \rho^w}{\rho^{b,0} - \rho^w} = \begin{cases} 1, & \text{if } t \leq t^{**} \\ \frac{P_{tot}}{P_{tot}(0h)} \cdot \frac{v_1}{V}, & \text{if } t \geq t^{**} \end{cases} \quad (\text{S.65})$$

833 We use a density of water 4% larger than that of pure water ($\rho^{w,eff} = 1.04\text{kg/L}$ instead of $\sim 1\text{kg/L}$) to compensate
834 for our approximation to consider the dry mass as entirely made of proteins. Proteins are known to only occupy
835 $\%_p^{mass} = 0.6$ of the dry mass, itself being of order $\rho = 0.1\text{kg/L}$ Tab.I. Thus, we simply use as the effective water mass
836 density, $\rho^{w,eff} = \rho^w + (1 - \%_p^{mass}) \cdot \rho \sim 1.04\text{kg/L}$.

837

5. Fitting procedure

838 We detail in this appendix the method used to determine the four fitting parameters: τ_p , t^{**} , k_r , v_1 from the cell
839 volume data Fig.2.B. Our model (Eq.S.61,S.62) displays two different regimes of growth according to the saturation
840 state of mRNAs. Our fitting procedure is thus divided into two steps. First, we impose an arbitrary transition time
841 t^{**} to determine by a least mean square minimization the three other parameters. Then, we minimize the variance
842 between the obtained solution with the data to determine t^{**} . The optimal values of the fitting parameters are:

$$t^{**} = 2h44\text{min} \quad , \quad \tau_p = 1h9\text{min} \quad , \quad k_r = 0.62\text{h}^{-1} \quad , \quad v_1 = 30\text{fL} \quad (\text{S.66})$$

843

E. Manning condensation

844 We give a simple description of the phenomenon of Manning condensation, based on [57]. The electrostatic potential
845 close to an infinitely charged thin rod, in a salt bath, reads:

$$\psi = \frac{2 \cdot l_b}{A} \cdot \ln(\kappa r) \quad (\text{S.67})$$

846 where, l_b is the Bjerrum length. It is the length at which the electrostatic interaction between two elementary particles
847 is on the order of kT. Its value in water at room temperature is $l_B \approx 0.7\text{nm}$. A is the average distance between two
848 charges on the polymer. $\kappa^2 = 8\pi l_B(n^+ + n^-)$ is the inverse of the Debye length. At equilibrium, the distribution of
849 charges around the rod follows a Boltzmann distribution:

$$n^+ = n_0 \cdot e^{-\Psi} = \frac{n_0}{(\kappa r)^{2 \cdot \frac{l_b}{A}}} \quad (\text{S.68})$$

850 The total number of positive charges per unit length of the rod reads within a distance \mathcal{R} :

$$N(\mathcal{R}) = \int_0^{\mathcal{R}} n^+ 2\pi r dr = \frac{2\pi \cdot n_0}{\kappa^2 \cdot \frac{l_b}{A}} \cdot \int_0^{\mathcal{R}} \frac{1}{(r)^{2 \cdot \frac{l_b}{A} - 1}} dr \quad (\text{S.69})$$

851 When $u = \frac{l_B}{A} < 1$, $N(\mathcal{R})$ is dominated by its upper bond and goes to 0 close to the rod. On the other hand, when
 852 $u = \frac{l_B}{A} > 1$, $N(\mathcal{R})$ diverges as $\mathcal{R} \rightarrow 0$ indicating a strong condensation of the counterions on the rod. This singularity
 853 is symptomatic of the breakdown of the linear Debye-Huckel theory. The solution of the nonlinear Poisson-Boltzmann
 854 equation shows that there is formation of a tightly bound layer of counterions very near the rod, which effectively
 855 decreases the charge density (increases A) up to the value $u_{eff} = 1$ [59]. It means that if A is smaller than l_B the
 856 Manning condensation will renormalize A to $A^{eff} = l_B$. The rationale behind this renormalization is to decrease
 857 the electrostatic energy of the system by condensing free ions on the polymer. Note that there is an energy penalty
 858 associated to the loss of entropy of the condensed counterions. For weakly charged polymers this loss of entropy is not
 859 energetically favorable - case where $u = \frac{l_B}{A} < 1$ and no condensation occurs. If the density of charge of the polymer
 860 increases, Manning condensation becomes energetically favorable - case where $u = \frac{l_B}{A} > 1$. By virtue of the high
 861 lineic charge of DNA, Manning condensation will be favorable, $u^{DNA} \sim 4$.

862 F. The Nested PLM Model

863 The nested PLM is described by a set of non-linear equations, i.e., the electroneutrality, the balance of pressures,
 864 and the balance of ionic fluxes, in the cytoplasm, subscript c, and in the nucleus, subscript n. In its most general
 865 form the system reads:

$$866 \left\{ \begin{array}{l} n_c^+ - n_c^- - z_p \cdot p_c - z_a \cdot a_c = 0 \\ n_n^+ - n_n^- - z_p \cdot p_n - z_a \cdot a_n - q = 0 \\ \Delta \Pi_c = \Delta P_c \\ \Delta \Pi_n = \Delta P_n \\ n_c^+ \cdot n_c^- = \alpha_0 \cdot n_0^2 \\ n_n^+ \cdot n_n^- = \alpha_0 \cdot n_0^2 \\ (n_n^+)^{z_a} \cdot a_n = (n_c^+)^{z_a} \cdot a_c \end{array} \right. \quad (S.70)$$

866 Here, we apply the nested PLM to mammalian cells, such that we can neglect the cytoplasmic difference of hydrostatic
 867 pressure with respect to the external osmotic pressure. If the NE is not under tension, the condition of osmotic balance
 868 at the NE simply implies that the volume of each compartment takes the same functional form as in the PLM model:

$$869 \left\{ \begin{array}{l} V_n = R_n + \frac{N_n^{tot}}{2n_0} \\ V_c = R_c + \frac{N_c^{tot}}{2n_0} \end{array} \right. \quad (S.71)$$

869 It is thus straightforward to show that both the volume of the nucleus and the volume of the cytoplasm scale with
 870 each other Eq.12.

871 1. Dry volumes in the nucleus and in the cytoplasm

872 We assume that the dry volumes in the nucleus and in the cytoplasm are proportional to the total volumes of each
 873 compartments and are equal to each other: $R_n = r \cdot V_n$ and $R_c = r \cdot V_c$. Under this assumption the NC ratio simply
 874 becomes the ratio of the wet volumes:

$$875 NC = \frac{V_n}{V_c} = \frac{V_n - R_n}{V_c - R_c} \quad (S.72)$$

875 This hypothesis is practical rather than purely rigorous. It is based on experiments that suggest that dry mass
 876 occupies about 30% of the volume of both the nucleus and the cytoplasm for several cell types and conditions [32],
 877 [16],[60]. Nonetheless, even if this assumption were to be inexact, our discussion would then rigorously describe the
 878 slope of the linear relationship between nucleus and cell volume (Eq.12) which was shown to be robust to perturbation
 879 [15].

2. Membrane potential in the simple PLM model

880

881 Using the results provided earlier we find that a transmembrane potential exists as soon as there are trapped
882 charged particles. The plasma membrane potential reads:

$$\left\{ \begin{array}{l} U = \ln \left(\frac{-z \cdot (-1+r) + \sqrt{z^4 + \alpha_0 - z^2 \cdot (-1 + \alpha_0 + 2 \cdot r)}}{z^2 - 1} \right) \\ \text{With, } r = \sqrt{1 + (z^2 - 1) \cdot (1 - \alpha_0)} \end{array} \right. \quad (\text{S.73})$$

883 We find that U monotonically increases (in absolute value) with the average charge of the cell trapped components.
884 This differs from the nuclear membrane potential that vanishes when the charge of the chromatin is diluted regardless
885 of the properties of the trapped proteins Eq.14.

886

3. General Formula for the regime NC_2 , i.e., no metabolites

887 As stated in the main text an important limit regime, NC_2 , is achieved when there are no metabolites in the cell.
888 Specifically, the previous system of equations becomes uncoupled with respect to the nuclear and cytoplasmic set of
889 variables such that we can solve the system analytically. Using the exact same algebra as used in the simple PLM we
890 express the volumes and the NC ratio as:

$$\left\{ \begin{array}{l} V_{tot} = (R_c + R_n) + \frac{N_n^{tot} + N_c^{tot}}{2n_0} \\ N_c^{tot} = P_c \cdot \frac{z_p^2 - 1}{-1 + \sqrt{1 + (1 - \alpha_0) \cdot (z_p^2 - 1)}} \\ N_n^{tot} = P_n \cdot \frac{(z_{n,eff}^2 - 1)}{-1 + \sqrt{1 + (1 - \alpha_0) \cdot (z_{n,eff}^2 - 1)}} \\ z_{n,eff} = z_p + \frac{Q^{eff}}{P_n} \\ NC_2 = NC_1 \cdot \frac{(z_{n,eff}^2 - 1)}{(z_p^2 - 1)} \cdot \frac{-1 + \sqrt{1 + (1 - \alpha_0) \cdot (z_p^2 - 1)}}{-1 + \sqrt{1 + (1 - \alpha_0) \cdot (z_{n,eff}^2 - 1)}} \end{array} \right. \quad (\text{S.74})$$

891

4. Analytical solutions in the regime $z_p = 1$, $z_a = 1$, and $\alpha_0 \sim 0$

892 In this regime of high pumping, no anions occupy the cell. We simplify the notations by denoting by n the
893 concentration of cations. The system of equation to solve is stated in the main text Eq.13. We first express the
894 concentrations of cations and metabolites in the cytoplasm and nucleus as a function of n_0 , q , and p thanks to the
895 electroneutrality equations and balance of osmotic pressures:

$$\left\{ \begin{array}{l} n_n = n_0 + \frac{q}{2} \\ a_n^f = \left(n_0 - \frac{q}{2} \right) - p_n \\ n_c = n_0 \\ a_c^f = n_0 - p_c \end{array} \right. \quad (\text{S.75})$$

896 This allows us to write the NE potential as Eq.14 in the main text. Using the balance of nuclear osmotic pressure we
897 express the nuclear volume function of the number of nuclear osmolytes:

$$V_n - R_n = \frac{Q^{eff} + 2A_n^f + 2P_n}{2n_0} \quad (\text{S.76})$$

898 This implies that the NE potential can be written without the dependence on n_0 as in Eq.14. We then express the NC
899 ratio in two different manners. First, using the interpretation of wet volumes namely, the total number of osmolytes
900 in the compartments over $2n_0$. Second, we take advantage of the concentrations of metabolites and cations in Eq.S.75
901 to express the ratio of protein concentrations. After simple algebra we obtain:

$$\begin{cases} NC = \frac{P_n}{P_c} \cdot \frac{p_c}{p_n} = NC_1 \cdot \left(1 + \frac{Q^{eff}}{2P_n + 2A_n^f + Q^{eff}} + \frac{Q^{eff^2}}{2P_n + 2A_n^f + Q^{eff}} \right) \\ NC = \frac{1}{2} \cdot \frac{2A_n^f + 2P_n + Q^{eff}}{A_{tot}^f - A_n^f + P_c} \end{cases} \quad (\text{S.77})$$

902 For clarity, we now normalize each number by $2P_n$, e.g. $\bar{A}_{tot} = \frac{A_{tot}}{2P_n}$. Equating both expressions of the NC ratio leads
903 to a second order polynomial in \bar{A}_n :

$$2\left(1 + \frac{1}{NC_1}\right) \cdot \bar{A}_n^2 + \left(-2\bar{A}_{tot} + (1 + \bar{Q}^{eff})^2 + \frac{1}{NC_1} \cdot (1 + 2\bar{Q}^{eff})\right) \cdot \bar{A}_n - \bar{A}_{tot} \cdot (1 + \bar{Q}^{eff})^2 = 0 \quad (\text{S.78})$$

904 The solution \bar{A}_n now reads:

$$\bar{A}_n = \frac{2\bar{A}_{tot} - \frac{1}{NC_1} \cdot (1 + 2\bar{Q}^{eff}) - (1 + \bar{Q}^{eff})^2 + \sqrt{\left(2\bar{A}_{tot} - \frac{1}{NC_1} \cdot (1 + 2\bar{Q}^{eff}) - (1 + \bar{Q}^{eff})^2\right)^2 + 8 \cdot (1 + \frac{1}{NC_1}) \cdot \bar{A}_{tot} \cdot (1 + \bar{Q}^{eff})^2}}{4 \cdot (1 + \frac{1}{NC_1})} \quad (\text{S.79})$$

905 Which leads to the following expression for NC:

$$NC = NC_1 \cdot \frac{2\bar{A}_{tot} + \frac{1}{NC_1} + (1 + \bar{Q}^{eff})^2 + \sqrt{\left(2\bar{A}_{tot} - \frac{1}{NC_1} \cdot (1 + 2\bar{Q}^{eff}) - (1 + \bar{Q}^{eff})^2\right)^2 + 8 \cdot (1 + \frac{1}{NC_1}) \cdot \bar{A}_{tot} \cdot (1 + \bar{Q}^{eff})^2}}{2 \cdot (1 + 2\bar{A}_{tot} + \frac{1}{NC_1} + \bar{Q}^{eff})} \quad (\text{S.80})$$

906 As a sanity check, we verify some asymptotic expressions discussed in the main text. For example, when $\bar{Q}^{eff} \ll 1$
907 or $\bar{A}_{tot} \gg 1$ we recover that NC becomes equal to NC_1 . On the other hand, when $\bar{A}_{tot} \ll 1$, we recover that
908 $NC = NC_1 \cdot (1 + \bar{Q}^{eff}) = NC_2$

5. Control parameters of the nested PLM during growth

910 The precise value of the parameter $NC_1 = \frac{P_n}{P_c}$ is biologically set by an ensemble of complex active processes
911 ranging from transcription, translation to the Ran GTPase cycle and nuclear transport. The precise modelling of
912 nucleo-cytoplasmic transport is out of the scope of this paper but could easily be incorporated to our framework.
913 Nonetheless, we can safely assume that nucleo-cytoplasmic transport is fast compared to the typical timescale of
914 growth. In this case, neglecting protein degradation on the timescale of the G1 phase, the total number of proteins in
915 the nucleus is simply the number of proteins assembled that possessed a nuclear import signal (NIS) in their sequence.
916 Using the same notation as earlier, in the exponential growth regime, the total number of proteins in the nucleus
917 reads:

$$P_{tot,n}(t) = \sum_{j \in NIS} \frac{\phi_j}{\phi_r} \cdot P_r(t) \quad (\text{S.81})$$

918 where $P_r(t)$ accounts for the number of ribosomes, ϕ_j is the fraction of genes coding for the protein j (see Appendix
919 **VD**). The subscript j is summed over the genes coding for proteins having nuclear import signals in their sequence.
920 Proteins in the nucleus can either be DNA bound or unbound. For example, histones or DNA polymerases bind to
921 the DNA. Only the unbound proteins contribute to the osmotic pressure. Denoting $k_{u,j}$ and $k_{b,j}$ the reaction rate of
922 binding and unbinding of protein j and assuming that the reactions of binding and unbinding are fast compared to
923 the timescale of growth, we finally express the number of free proteins in the nucleus as :

$$P_{free,n}(t) = \sum_{j \in NIS} \frac{k_{u,j}}{k_{b,j} + k_{u,j}} \cdot \frac{\phi_j}{\phi_r} \cdot P_r(t) \quad (\text{S.82})$$

924 It is then straightforward to express NC_1 as:

$$NC_1 = \frac{\sum_{j \in NIS} \frac{k_{u,j}}{k_{b,j} + k_{u,j}} \cdot \frac{\phi_j}{\phi_r}}{\sum_{j \notin NIS} \frac{k_{u,j}}{k_{b,j} + k_{u,j}} \cdot \frac{\phi_j}{\phi_r}} \quad (\text{S.83})$$

925 An important result of this abstract modelling is that NC_1 is independent of time during the exponential growth
 926 due to the fact that both $P_n(t)$ and $P_c(t)$ are proportional to $P_r(t)$, which is why we adopted it as a control parameter.
 927 The same goes for our second control parameter $\frac{A_{tot}}{2P_n}$, which is also constant during exponential growth.

928 6. Phase Diagram

929 In this paragraph we address the case $\Delta P_n \neq 0$ and assume that the cell does not adhere to the substrate such
 930 that we consider the nucleus to be spherical. For simplicity, we neglect the dry volume because we want to consider
 931 hypo-osmotic shock experiment where dry mass will be diluted, making a dry volume a second order effect of the order
 932 10%. We first make the problem dimensionless. There are two dimensions in our problem: an energy and a length.
 933 This means that we can express all our parameters that possess a dimension with a unit energy and a unit length.
 934 Moreover, we have three parameters with physical dimensions: the extracellular osmolarity n_0 , the NE tension γ ,
 935 and the thermal energy kT . The theorem of Buckingham [61] tells us that we can fully describe our problem with a
 936 single dimensionless parameter and the 3 parameters with by definition no dimensions. In this geometry, we choose,
 937 $[(\frac{4\pi}{3})^{1/3} \cdot \frac{\gamma_0}{kTX_n^{1/3} n_0^{2/3}}, \alpha_0, z_n, X_n]$. Laplace law reads:

$$\Delta P_n = \frac{2\gamma_n}{(\frac{3}{4\pi} V_n)^{1/3}} \quad (\text{S.84})$$

938 Using the following dimensionless quantities:

$$\begin{cases} \bar{V}_n = \frac{2n_0}{X_n} \cdot V_n \\ \bar{\gamma}_n = (\frac{4\pi}{3})^{1/3} \cdot \frac{\gamma_0}{kTX_n^{1/3} n_0^{2/3}} \end{cases} \quad (\text{S.85})$$

939 Equality of pressures becomes:

$$\sqrt{\left(\frac{z_n}{\bar{V}_n}\right)^2} + \alpha_0 + \frac{1}{\bar{V}_n} - 1 - \frac{\bar{\gamma}_n}{\bar{V}_n^{1/3}} = 0 \quad (\text{S.86})$$

940 Eq.S.86 cannot be solved analytically for \bar{V}_n . However, five asymptotic regimes can be identified (see Fig.5):

$$\begin{cases} V_1 = \left(\frac{3}{16\pi}\right)^{\frac{1}{2}} \cdot \left(\frac{kTX_n}{z_n \cdot \gamma_n}\right)^{\frac{3}{2}} \\ V_2 = \left(\frac{3}{2^{10} \cdot \pi}\right)^{\frac{1}{5}} \cdot \left(\frac{kT \cdot z_n^2 \cdot X_n^2}{n_0 \cdot \sqrt{\alpha_0} \cdot \gamma_n}\right)^{\frac{3}{5}} \\ V_3 = \left(\frac{3}{16\pi}\right)^{\frac{1}{2}} \cdot \left(\frac{kT \cdot X_n}{\gamma_n}\right)^{\frac{3}{2}} \\ V_4 = \frac{X_n}{2n_0} \cdot \frac{1}{1 - \sqrt{\alpha_0}} \\ V_5 = \frac{X_n}{2n_0} \cdot \frac{z_n}{\sqrt{1 - \alpha_0}} \end{cases} \quad (\text{S.87})$$

- 941 • V_4 and V_5 are the limit regimes where osmotic pressure is balanced at the NE.
- 942 • V_3 is the limit regime where the difference of osmotic pressure is dominated by the impermeant molecules trapped
 943 inside the nucleus. This happens when the proteins are not or very weakly charged. This difference of osmotic
 944 pressure is balanced by the Laplace pressure of the lamina.
- 945 • V_1 is the limit regime where the difference of osmotic pressure is dominated by the counterions of the impermeant
 946 molecules. This difference of osmotic pressure is balanced by the Laplace pressure of the lamina.

- 947 • V_2 is an intermediate regime that can arise when $\alpha_0 \approx 1$. The difference of osmotic pressure takes the form
 948 of $\Delta\Pi_n \approx kT \cdot \frac{1}{\sqrt{\alpha_0}} \cdot \frac{(z_n \cdot x_n)^2}{4n_0}$. This osmotic pressure defines an effective virial coefficient between monomers of
 949 DNA and proteins $v_{el} = \frac{1}{\sqrt{\alpha_0}} \frac{z_n^2}{2n_0}$. This difference of osmotic pressure is balanced by the Laplace pressure at the
 950 NE.
- 951 • Note that when $\alpha_0 \approx 0$ (strong pumping), only the counterion necessary for electroneutrality remain in the
 952 nucleus. Π_n is simply $(z_n + 1) \cdot x_n$ and is either balanced by the Laplace pressure of the lamina or the external
 953 osmotic pressure (see Fig.5)

954 Finally, the analytical expressions for the crossover lines $\bar{\gamma}_{i,j}$ between regime of volume V_i and volume V_j , plotted
 955 in Fig.5 read :

$$\left\{ \begin{array}{l} \bar{\gamma}_{1,2} = (4 \cdot \alpha_0 \cdot z_n)^{\frac{1}{3}} \\ \bar{\gamma}_{1,4} = z_n \cdot (1 - \sqrt{\alpha_0})^{\frac{2}{3}} \\ \bar{\gamma}_{1,5} = z_n^{\frac{1}{3}} \cdot (1 - \alpha_0)^{\frac{1}{3}} \\ \bar{\gamma}_{2,5} = \frac{z_n^{\frac{1}{3}} \cdot (1 - \alpha_0)^{\frac{5}{6}}}{2 \cdot \sqrt{\alpha_0}} \\ \bar{\gamma}_{2,4} = \frac{z_n^2 \cdot (1 - \sqrt{\alpha_0})^{\frac{5}{3}}}{2 \cdot \sqrt{\alpha_0}} \\ \bar{\gamma}_{2,3} = z_n^{-\frac{4}{3}} \cdot (4 \cdot \alpha_0)^{\frac{1}{3}} \\ \bar{\gamma}_{3,5} = z_n^{-\frac{2}{3}} \cdot (1 - \alpha_0)^{\frac{1}{3}} \\ \bar{\gamma}_{3,4} = (1 - \sqrt{\alpha_0})^{\frac{2}{3}} \\ z_{1,3} = 1 \\ z_{4,5} = \frac{\sqrt{1 - \alpha_0}}{1 - \sqrt{\alpha_0}} \end{array} \right. \quad (S.88)$$

956 7. Saturating volume after a hypo-osmotic shock

957 The saturation occurs when the nuclear osmotic pressure is balanced by the Laplace pressure making nuclear volume
 958 insensitive to the external osmolarity Eq.S.87. We assume that the NE behaves elastically with a stretching modulus
 959 K beyond a surface area S^* for which NE folds are flattened:

$$\gamma_n = \begin{cases} 0 & , \text{if } S_n \leq S^* \\ K \cdot \left(\frac{S_n}{S^*} - 1\right) & , \text{if } S_n \geq S^* \end{cases} \quad (S.89)$$

960 As justified in the main text, metabolites tend to leave the nucleus with decreasing external osmolarity. The
 961 saturating volume is obtained when $\Delta P_n \gg \pi_0$ and $A_n^f \ll P_n$. From Eq.S.30 applied to the volume of the nucleus,
 962 we thus obtain :

$$\Delta P = (z_n^{eff} + 1) \cdot \frac{P_n}{V_n^{max}} \quad (S.90)$$

963 where, $z_n^{eff} = z_p + \frac{Q}{P_n}$. Similarly to the last subsection, we normalize tensions by $(\frac{3}{4\pi})^{1/3} \cdot kT \cdot P_n^{1/3} \cdot n_0^{2/3}$ and
 964 volumes by $\frac{2 \cdot P_n}{2n_0}$. Eq.S.90 leads to the equation ruling the saturating volume :

$$(v_n^{max})^{4/3} - (v_n^{iso})^{2/3} \cdot (1 + s) \cdot \left(\frac{n_0}{n_0^{iso}}\right)^{2/3} \cdot (v_n^{max})^{2/3} - (v_n^{iso})^{2/3} \cdot (1 + s) \cdot \left(\frac{n_0}{n_0^{iso}}\right)^{2/3} \cdot \frac{1}{2} \cdot \frac{(z_n^{eff} + 1)}{\bar{K}} = 0 \quad (S.91)$$

965 where, $s = \frac{S^*}{S_n^{iso}} - 1$ is the fraction of folds that the nucleus possesses at the isotonic osmolarity. $v_n^{max} = \frac{2n_0 \cdot V_n^{max}}{2P_n}$
 966 is the normalized saturating nuclear volume and v_n^{iso} the normalized nuclear volume at the isotonic osmolarity.
 967 $\bar{K} = \frac{K}{(\frac{3}{4\pi})^{1/3} \cdot kT \cdot P_n^{1/3} \cdot n_0^{2/3}}$ is the normalized effective stretching modulus of the NE. Solving the previous equation,
 968 coming back to real volumes $\frac{V_n^{max}}{V_n^{iso}} = \frac{v_n^{max}}{v_n^{iso}} \cdot \frac{n_0^{iso}}{n_0}$ and taylor develop the result for $n_0 \rightarrow 0$ leads to Eq.17 in the main
 969 text.

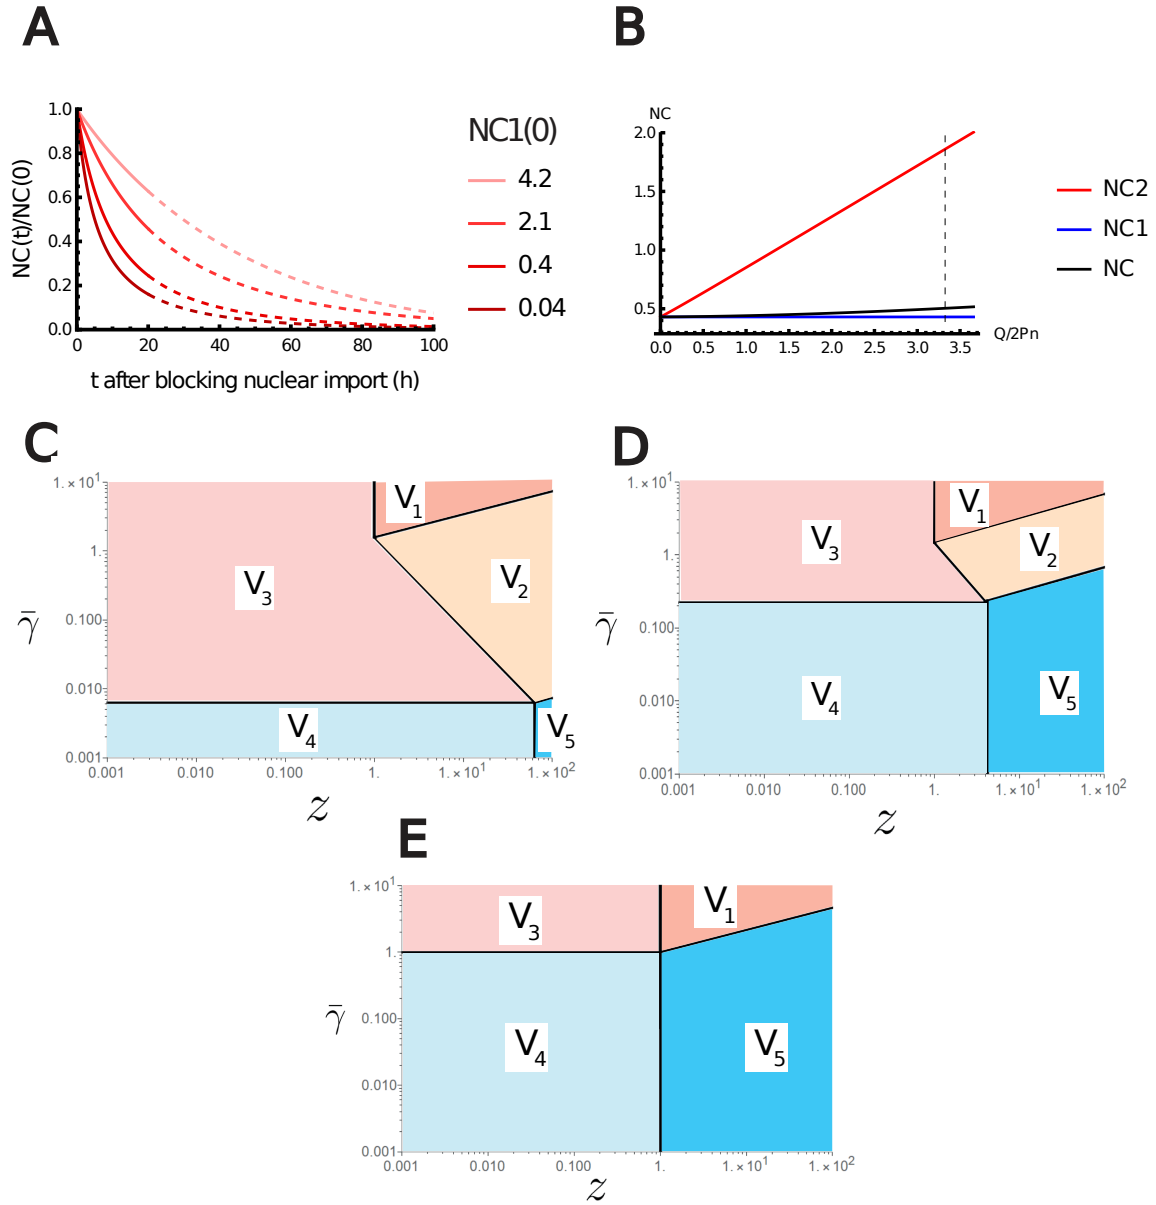

FIG. 5. Additional results of the Nested PLM. (A) Variation of the NC ratio during growth after blocking nuclear import. (B) Variations of the NC ratio according to the effective charge of the chromatin normalized by the number of trapped proteins in the nucleus $\frac{Q}{2P_n}$. The NC ratio is bounded by two limit regimes. NC1, if the number of metabolites is assumed infinite. NC2, if there are no metabolites. The vertical black dashed line depicts the value of $\frac{Q}{2P_n}$ estimated in Appendix VC for diploid mammalian cells (C) to (E) Log-Log plot of the different regimes of V Eq.S.87 in the plan $(z_n, \bar{\gamma}_n)$ for α_0 fixed (C) $\alpha_0 = 0.99$ (D) $\alpha_0 = 0.8$ (E) $\alpha_0 = 0.001$. The crossover lines plotted are given in Eq.S.88

970

8. Geometrical impact

971 The previous equations were conducted for a spherical geometry. Interestingly, while the precise geometry does not
 972 qualitatively change our results, we expect the saturation of nuclear volume to occur more easily for a pancake shape -
 973 a shape closer to the shape of adhered cells. Indeed, the scaling between surface and volume is approximately linear
 974 in this case: $V \sim h \cdot S$, while it is sub-linear for spheres $S \sim V^{2/3}$. Thus, smaller osmotic shocks will be required to
 975 tense the NE and so as to reach the saturating regime.

G. Electrostatic interactions are encompassed within our framework

976

977 We directly compute the contribution of electrostatic interactions to the osmotic pressure based on [57]. The total
 978 interaction energy of a solution of charged particles of average density x within a volume V is, using the Poisson-
 979 Boltzmann framework:

$$\frac{E_{el}}{kT} = \frac{l_B \cdot z^2}{2} \int \int x(\vec{r}) \cdot x(\vec{r}') \cdot \frac{e^{-\kappa|\vec{r}-\vec{r}'|}}{|\vec{r}-\vec{r}'|} d^3\vec{r} \cdot d^3\vec{r}' \quad (\text{S.92})$$

980 where $x(\vec{r})$ is the local density of impermeant molecules in the cell. Fourier analysis allows us to rewrite this equation:

$$\frac{E_{el}}{kT} = \frac{l_B \cdot z^2}{2} \int x(\vec{k}) \cdot x(-\vec{k}) \cdot \frac{4\pi}{k^2 + \kappa^2} d^3\vec{k} \approx \frac{l_B \cdot z^2}{2} \cdot x^2 \cdot \frac{4\pi}{\kappa^2} \cdot V \quad (\text{S.93})$$

981 From which we derive the expression of the osmotic pressure:

$$\frac{\pi_{el}}{kT} \approx \frac{1}{2} \cdot \frac{z^2}{2n_0} \cdot x^2 \quad (\text{S.94})$$

982 We now show that this term is already encompassed within our framework. For the simplicity of the discussion we
 983 neglect pumping, i.e., $\alpha_0 \sim 1$. The difference of osmotic pressure then reads (see Eq.S.26):

$$\frac{\Delta\pi}{kT} = \sqrt{(zx)^2 + 4n_0^2} + x - 2n_0 \quad (\text{S.95})$$

984 which, under the right regime, i.e., $zx \ll 2n_0$, leads to the same term. As mentioned above, this osmotic pressure
 985 defines an effective electrostatic virial coefficient between monomers:

$$v_{el} = \frac{z^2}{2n_0} \quad (\text{S.96})$$

986

H. Possible extension to explain the scaling of other organelles

987 Organelles are also known to display characteristic scaling trends with cell size ([40]). Eventhough these scalings
 988 may be of different origins and would require much careful treatment with respect to the specificity of the organelle,
 989 we highlight in this subsection that our model can easily be extended to also include organelles.

990 We model an organelle in our theory by a compartment bound by a membrane that trap some molecules. For the sake
 991 of generality we assume that there is an active transport of cations through this membrane. As a matter of coherence
 992 with the previous notations we will call by $\alpha_{org} = e^{-\frac{p_{org}}{g^+}}$ the parameter that compares the active pumping through
 993 the organelle's membrane versus the passive leakage. Donnan Equilibrium on both side of the organelle reads :

$$n_{org}^+ \cdot n_{org}^- = \alpha_{org} \cdot (n_c^+ \cdot n_c^-) = \alpha_{org} \cdot \alpha_0 \cdot n_0^2 \quad (\text{S.97})$$

994 Hence, the results derived previously also apply to the organelle provided the parameter α_0 is changed into $\alpha_{org} \cdot \alpha_0$.
 995 Interestingly, in the case of osmotic balance at the membrane of the organelle, it is straightforward to show that the
 996 the volume of the organelle also scales with the cell volume:

$$\left\{ \begin{array}{l} V_{org} = \left(\frac{N_{org}^{tot}}{N^{tot}} \right) \cdot V_{tot} + \left[\left(\frac{N_c^{tot} + N_n^{tot}}{N^{tot}} \right) \cdot R_{org} - \left(\frac{N_{org}^{tot}}{N^{tot}} \right) \cdot (R_c + R_n) \right] \\ N^{tot} = N_c^{tot} + N_n^{tot} + N_{org}^{tot} \\ N_{org}^{tot} = X_{org} \cdot \frac{(z_{org}^2 - 1)}{-1 + \sqrt{1 + (1 - \alpha_0 \cdot \alpha_{org})(z_{org}^2 - 1)}} \end{array} \right. \quad (\text{S.98})$$

A**B**

| Symbol | Typical Value | Meaning |
|---------------|---------------------|---|
| n^+ | 160 mMol | Cation concentration [24] |
| n^- | 20 mMol | Anion concentration [24] |
| n_0 | 150mMol | External cationic / anionic concentrations [24] |
| ΔP | 10-100 Pa | Difference of hydrostatic pressure through the plasma membrane ([58],[59]) |
| $\frac{R}{V}$ | 30% | Volume fraction occupied by the dry mass [26] |
| α_0 | 0.14 | Dimensionless parameter comparing pumping and passive leaking of cations (Eq.3) |
| U_c | -52 mV | Cytoplasmic membrane potential (Eq.S.5) |
| Π_0 | $7.2 \cdot 10^5$ Pa | External osmotic pressure |
| Π | $7.2 \cdot 10^5$ Pa | Cellular Van't Hoff osmotic pressure (Eq.2) |
| x | 120 mMol | Cellular concentrations of species other than ions (Eq.2) |
| $-z$ | -1.2 | Average charge of species other than ions (Eq.1) |
