24 AUTHOR CONTRIBUTIONS

25

26 S.P. and M.S. conceived the study, designed and performed the experiments, analysed the
27 data and wrote the manuscript. M.M., M. P. and S.P collected embryos and performed *in*
28 *situ* hybridizations. KS performed immunostaining and 3D reconstructions. Models and
29 code for cusp patterning were developed and refined by L.G, and models of temporal
30 expression were initiated by P.V. All authors read and commented on the manuscript.

31 ABSTRACT

32 Serial appendages are similar organs found at different places in the body, such as
33 fore/hindlimbs or different teeth. They are bound to develop with the same pleiotropic
34 genes, apart from identity genes. These identity genes have logically been implicated in
35 cases where a single appendage evolved a drastically new shape while the other retained
36 an ancestral shape, by enabling developmental changes *specifically* in one organ. Here, we
37 showed that independent evolution involved developmental changes happening *in both*
38 organs, in two well characterized model systems.

39 Mouse upper molars evolved a new dental plan with two more cusps on the lingual side,
40 while the lower molar kept a much more ancestral morphology, as did the molars of
41 hamster, our control species. We obtained quantitative timelines of cusp formation and
42 corresponding transcriptomic timeseries in the 4 molars. We found that a molecular and
43 morphogenetic identity of lower and upper molars predated the mouse and hamster
44 divergence and likely facilitated the independent evolution of molar's lingual side in the
45 mouse lineage. We found 3 morphogenetic changes which could combine to cause the
46 supplementary cusps in the upper molar and a candidate gene, *Bmper*.

47 Unexpectedly given its milder morphological divergence, we observed extensive changes
48 in mouse lower molar development. Its transcriptomic profiles diverged as much as, and co-
49 evolved extensively with, those of the upper molar. Consistent with the transcriptomic
50 quantifications, two out of the three morphogenetic changes also impacted lower molar
51 development.

52 Moving to limbs, we show the drastic evolution of the bat wing also involved gene
53 expression co-evolution and a combination of specific and pleiotropic changes.

54 Independent morphological innovation in one organ therefore involves concerted
55 developmental evolution of the other organ. This is facilitated by evolutionary flexibility of
56 its development, a phenomenon known as Developmental System Drift.

60

61 AUTHOR SUMMARY

62 Serial organs, such as the different wings of an insect or the different limbs or teeth of a
63 vertebrate, can develop into drastically different shapes due to the position-specific
64 expression of so-called “identity” genes. Often during evolution, one organ evolves a new
65 shape while another retains a conserved shape. It was thought that identity genes were
66 responsible for these cases of independent evolution, by enabling developmental changes
67 specifically in one organ. Here, we showed that developmental changes evolved *in both*
68 organs to enable the independent evolution of the upper molar in mice and the wing in
69 bats. In the organ with the new shape, several developmental changes combine. In the
70 organ with the conserved shape, part of these developmental changes are seen as well.
71 This modifies the development but is not sufficient to drastically change the phenotype, a
72 phenomenon known as “Developmental System Drift”, DSD. Thus, the independent
73 evolution of one organ relies on concerted molecular changes, which will contribute to
74 adaptation in one organ and be no more than DSD in another organ. This concerted
75 evolution could apply more generally to very different body parts and explain previous
76 observations on gene expression evolution.

77

78

79

80

81 INTRODUCTION

82 Serial appendages are repetitions of similar appendages in the body, such as different legs
83 or wings in arthropods, vertebrate fore- and hindlimbs, or different teeth. According to their
84 position and function, they can have very similar or very different shapes. Although a certain
85 degree of individuation is often present deeply in evolution, its magnitude can evolve, with
86 new shapes appearing specifically in one appendage. For example, fore- and hindlimb have
87 had different shapes since early tetrapod evolution (Minelli, 2003; Siomava et al., 2020). In
88 bats, the forelimb evolved into a wing, while the hindlimb conserved a more ancestral
89 morphology (Cooper et al., 2012; Sadier et al., 2021). Similarly, in insects, one of the two
90 pairs of wings was modified to form elytra and haltere in coleoptera and diptera,
91 respectively (Tomoyasu, 2017). How selection could act to drastically change the shape of
92 one serial appendage independently of another is an intriguing question.

93
94 The reason for that is the pleiotropy constraint. During development, serial organs develop
95 with the same pleiotropic genes, except a handful of key transcriptional regulators, whose
96 expression is appendage-specific. These “selector genes” or “identity genes”, including
97 the famous homeotic genes, are necessary to form the right appendage at the right place
98 (Mann & Carroll, 2002; Tomoyasu, 2017; Weatherbee & Carroll, 1999). For example, *Ubx* is
99 necessary to form a haltere instead of a wing by regulating hundreds of pleiotropic target
100 genes specifically in the haltere (Hersh et al., 2007; Pavlopoulos & Akam, 2011)). The
101 enhancers of these target genes are surprisingly pleiotropic as they are shared with the
102 wing (McKay & Lieb, 2013). Intuitively, mutations in identity genes, or in the regulatory
103 regions they target, might be easily selected because they will inherently have appendage-
104 specific effects (Carroll, 2008; Morgalev et al., 2023). In contrast, mutations in other parts of
105 pleiotropic genes might more often be counterselected, because they may have an effect
106 on development of both appendages, which may be advantageous in one appendage but
107 deleterious in the other. Therefore, there is an expectation that identity genes will play a
108 central role in the independent evolution of serial appendages.

109

110 Many examples of independent appendage evolution have been studied, which confirm the
111 role of identity genes, but not only.

112 In the simplest cases, just a subpart of the appendage has changed, such as hairless parts
113 or specialized hair structures (eg. sexcombs) in fly legs. As expected, these new traits were
114 associated with new expression patterns of homeotic genes specific of one leg (eg. *Ubx*;
115 *Scr*) or their targets (eg. *Dsx*) and with the evolution of their cis-regulatory regions (G. K.
116 Davis et al., 2007; Eksi et al., 2018; Stern, 1998; Tanaka et al., 2011) . This nicely explains
117 why these fly leg structures evolved at a specific position (or in one sex), but the
118 developmental and genetic changes through which selection has shaped these structures is
119 still under study (Atallah et al., 2014).

120

121 More complex cases concern the whole appendage, such as halteres and elytra in insects
122 (Tomoyasu, 2017), jump-adapted legs in insects (Mahfooz et al., 2007; Refki et al., 2014)
123 and rodents (Saxena et al., 2022), wings in bats (Cooper et al., 2012; Sadier et al., 2021), or
124 patterns of eyespots in butterflies fore- and hindwings (Matsuoka & Monteiro, 2021, 2022).
125 Here again studies have pointed to a role for homeotic and identity genes in general
126 (Booker et al., 2016; Matsuoka & Monteiro, 2022; Refki et al., 2014; Saxena et al., 2022).
127 Moreover, in species where wings are well differentiated (e.g. wing/haltere of flies, or to a
128 lesser extent, anterior/posterior wings of bees), the overall dose of hox genes appears more
129 different between the two appendages than in species with less differentiated appendages
130 (e.g. anterior/posterior wing of dragonflies), suggesting that the evolution of a differential
131 hox dose is an important determinant of appendage differentiation (Paul et al., 2021). Other
132 developmental genes have been implicated as well, because they evolved a new
133 expression pattern in the modified appendage that is consistent with its phenotype.
134 (Saxena et al., 2022; Z. Wang et al., 2014). More intriguingly, transcription factors which are
135 expressed in both appendages have appendage-specific functions revealed by knock-out
136 experiments or tests in heterologous species (Cretekos et al., 2008; Matsuoka & Monteiro,
137 2022; Ravisankar et al., 2016; Tomoyasu et al., 2009). It is assumed that this appendage-
138 specific function is provided by identity genes, either directly (through unknown differential
139 cis-regulation in the two appendages) or indirectly by providing context-dependency, but

140 this remains generally untested. Together this indicates that the independent evolution of
141 serial organs does cope with pleiotropic genes, but does not fully explain how.

142

143 Here we chose a new model and a different approach to address this question, focusing on
144 developmental dynamics. We studied the independent evolution of a drastically new shape
145 in the mouse upper molar, which is nicely described in the fossil record. Since it occurred
146 relatively recently, we could compare closely related species. Another strong advantage of
147 this model is that the development of mouse molars is very well understood
148 mechanistically, from years of developmental genetics and morphogenesis modeling.
149 Finally, we devised specific ways to quantify and decipher the evolution of development
150 based on the comparison of transcriptome time series.

151

152 Between 18-12 million years ago, the upper molars of mouse and rat ancestors gradually
153 acquired a new cusp row on the lingual side of the molar, and reduced cusps size on the
154 buccal side (Figure 1). This new dental plan and accompanying changes in mastication
155 movements are adaptive and associated with the success of murine rodent radiation (Lazzari
156 et al., 2008; Tiphaine et al., 2013). Changes in the lower molar were limited to the
157 connections between cusps, keeping cusp number and size constant (Figure 1). Because the
158 shape of upper and lower molars were different although less individuated in the basal
159 "cricetine" rodents, from which murine rodents emerged (Figure 1) this is not a case of *de*
160 *novo* individuation. In fact, lower and upper molars already had different morphologies in
161 the first mammals (B. M. Davis, 2011; Hillson, 2005). Hamsters are today's good
162 representative of the basal "cricetine" rodents. In the golden hamster lineage, both molars
163 kept the ancestral cusp number and organization. We can make the reasonable assumption
164 that the hamster presents ancestral developmental features, and in this study we use this
165 species as a phylogenetic control.

171 **Fig 1 | Comparing molar development in different tooth types and species**

172 A. Drawings of the epithelium and mesenchyme compartments at four stages of molar development:
173 at “bud” stage, an epithelial signalling centre called PEK (for Primary Enamel Knot) triggers the
174 formation of a “cap” defining the future crown. Between “cap” and “bell” stage, SEKs (Secondary
175 Enamel Knots) are patterned sequentially in the epithelium, and drive cusp formation. By the end of
176 morphogenesis, the mesenchyme has the shape of the future tooth and the epithelium is a kind of
177 dental impression.

178 B. Dynamic and pattern of PEK/SEK addition in mouse and hamster lower and upper molars. Each
179 panel is a series of developing molars hybridised against Fgf4 to reveal signalling centres (back dots).
180 x axis: developmental age, y axis: morphological stage, with diagrams of signalling centres
181 arrangements and 3D scans for final morphologies. Time series were modelled using Markov
182 processes as a series of stages with specific durations (grey bars). Arrowheads show homology
183 established on morphological criteria at early cap stages and late bell stage.

184 C. Embryo sampling used for expression profiling, in whole tooth germs, tooth tissues
185 (mesenchyme/epithelium) and tooth halves (bucco/lingual). Each embryo provided upper and lower
186 samples. Relative developmental time established from embryonic weight and boundaries for stage
187 homology as in D.

188 D. Principal component (PC) analysis of 64 whole molar bulk transcriptomes based on 14532 1:1
189 orthologues. Each symbol is an individual transcriptome with a colour gradient for relative
190 development time. Dotted lines: Stage homology established by morphology is confirmed and used
191 as boundaries for relative developmental time.

192

193

194 Molars develop from the physical and molecular interaction between an epithelium and a
195 mesenchyme (Jernvall & Thesleff, 2012), Figure 1A). The epithelium grows and folds to form
196 the crown and its cusps under the influence of two types of signalling centres, PEK and SEK
197 (Primary and Secondary Enamel Knots respectively) (Jernvall & Thesleff, 2012). First, the PEK
198 determines the field of the molar crown. As this field grows, the SEKs are patterned
199 sequentially and determine the cusps, starting with a buccal cusp (Cho et al., 2007;
200 Pantalacci et al., 2017). This spatio-temporal sequence depends on activation-inhibition
201 loops involving both epithelium and mesenchyme in a Turing-like mechanism (Salazar-
202 Ciudad, 2012). Tooth morphogenesis models and *in vivo* experiments have shown that

203 changes in the pathways controlling these loops can modify the number of cusps and
204 recapitulate evolutionary changes (Harjunmaa et al., 2012, 2014; Morita et al., 2020;
205 Salazar-Ciudad & Jernvall, 2010). More minimal modeling of Turing-like mechanisms in
206 teeth has shown how the interaction between activation-inhibition loops and growth of the
207 field dynamically determines the output pattern (Morita et al., 2022; Sadier et al., 2019) .
208 Applied to the case of supplementary lingual cusps, this theoretical framework predicts that
209 the new phenotype could be achieved by a change in the activation-inhibition loops (e.g.
210 allowing cusps forming closer from each other), a change in bucco-lingual (B/L) growth
211 (allowing more cusps to be fitted in a bigger field), or a combination of both.

212

213 Almost all what is known was established on the lower first molar of the mouse and few
214 studies have compared lower and upper molar development. The homeotic-code present
215 in the jaws at the early stages of development is still present when molars are initiated
216 (*Dlx1/2* and *Pou3f3* for upper jaw, *Dlx1/2/5/6* and *Nkx2.3* for lower jaw (Cobourne &
217 Sharpe, 2003; Hirschberger et al., 2021; Jeong et al., 2008). We have previously
218 demonstrated that later during morphogenesis, the expression of *Dlx5/6* genes is no longer
219 specific but remains biased (Pantalacci et al., 2017). Only three genes remain specific: in the
220 upper molar, *Pou3f3* and its non-coding regulator and in the lower molar, *Nkx2.3*. On top
221 of that, many genes are consistently biased throughout morphogenesis (Pantalacci et al.,
222 2017). The genetic architecture of lower and upper molars differs in mouse, since a few
223 mouse mutants have molar-specific phenotypes (including *Dlx1/2* and *Pitx1*; reviewed in
224 (Hallikas et al., 2021; Kwon et al., 2017)), and molar specific loci are evidenced in the two
225 available quantitative genetic studies (Navarro & Murat Maga, 2018; Shimizu et al., 2004).

226

227 On top of working with this well characterized system, we took a comparative analysis of
228 RNA-seq timeseries, which proved successful to study development and its evolution. RNA-
229 seq temporal profiles describe the dynamic changes which orchestrate the development of
230 a complex structure, such as the many transcriptional and cell proportions changes
231 (Pantalacci & Sémon, 2015). In our published RNAseq timeseries comparing the
232 development of the mouse lower and upper first molar, we found that differences in their

233 transcriptomes were reflecting differences in their morphogenesis, such as different
234 proportions in the respective tissues of the tooth or different rates of cusp formation in the
235 tooth (Pantalacci et al., 2017). This showed that transcriptome timeseries contain valuable
236 information to compare the morphogenesis of two organs, even though this information is
237 not immediately noticeable. Comparing the transcriptomes of different species provides a
238 useful quantification of developmental similarity - once possible biases in estimating
239 expression levels have been controlled for (Cardoso-Moreira et al., 2019; Pantalacci &
240 Sémon, 2015). This has been successfully applied to answer questions on the periods of
241 maximal conservation of embryogenesis (so-called hourglass pattern, eg (Kalinka et al.,
242 2010; Levin et al., 2016)) or on the homology of organs (Fisher et al., 2020; Tschopp et al.,
243 2014; Z. Wang et al., 2011).

244

245 Here, to understand how lower and upper molars evolved independently from one another,
246 we compared the dynamics of their developmental systems in mouse and hamster with a
247 twofold strategy, analyzing 1) RNA-Seq time series and 2) the dynamics of cusp formation,
248 obtained by tracking a cusp marker in hundreds of molar samples. This revealed an
249 ancestral molecular identity for each molar type, associated with
250 morphogeneticspecificities. Consistent with the very peculiar mouse upper molar
251 morphology, the two mouse molars have more different temporal profiles than the two
252 hamster's. We found three morphogenetic changes which could combine to cause the
253 supplementary cusps in the upper molar, one of them building on the ancestral specificity
254 of upper molars. The biggest surprise came from the lower molar, which was first thought of
255 as an additional control. As many gene expression temporal profiles diverged in the lower
256 molar as in the upper molar, and a great part of them are co-evolving in the two molars.
257 This is associated with changes in B/L polarity and activation-inhibition mechanisms of cusp
258 formation seen in both molars. Based on these results, we propose that several mutations
259 combined to reach the new upper molar dental plan, some with specific developmental
260 effects, and others with effects in both molars. As a consequence, drift in lower molar
261 development went along with adaptation in upper molar development. We generalised our
262 findings by re-analysing transcriptome and literature data on bat foot and wing evolution.

263 We propose that mutations producing shared gene expression changes have a major
264 contribution to appendage-specific adaptation.

265

266 RESULTS

267

268 Mouse and hamster molars develop at different paces. We predicted developmental age
269 from embryonic weight in each species and aligned temporal series between species with
270 homologous start and end points of first molar morphogenesis (Figures 1 and S1). We then
271 devised a twofold strategy to compare the dynamics of cusp formation along with the
272 dynamics of gene expression. First, we established the sequence of PEK and SEKs
273 formation and modelled the relative stage durations with continuous Markov processes
274 (Figure 1B). Second, we obtained RNA-seq data from whole first molar germ at high time
275 resolution (Figure 1C) to model temporal profiles and added samples for dissociated
276 epithelium and mesenchyme as well as buccal and lingual half germs for specific purposes
277 (Figure 1C).

278

279 Conserved transcriptomic and morphogenetic features point to an 280 ancestral identity of lower and upper molars

281

282 Before focusing on the independent evolution of the first upper molar in mouse, we first
283 looked for molecular and developmental features which discriminate between lower and
284 upper molar development in the two species. This would form a molecular and
285 developmental identity of the molars common to both species, and likely present in their
286 common ancestor. It could have served as a basis for the independent evolution of the
287 upper molar in the mouse lineage.

288

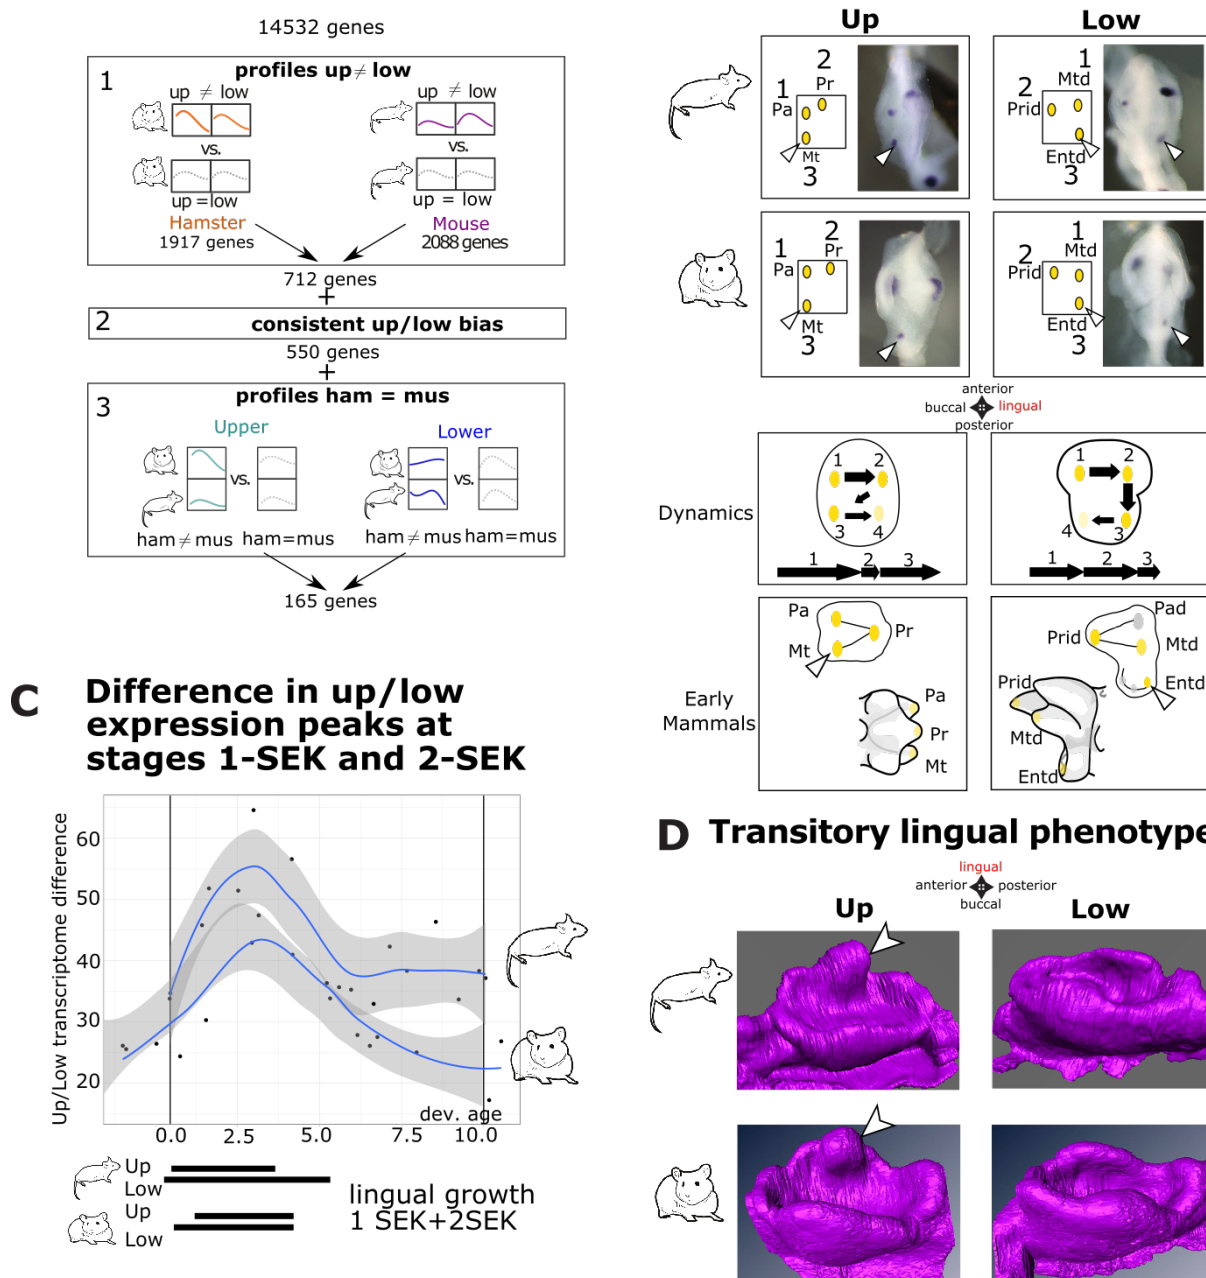

289 Identity genes and many other key genes for tooth morphogenesis showed a conserved
290 expression bias that distinguish lower and upper molars in both species

291 Principal components in a PCA analysis separate samples according to the main axes of
292 variation in the data. In our dataset, the main effect was the species, followed by
293 development time (Figure 1C). Upper and lower molar samples were only separated from
294 each other on the sixth component, which carried 3% of the total variance. Hence only a
295 minor part of the variation distinguishes upper and lower samples while being common to
296 both species.

297
298 To detect genes carrying this conserved variation between upper and lower molars, we
299 modelled their temporal profiles with polynomials (Figure 2A). In each species, we fitted
300 two models: one with two distinct curves, one per tooth, and another with a single curve,
301 common for both teeth. By comparing the fit of these two models, we detected
302 differentially expressed genes between the two teeth (Table S2). In each species, we found
303 a similar proportion of differentially expressed genes (about 13%). There are 712 genes in
304 common between the two species (only a third of the genes in each species), including 550
305 genes with a consistent upper/lower bias.

306

A Set of genes with consistent upper/lower bias in both species **B** Bucco-lingual difference in third cusp patterning

307

308

309 **Fig 2 | Conserved differences of upper and lower molar development.**

310 **A. Pipeline to search for genes that distinguish lower and upper molars in the two species. 1/**

311 Expression profiles were modelled separately in hamster (left) and mouse (right) to detect genes with

312 distinct profiles in upper and lower molars in each species. Colored curves are models allowing for

313 distinct profiles in upper and lower molars. Grey curves allow a single profile, common for both

314 teeth. The resulting number of differentially expressed genes is shown. 2/ Filtering for a consistent

315 upper/lower bias in both species. 3/ Filtering for conserved expression profiles in both species by
316 modelling separately upper (left) and lower (molars). Colored curves: with distinct profiles in mouse
317 and hamster. grey curve: single profile.

318 B. Bucco-lingual difference in cusp patterning. The 3-SEK pattern involves a lingual cusp (Entd) in the
319 lower molar and a buccal cusp (Mt) in the upper molar (arrowheads). Images show the epithelium at
320 the 3-SEK stage, hybridized with a *Fgf4* probe. The dynamics of cusp formation is also specific to
321 upper and lower molars. Both are reminiscent of the bucco-lingual pattern in early mammals'
322 tribosphenic molars (drawn from top and side views). Protoconid-Prid, Metaconid-Mtd, Entoconid -
323 Entd, Paraconid-Pad (no homologous cusp in rodent's molars), Paracone-Pa, Protocone-Pr,
324 Metacone-Mt.

325 C. The development of upper and lower molars differ mostly at early/mid-morphogenesis. The axis
326 produced by BCA (Between Component multivariate Analysis) captures a variation between upper
327 and lower molar that is common to both species. Each dot represents the variation measured for one
328 individual. Peaks correspond to stages 1-SEK and 2-SEKs in the 4 molars (black bars taken from stage
329 duration in Figure 1).

330 D. Transitory phenotype in upper molars. At the end of the cap stage, upper molars of both species
331 show an epithelial bulge (arrowhead) never seen in the lower molar.

332

333 The set of 550 genes with significant and consistent upper/lower bias in both species is
334 highly relevant: it contains the expected jaw-identity genes known for mouse (*Nkx2.3*,
335 *Pou3f3*, *Dlx1*, but also *Dlx5* and *6* which are no longer lower-jaw specific at this stage, but
336 show a lower molar bias as already described in mouse (Pantalacci et al., 2017)), a fifth of
337 the genes whose mutant shows a phenotype in the lower molar (21 out of 87 "keystone
338 genes" from (Hallikas et al., 2021)) and key transcriptional regulators of molar
339 morphogenesis (*Barx1*, *Msx1*, *Pitx1* Figure S2). Overall, these genes are strongly enriched
340 for transcriptional regulators. They are involved in epithelial and mesenchymal
341 development, cell adhesion, proliferation and differentiation and signalling, especially
342 WNT, BMP and NOTCH (enrichment for Gene Ontology terms, Figure S3). Among the 550
343 genes with a consistent upper/lower bias, only 165 display evolutionary conserved temporal
344 dynamics in both teeth (stars Figure S2, Table S2).

345

346

347 The earliest phase of cusp patterning gathers many features that distinguish lower and
348 upper molars in both species

349

350 We next looked for criteria that would distinguish cusp patterning dynamics in lower and
351 upper molar in both species, and may have been conserved from the common ancestor of
352 mouse and hamster.

353

354 First, we noticed that in both species, SEK formation is initiated (transition to 1-SEK stage
355 and 2-SEK stage) and completed (transition to 6-SEK stage) later in the upper molar as
356 compared to the lower molar of the same embryo. This delay was also obvious in the
357 transcriptome: the upper molar transcriptome looks “younger” than the lower molar
358 transcriptome of the same embryo (Figure S4).

359

360 Second, we examined the details of the sequence of cusp acquisition. The first and second
361 SEK are homologous in all teeth, the first SEK being buccal, and the second being its
362 lingual neighbor. This bucco-lingual sequence is thus similar in lower and upper molars in
363 both species, as previously shown in mouse (Cho et al., 2007; Pantalacci et al., 2017). The 3-
364 SEK stage however distinguishes lower and upper molars in both species, with a buccal
365 third SEK in upper molars, and a lingual third third SEK in lower molars (Figures 1B, 2B). It
366 is striking that the three cups patterned at this 3-SEK stage recapitulate the bucco-lingual
367 arrangement of their homologous cusps in the molars of early mammalian ancestors
368 (Figures 2B, S5). These so-called “tribosphenic molars” were markedly asymmetric along
369 the B/L axis (B. M. Davis, 2011; Hillson, 2005). On top of this geometric pattern, we found
370 two other conserved distinctive features: the dynamics of the three first SEK stages (Figure
371 2B and figure S5), and a peculiar lingual epithelial bulge specific to the upper molar (Figure
372 2D). Both occur at this same early period of development. In fact this is the period where
373 lower and upper molar transcriptomes differ most from one another, as seen on a
374 multivariate analysis (BCA) performed on all samples to capture a lower/upper molar
375 variation common to both species (Figure 2C).

376

377 Together, we found a clear conserved transcriptomic identity of each molar in the form of a
378 conserved expression bias for identity genes and many key regulators of tooth
379 development, and a conserved transcriptomic signature. A clear conserved morphogenetic
380 identity was obvious in the earliest phase of cusp formation, with different dynamics of cusp
381 formation along the bucco-lingual axis, that recapitulated the bucco-lingual specificities of
382 early mammals' molars. We next asked how the mouse upper molar evolved its new
383 morphology.

384

385 Increased upper-lower molar dissimilarity of mouse transcriptomes

386

387 Some transcription factors which made the ancestral identity showed increased levels and/or
388 biases in mouse molars

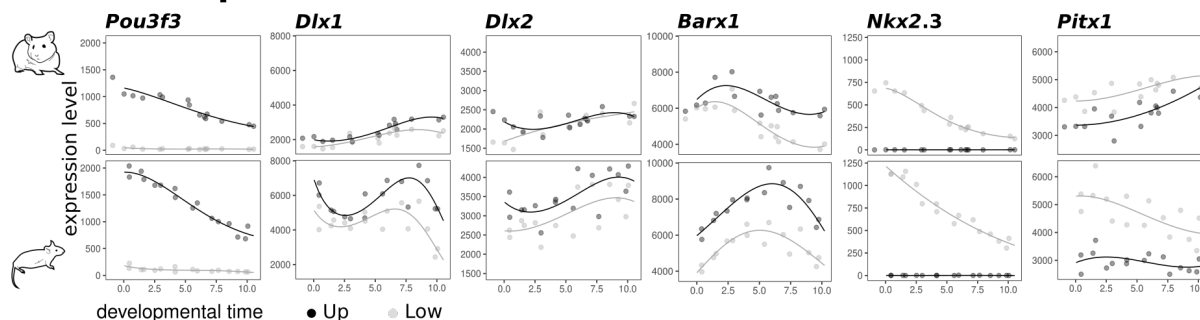

389

390 Because the dose of identity transcription factors was shown to correlate with the degree of
391 appendage differentiation, we first first asked whether the dose of transcription factors
392 forming the conserved transcriptomic identity has changed in mouse (Figure 3A). We
393 expected to observe an increased bias in mouse, especially in the upper molar.

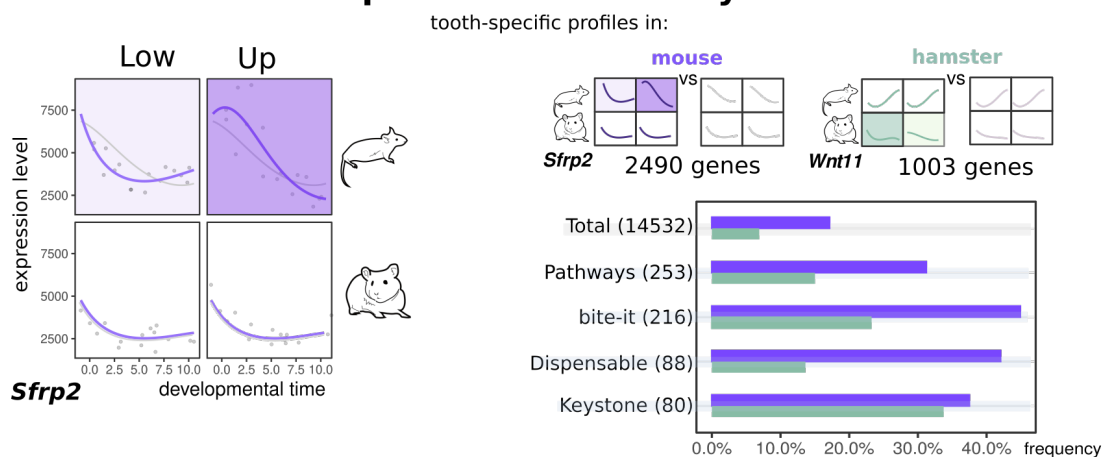

394

395

A. Transcription factors with increased bias in mouse

B. Increased transcriptomic dissimilarity in mouse

396

397 Fig 3 | Increased upper-lower molar dissimilarity of mouse transcriptomes.

398 A. Temporal profiles for 6 key transcription factors, distinct curves were fit for upper (black) and lower
 399 (grey) molars.

400 B Left: Model to detect genes which differ in their upper-lower expression profiles in one species.

401 Example of *Sfrp2* gene expression levels (grey dots), significantly better modelled by two curves in

402 mouse and one in hamster (purple curves), compared with one curve per species (grey curves). Right:

403 Number of genes detected by this tooth-specific model in mouse (purple) and in hamster (green, LRT

404 with adjusted $p < 0.05$). Barplots show their frequencies for the "total" gene set, genes from

405 developmental "pathways", genes from "bite-it" database, and genes with a mild or strong

406 phenotype in tooth mutants ("Dispensable" or "Keystone"). Size of each gene set into brackets.

407 *Pou3f3* is the only TF specific of the upper molar in both species. Its expression showed a
408 twofold increase in mouse upper molar. *Dlx1/2* genes are expressed in both molars, but are
409 essential only for upper molar formation in mouse (Qiu et al., 1997). Their expression levels
410 were more than twice increased in mouse molars and the ratio, slightly in favor of the upper
411 molar in hamster, is increased in mouse. *Barx1* is a key molar-specific TF whose levels have
412 been correlated with cusp number in mammalian molars (Miletich et al., 2011). The bias in
413 favor of the upper molar was markedly increased in mouse. This effect is selective since
414 *Msx1*, another TF which cooperates with *Barx1* (Miletich et al., 2011), showed similar bias in
415 the two species (Figure S2).

416

417 Surprisingly, such changes were not restricted to the upper molar. The expression of
418 *Nkx2.3*, the specific TF of the lower molar, showed an almost twofold increase in mouse.
419 For *Pitx1*, a shared TF whose mutation impairs more specifically lower molar development
420 (Mitsiadis & Drouin, 2008), the ancestral bias in favor of the lower molar was increased. *Dlx1*
421 expression levels were also twice increased in the lower molar. This is not true for the *Dlx5-*
422 *6* genes, which were more specifically associated with lower jaw identity (Depew et al.,
423 2005), but are expressed at this stage in the two molars (Pantalacci et al., 2017) (Figure S2).
424 Thus, the molecular identity of each molar was reinforced in mouse, partly in line with an
425 ancestral bias.

426

427 The dissimilarity of upper/lower molar transcriptomes is increased in mouse

428 Next, we asked whether the transcriptomes would capture a general increase of
429 differentiation of molar development in mouse as compared to hamster.

430 As exemplified above, a number of genes have a marginally or small significant bias in
431 hamster, which is increased in mouse. This is in agreement with the multivariate analysis
432 presented in Figure 2C. Along an axis that captures a lower/upper molar variation common
433 to both species, the variation is higher for mouse than for hamster. Thus, an ancestral
434 dissimilarity is exaggerated in mouse.

435

436 We detected genes whose expression profiles differ between upper and lower molars in
437 mouse but not in hamster, by a dedicated model based on the 4 molars altogether (Figure
438 3B). As a control, we built a reciprocal model to detect genes with tooth specific profiles in
439 the hamster. We found 2.5 times more genes with tooth-specific profiles in mouse as
440 compared to hamster. Even after removing the effect of baseline expression levels, which
441 may be impacted by differences in cell composition (Pantalacci et al., 2017), we still
442 observed 1.6 times more tooth-specific profiles in mouse. The function of the genes with
443 tooth specific profiles differs markedly between mouse and hamster (Figure S6). In mouse,
444 genes are linked to cell adhesion and migration, as well as cell cycle and mitosis. This is
445 consistent with our previous findings suggesting that morphogenetic movements are
446 enhanced in mouse upper molar during the period of lingual growth (Pantalacci et al.,
447 2017).
448 Thus, we quantify an increased dissimilarity of temporal profiles in mouse, consistent with
449 the increased morphological dissimilarity of the adult teeth. This involved the reinforcement
450 of an ancestral molecular identity as well as newly evolved gene expression differences.

451

452

453 Morphogenetic changes associated with mouse upper molar evolution

454

455 Next, we used the transcriptome as a starting point to investigate several possible
456 developmental mechanisms how the mouse upper molar forms additional lingual cusps. We
457 logically focused on specificities of mouse upper molar development as compared to any
458 other teeth.

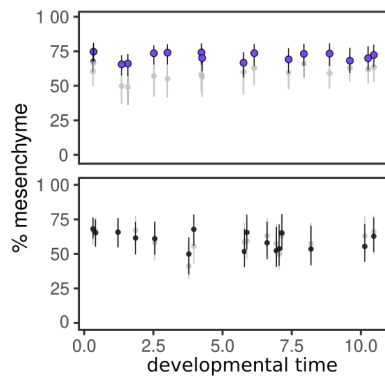

459

460 The proportion of mesenchyme is increased in the mouse upper molar

461 We previously showed that the upper molar germ of the mouse contains more
462 mesenchyme relative to the epithelium than the lower germ since early cap stage. Tooth
463 engineering studies suggest that this higher proportion may help to form the
464 supplementary cusps. Indeed, in artificial teeth made by reassociating a varying amount of

465 mesenchymal cells to a single epithelium, the number of cusps formed increases with the
466 number of mesenchymal cells (Hu et al., 2006). To control whether this higher
467 mesenchyme:epithelium ratio is specific to the mouse, we extracted mesenchyme and
468 epithelium-specific marker genes from tissue-specific transcriptomes (Figure 1C), and used
469 *in silico* deconvolution to estimate the mesenchyme proportions from whole tooth germ
470 transcriptomes (Figure 4A). The proportion of mesenchyme was indeed significantly higher
471 in the upper molar in mouse, but not in hamster (Wilcoxon tests, $p < 2e-16$ and $p = 0.152$).
472 As shown in a previous publication (Pantalacci et al., 2017), and suggested above, this
473 change in tissue proportion should inflate the transcriptomic differences between mouse
474 and hamster.

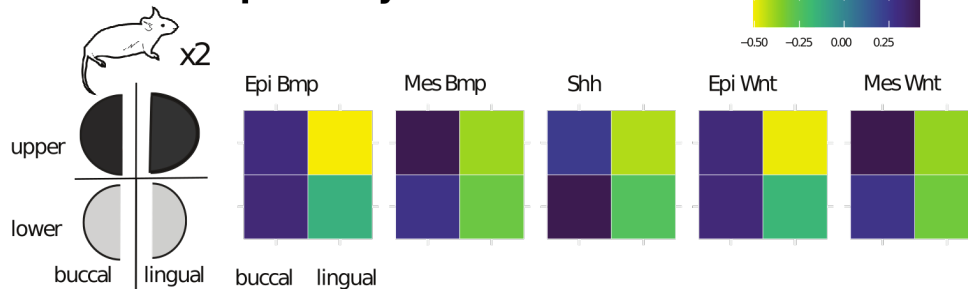

A. %mesenchyme

D. %lingual tissue

475

476 Fig 4 | Morphogenetic changes specific to the mouse upper molar.

477 A. Percentage of mesenchymal tissue in tooth germs estimated by deconvolution of the RNAseq
 478 time series with tissue-specific marker genes. Time scale in relative 0-10 scale (x axis) for each
 479 species. Color code indicated for each molar.

480 B. Relative duration of the first morphological stages highlights a longer period of lingual growth in
 481 mouse upper molar (1-SEK, purple). Stage durations from Figure 1B. PEK and SEK: primary and
 482 secondary enamel knots respectively.

483 C. Levels of activation of BMP, SHH and WNT pathways in buccal and lingual sides of the mouse
 484 molars at 15.0 dpc (1 SEK stage). Measurements made with an *in silico* method, ROMA, which

485 compares pathway activity in transcriptomic samples based on a list of targets for the pathway. Two

486 separate lists of target genes to estimate both an epithelial (epi) and a mesenchymal (mes) pathway
487 activity in the 15.0 buccal and lingual RNAseq samples. Drawing on the left represents the dataset
488 design.

489 D. Proportion of lingual tissue in mouse and hamster molars estimated by deconvolution of the
490 RNAseq time series with lingual and buccal marker genes.

491

492 A bucco-lingual polarity is maintained in mouse molars during the first steps of cusp
493 formation, and further enhanced in the upper molar

494 The supplementary cusps of the upper molar form last, on the lingual side of the tooth
495 (Figure 1B), but the dynamics of SEK formation differs much earlier between mouse and
496 hamster upper molars. Indeed, the 1-SEK stage is longer in the mouse upper molar than in
497 any other tooth (likelihood ratio test, $p < 1e-16$, Figure 4B). At that stage, the tooth germ
498 grows rapidly on the lingual side. This finding prompted us to look into changes of the
499 bucco-lingual development in the mouse upper molar.

500

501 We do not know the molecular mechanisms whereby the first cusp forms on the buccal side
502 and a second one forms on its lingual side. However, we know the mechanisms which
503 decide if a first tooth is formed, and whether a second tooth can form lingually (Jia et al.,
504 2013, 2016; Lan et al., 2014; Zhang et al., 2009). To form a tooth, the WNT pathway must
505 be activated on the buccal side of the mouse jaw, while on the lingual side, WNT pathway
506 activation is prevented by OSR2, notably through the WNT inhibitor SFRP2 (Jia et al., 2016).
507 This bucco-lingual polarity of the jaw is set up by a mutual antagonism between BMP4
508 activity on the buccal side and OSR2 activity on the lingual side. In mice, displacing this
509 BMP4/OSR2 balance can suppress tooth formation (following loss of BMP4) or induce the
510 formation of a supplementary tooth on the lingual side (following the loss of OSR2 or of the
511 Wnt inhibitors) (Jia et al., 2013, 2016; Lan et al., 2014; Zhang et al., 2009)). Since the
512 mechanisms for tooth (PEK) formation are largely re-used for cusps (SEK) (Jernvall &
513 Thesleff, 2012), it would be unsurprising that this BMP4/OSR2 balance also controls the B/L
514 polarity of cusp formation.

515

516 To look for evidence of persistent molecular B/L polarity during cusp morphogenesis, we
517 collected and analyzed mouse transcriptomes of buccal and lingual halves at the early 1-
518 SEK stage (Figure 1C). We found that *Osr2* and *Sfrp2* are still expressed with a strong
519 lingual bias at 1-SEK stage, and in the timeseries, their expression is maintained at high
520 levels during the period of bucco-lingual development of the tooth germ (Figure S7). To
521 determine if the tooth germ is polarized at the 1-SEK stage, we estimated the levels of
522 activation of 3 pathways controlling cusp formation (BMP, WNT and SHH), in the buccal and
523 lingual halves separately. We used ROMA, a method that exploits the level of expression of
524 up and down-regulated transcriptional targets to quantify signaling pathway activity directly
525 from the transcriptomes (Martignetti et al., 2016). The list of WNT and BMP target genes
526 was specifically established in tooth epithelium and mesenchyme by others (O'Connell et al.
527 2012). WNT, BMP4 and SHH pathways are strongly activated on the buccal halves of both
528 molars, but very weakly on the lingual halves, which therefore still appears as a naive tissue
529 (Figure 4C). In the upper molar, the lingual half looked even more naive than in the lower
530 molar, with even lower levels of pathway activities, consistent with twice higher levels of
531 *Sfrp2* expression, and delayed downregulation (Figures 4C, S2, S3). In the buccal half,
532 activation of the BMP4 and WNT pathways in the mesenchyme is stronger in the upper
533 molar, which thus appears as more polarized than the lower molar. These findings support
534 the idea that the BMP4/OSR2 antagonism is still acting during early mouse molar
535 morphogenesis to set up the B/L polarity of the tooth. This polarity maintains naive tissue
536 on the lingual side of the germ at 15.0, which grows faster and shows delayed cusp
537 formation relative to the buccal side.

538

539 We reasoned that the larger the proportion of this naive lingual tissue, the stronger the
540 germ growth potential and its capacity to form cusps on its lingual side. We therefore
541 quantified this proportion in mouse and hamster tooth germs, by deconvoluting the
542 timeseries dataset with buccal and lingual tissue transcriptomes (Gong & Szustakowski,
543 2013). As expected due to progressive cusp formation, we found that the proportion of
544 naive lingual tissue decreases during morphogenesis in both species (Figure 4D). But in
545 mouse molars, and even more markedly in the mouse upper molar, the initial proportion of

546 naive tissue is larger, and diminishes more slowly. We noted that the naive tissue proportion
547 correlates with levels and temporal pattern of *Sfrp2* expression in mouse and hamster
548 molars (Figure S7).

549

550 In summary, a B/L polarity of the tooth germ is maintained during the first steps of cusp
551 formation. This is especially true in mouse molars whose proportion of lingual naive tissue is
552 increased, and correlates with higher levels of *Sfrp2* expression. This polarization is further
553 exaggerated in the mouse upper molar.

554

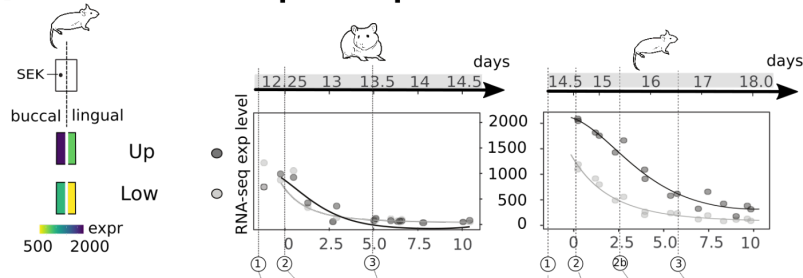

555 A change in the BMP pathway may underlie the maintenance of the B/L polarity in the
556 mouse molars

557 The findings above suggest a change in the BMP4/OSR2 balance in mouse molars, with an
558 exaggeration in the mouse upper molar. We came back to the list of genes with mouse
559 upper specific profiles (Figure 3B) and compared it with the list of genes with a marked
560 bucco-lingual bias. The *Bmper* gene is a good candidate since it is a regulator of the BMP4
561 pathway in many tissues, and it ranked well in both lists (respectively 211/14532 and
562 9/12008). In mouse early 1-SEK stage molars, *Bmper* is more expressed on the buccal side
563 in both molars and more expressed in the upper molars on both buccal and lingual sides. In
564 the time series, *Bmper* expression levels are higher in mouse than in hamster. It decreases
565 with time in all teeth, but this decrease is slower in the mouse upper molar (Figure 5A). This
566 is similar to the levels and dynamics observed for the proportion of naive lingual tissue, or
567 the expression of *Sfrp2* gene (Figures 2C, S2). This pattern suggested us that *Bmper*
568 participates in the regulation of the B/L polarity.

571

572

573 **Fig 5 | Expression and null mutant phenotype of the *Bmper* gene.**

574 A. *Bmper* transcriptomic profile. left: Colors represent expression levels in buccal and lingual parts of
 575 the mouse tooth germs (15 days). right: *Bmper* expression decreases with time and reaches a
 576 minimum when the tooth germ stops expanding on the lingual side (bell stage, n°3). Expression is
 577 higher and lasts longer in the mouse upper molar. Ages in days above the plots, in relative time on
 578 the x axis.

579 B. Drawings of tooth germ sections at bud, cap and bell stage summarise *Bmper* expression
 580 established by *in situ* hybridization (Figure S6). Stage correspondence with dashed lines and
 581 numbers.

582 C. Foetal molar morphology of wild type (Wt) and *Bmper* null mutant (KO). Semi-automatic
 583 reconstruction of tooth mesenchyme was performed on micro-CT scans of PTA-stained heads taken
 584 at 19.5 days. Arrows point to the enlarged lingual cusp in both mutant molars. Arrowheads point to
 585 the third-forming buccal cusp, missing in the mutant upper molar.

586

587 *In situ* hybridizations showed that in mouse molars, *Bmper* rapidly withdraws from the
 588 lingual side to remain strongly expressed in a small buccal domain only. This process is
 589 delayed in the upper molar. In the hamster, the withdrawal is symmetrical and similar in
 590 both teeth (Figures 5B, S6). Thus *Bmper* expression changed at two levels. First, it acquired
 591 a new bucco-lingual regulation leading to a strong buccal expression and an early
 592 withdrawal from the lingual side. This co-evolved in both teeth. Second, it acquired a new
 593 lower-upper molar difference, with delayed withdrawal in the upper molar.

594

595 To gain insight into the function of *Bmper*, we obtained a mouse null mutant and studied
596 the shape of its molars. Since the homozygous *Bmper* mutant are lethal at birth, this had to
597 be done by reconstructing the enamel-dentin junction at 19.5 days, carefully matching them
598 with controls of similar developmental age (see material and methods). The upper molar is
599 modified: one of the buccal cusp is absent or poorly grown (Figure 5C, arrowheads) and
600 one lingual supplementary cusp is more prominent (arrows). The lower molar is also
601 modified: the central lingual cusp, which is determined by formation of the 2-SEK following
602 lingual growth, is more prominent. Thus, the loss of *Bmper* modifies the bucco-lingual
603 equilibrium, favoring the lingual side of the molar at the expense of the buccal side. Since
604 *Bmper* modulates the BMP4 pathway, this mutant phenotype reinforces the idea that the
605 BMP4 pathway regulates B/L polarity during cusp formation, and that *Bmper* might have a
606 causative role in displacing the BMP4/OSR2 balance in mouse.

607

608 In summary, we show that the BMP4/OSR2 antagonism persists in mouse to regulate the
609 B/L polarity of the tooth during morphogenesis. As compared to hamster upper molar, the
610 mouse upper molar has an asymmetrical expression of *Bmper* (buccal side) and an
611 increased expression of *Sfrp2* (lingual side). This is associated with an increased and
612 persistent proportion of naïve lingual tissue. These differences seem very consistent with
613 the newly evolved lingual cusps of this tooth. We were very intrigued however that
614 qualitatively, these morphogenetic changes are also seen in the lower molar, although to a
615 lesser extent and without change in number and respective size of buccal/lingual cusps. We
616 next wanted to quantify this concerted developmental evolution of the lower molar with the
617 upper molar.

618

619

620

621

622

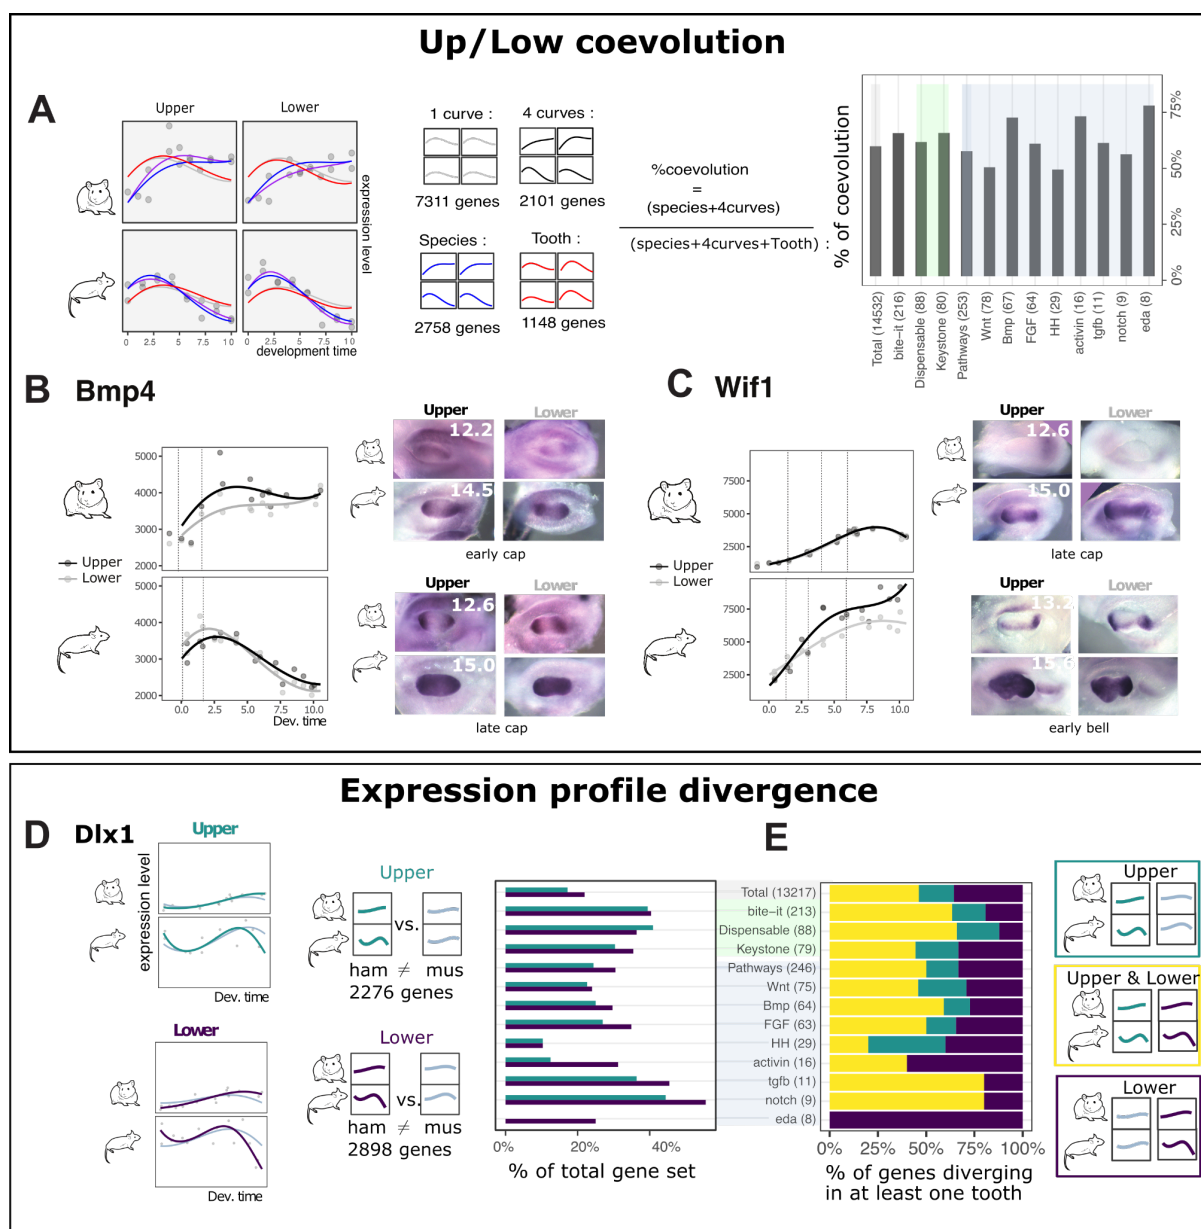

623 Concerted evolution of lower molar development with upper molar
624 development

625

626 Developmental gene expression in the lower molar largely evolve in a concerted manner
627 with the upper molar

628

629 We modelled the temporal profiles of the 4 molars altogether to quantify their concerted
630 evolution. We fitted four models (Figure 6A): The most complex model has four curves (one
631 distinct per tooth), intermediate models have two curves (distinguishing species:
632 hamster/mouse or distinguishing tooth: upper/lower), and the most simple model has a
633 single curve common to all teeth (1 curve). Models for different species account for different
634 baseline expression levels, to make sure that we focus on species differences in temporal
635 dynamics. We attributed the best model to each gene and from this we built an index of
636 coevolution. We estimated that the expression profiles of 61% genes have coevolved. This
637 is consistent with a cruder estimate from the PCA analysis, where the main axis of variation
638 in the transcriptomes separates samples by species, but groups upper and lower molars
639 (Figure 1D).

640

641 **Fig 6 | Divergence and coevolution of expression profiles.**

642 A. Nested models of temporal profiles taking the four teeth altogether. The percentage of
 643 coevolution is computed as the proportion of “divergent” genes, among genes varying between
 644 species and/or teeth.

645 B-C. *Bmp4* and *Wif1*'s expression profiles corroborated by *in situ* hybridization of dental
 646 mesenchyme show that expression in upper and lower molar has coevolved. Dashed lines and
 647 numbers map pictures to the timeseries. See Figure S9 for details.

648 D. Temporal profiles modelled by tooth type. *Dlx1* is shown with samples (grey dots), and models
 649 (curves). Top: the “upper divergent” model, allowing different profiles in mouse and hamster (green),
 650 is compared with the “upper non-divergent” fitting the same profile but different baseline

651 expression levels (grey). Bottom: Same modellings fitted independently for lower molars (purple and
652 grey). Best model was chosen for each molar by likelihood ratio test (adjusted $p < 0.05$). Barplots:
653 percentage of divergent profiles in upper and in lower molars for different gene categories taken
654 from (O'Connell et al. 2012) and (Hallikas et al., 2021). A-C, Gene categories as in Figure 2A with
655 numbers into brackets, genes from developmental "pathways" further splitted.
656 B. Percentage of "divergent" genes in upper and in lower molars (yellow), only in upper (green) or
657 only in lower (purple).

658

659 The profiles of many genes important for tooth development have coevolved, suggesting
660 that developmental processes have largely evolved in a concerted manner in the two teeth,
661 as seen earlier for the B/L axis. We decided to examine by *in situ* hybridization some of
662 those genes whose profile co-evolved in the transcriptomes. We wished to determine what
663 spatio-temporal profiles are behind this transcriptomic co-evolution, and which other
664 developmental processes besides B/L polarity may have co-evolved between the two teeth.

665

666

667 The early dynamics of cusp formation show concerted evolution, with anticipated cusp
668 formation in mouse.

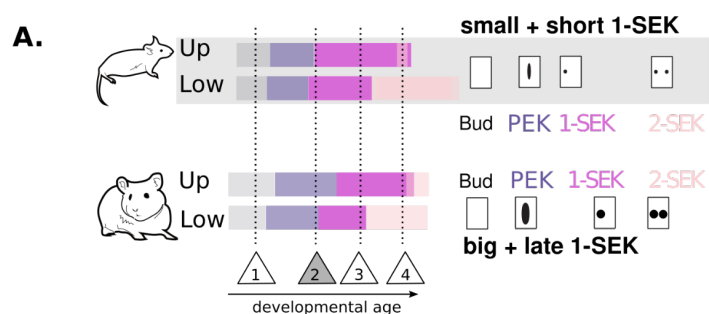

669 We first examined *Bmp4*, since finding this essential gene for tooth development among
670 co-evolving genes was a surprise (Figure 6B). *Bmp4* is expressed in both the epithelium and
671 the mesenchyme, but the epithelial domain is so small relative to the mesenchymal domain
672 (see later Figure 7 and S9), that the latter will dictate the bulk transcriptomic profile. We
673 therefore first looked at the *Bmp4* expression in the mesenchyme. *Bmp4* reached a spatially
674 homogeneous expression earlier in the mouse mesenchyme (Figure 6B), consistent with an
675 earlier peak of expression in mouse transcriptomes.

676 We picked up two other mesenchymally expressed genes for *in situ* hybridization, *Wif1* and
677 *Dkk1*, because 1) these genes are likely involved in the gene regulatory network of tooth
678 formation: they are known modulators of the Wnt pathway which is critical for cusp
679 formation, and their expression is changed when the *Bmp4* and/or Wnt pathways are

680 manipulated (data by O'Connell et al.) and 2) their temporal profiles markedly differ from
681 each other, as well as from *Bmp4*.

682 *Wif1* rises earlier in mouse transcriptomes, and its mesenchymal expression is seen both
683 earlier and in a larger territory in mouse tooth germs (Figures 6C, S9). *Dkk1* expression
684 transiently decreases in mouse transcriptomes, which coincides with an earlier relocation
685 of its expression at future cusp tips beneath the SEK (Figure S9). This expression pattern
686 suggested to us that cusp formation might in fact be anticipated in mouse as compared to
687 hamster.

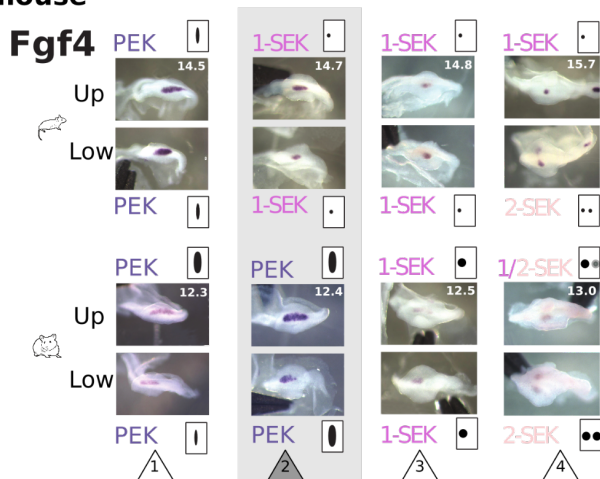

688 We thus turned back to our quantification of cusp formation dynamics, and realized that
689 both mouse molars quickly transition to 1-SEK after a rather short PEK stage (Figures 1, 7A).
690 By comparing epitheliums of the two species matched for growth advancement, we found
691 that both mouse molars already exhibit the rounded and focalized *Fgf4* expression typical
692 of a SEK when hamster's still exhibit the large and elongated *Fgf4* expression typical of the
693 PEK (Figure 7B stage 2). Thus, mouse PEK is rapidly turned into a precocious and focalized
694 1-SEK, marking an early beginning of cusp patterning in a very young cap stage, and this
695 happens very similarly for both mouse molars. The dynamics of activation-inhibition
696 mechanisms relative to the advancement of epithelial growth thus evolved in a concerted
697 manner in the two teeth. We have shown previously how the transcriptome carries
698 signatures of ongoing developmental processes, including cusp formation (Pantalacci et al.,
699 2017). We suspect that well beyond the few genes studied above, the transcriptome could
700 be deeply shaped by this anticipated formation of cusps in the young mouse molars, and
701 thereby be markedly different from hamster transcriptomes. Said differently, this
702 morphogenetic change could contribute to a substantial part of the transcriptomic
703 concerted evolution.

B. small-range signalling centers in mouse

C. precocious transition to cusp morphogenesis in mouse

704

705 Fig 7 | Activation-inhibition mechanisms co-evolved in mouse molars.

706 A. Duration of each stage estimated by Markov models from Figure 1B. Numbers in
707 triangles as in B. Timeline and cartoons on the right recapitulate changes in signalling
708 centres.

709 B. Mouse molars transition earlier to cusp patterning. Transition from the PEK to the 2-SEK
710 stage as seen on tooth germ epithelial parts hybridised against *Fgf4*. Pairs of
711 mouse/hamster embryos were selected to show four remarkable steps in this chronology (1-

712 4 in triangles). At stage 2, *Fgf4* expression is still elongated in hamster, as typical for a PEK,
713 while it is already roundish in mouse, as typical for a SEK.

714 C. Expression of *Bmp4* is more focalized in mouse than in hamster SEKs. Mouse and
715 hamster samples are paired for similar advancement of epithelial growth. Age of samples in
716 days is in the upper molar picture (for samples taken from the same embryo) or in both
717 pictures (samples taken from different embryos). See also Figure S10.

718

719 Spatial aspects of the activation-inhibition mechanisms controlling cusp formation also show
720 concerted evolution, with more local inhibition in mouse.

721 To get further insight into the evolution of activation-inhibition mechanisms in hamster and
722 mouse, we next studied the expression of diffusing signals, which are produced in the SEK
723 and inhibit the formation of other SEKs in the vicinity. Indeed, evolutionary changes in the
724 production and diffusion of these signals are thought to drive evolutionary changes in cusp
725 number (Salazar-Ciudad & Jernvall, 2010). We do not know how much each of these
726 molecules diffuses, but the spatial range of expression of each gene can be considered as a
727 minimal range for its inhibitory action on cusp formation. We studied two known inhibitors
728 of SEK formation, *Bmp4* (Meguro et al., 2019) and *Shh* (Kim et al., 2019). We also studied
729 *Wif1*, which we consider a likely inhibitor since it antagonizes the Wnt pathway, whose
730 activation in the epithelium promotes cusp formation (Järvinen et al., 2006; Liu et al., 2008).
731 *Bmp4* and *Wif1* are expressed from the signalling centers : their expression pattern is much
732 more narrow and roundish in mouse than in hamster (both in PEK and SEKs) (Figures 7B and
733 S10). *Shh*, which more largely marks cells committed to cusp formation, also shows a more
734 restricted expression in mouse (Figure S10). Hence for the three pathways involved in the
735 activation-inhibition mechanisms, inhibition is more local in both mouse molars.

736

737 In conclusion, both dynamics and spatiality of activation-inhibition mechanisms have
738 evolved in a concerted manner in the molars of the two species. Both of them, rapid switch
739 to SEK formation relative to epithelial growth and a more local inhibition, are predicted to
740 favor the formation of more cusps. Features that make sense for the formation of the

741 supplementary cusps in the upper molar are thus observed also in the lower molar, as seen
742 above for the B/L polarity.

743

744

745 Developmental gene expression diverged as much in lower as in upper
746 molar

747 These developmental phenotypes of the lower molar have evolved in concert with the
748 upper molar, but this evolution did not drive a major phenotypic change. Such discrepancy
749 between the divergence of development and the conservation of the final phenotype, is a
750 phenomenon known as Developmental System Drift (DSD). To measure the extent of this
751 phenomenon, we decided to compare levels of developmental evolution in both teeth.
752 Since the lower molar phenotype has been much more conserved during evolution, the
753 lower molar developmental phenotype captured by the temporal profiles should be more
754 conserved. Otherwise, this is an indication of DSD.

755

756 We scored the divergence between mouse and hamster upper and lower molars by
757 modelling temporal profiles with polynomials (LRT with adjusted $p < 0.05$). We found that
758 for 22.0% of genes, the profiles diverged in the lower molar, which is even more than in the
759 upper molar (17.3%, Figure 6D, Table S2). This is true as well for genes relevant for tooth
760 development and phenotype ("bite-it", "keystone", "pathways"; Figure 6E).

761 Put together, these observations suggest that the development of the lower molar has
762 drifted while co-evolving with the upper molar.

763

764

765 Bat limbs development show a similar pattern of concerted evolution

766 In order to generalize our results, we turned to another case of drastic independent
767 evolution: the bat limb. The evolution of the wing relied on drastic changes in the forelimb
768 development, including changes in digit patterning, growth, and webbing to form the wing
769 membrane. In comparison, the bat hindlimb kept a morphology more typical of

770 quadrupedal species, as did both mouse limbs. This provides a framework of independent
771 evolution allowing us to test the generality of our findings beyond mouse molars.

772

773 We collected raw sequencing data from a previous study comprising 3 stages of mouse and
774 bat fore/hindlimb development (Maier et al. 2017). We quantified expression levels and
775 classified temporal profiles with polynomial models dedicated to measure coevolution (as in
776 Figure 6A).

777 Just like in our molar dataset and consistent with the original analysis of this dataset (Maier
778 et al., 2017), the genes which have a limb-specific temporal profile and which have kept it in
779 mouse and bat are a minority (53 genes), but they are highly enriched for transcription
780 factors, including all the expected identity genes, eg. *Tbx4* and *Tbx5*, *Pitx1*, as well as 6
781 biased Hox genes.

782 The profiles of 714 genes differed both between species and limbs. The profiles of almost
783 four times more genes (2677) diverged between the two species, but co-evolved in the two
784 limbs, despite their drastic morphological differences. Such a large proportion of co-
785 evolving genes mirrors our finding in rodent molars. Importantly, genes with a well-
786 established role in controlling limb morphology co-evolved. It is the case of key genes
787 controlling limb patterning (*Shh*, *Fgf10*, *Fgf8*, *Grem1*...) and chondrogenesis (*Wnt3* and the
788 Activin pathway: *Inhba*, *Inhbb*, *Acvr2b*...). It is also the case of most of the genes known to
789 regulate webbing (*Fgf8*, *Grem1*, *Bmp7*, *Ihh*, Retinoic acid pathway: *Aldh1a2*, *Cyp26b1*).

790

791 We note that several of these genes have been pointed in the literature as key for bat wing
792 evolution. For three of them, we could compare the expression profile in the transcriptomic
793 dataset with published *in situ* hybridization in both limbs, and they were consistent with co-
794 evolution. The iconic *Shh* gene expression clearly peaks at the second stage in both bat
795 limbs, but not in mouse limbs (Figure S11), and peaking is exaggerated in the bat forelimb
796 (Figure S11). This is consistent with figure 2 in (Hockman et al., 2008). The new temporal
797 profiles of *Fgf8* and *Grem1* in both bat limbs are also consistent with a previous study,
798 which has shown the novel expression domain of these genes in both limbs (Weatherbee et
799 al., 2006).

800 As in mouse molars, co-evolution is pervasive in bats limbs and concerns genes whose
801 expression evolution was key for the independent phenotypic evolution of the forelimb.

802

803

804 DISCUSSION

805

806 Below we discuss how the independent phenotypic evolution of the mouse upper molar
807 involved reinforcing and building on ancestral specificities of the upper molar development,
808 in relation with identity genes. It was accompanied by extensive evolution of lower molar
809 development, including concerted evolution with upper molar development, which
810 contrasts with the limited phenotypic evolution in this tooth. These findings are best
811 understood in a model where developmental system evolution of the upper molar induced
812 developmental system drift in the lower molar.

813

814 Conserved specificities of lower and upper molar morphogenesis may date back to early
815 mammals

816 We found several conserved specificities which discriminate between lower and upper
817 molars. All mark the early period of cusp formation: the arrangement of cusps at 3-SEK
818 stage and the early dynamics of cusp formation, the morphology of lingual epithelium and a
819 transient reinforcement of transcriptomic identity (already seen in mouse in our previous
820 study (Pantalacci et al., 2017)). Since these findings were made in hamster and mouse,
821 these specificities of lower and upper molar were likely present in their common ancestor,
822 but we suspected they may even date from early mammals.

823

824 Early mammals evolved “tribosphenic molars”, a major innovation of lower and
825 upper molar shape which enabled unprecedented occlusion (B. M. Davis, 2011; Hillson,
826 2005). For the first time in the reptilian evolution, lower and upper molars were developing
827 into drastically different shapes. In the Figure S5, we discuss in detail how the
828 developmental specificities of lower and upper molars of mouse and hamster strikingly
829 mirror the specificities of the lower and upper tribosphenic molars, taking into consideration

830 known homologies in mammalian molar cusps. In particular, we show how the spatio-
831 temporal dynamics of cusp formation in the lingual and posterior directions are combined
832 differently in the two molars. We propose that evolving a jaw-specific control of this
833 combination was the key developmental innovation underlying the invention of the
834 tribosphenic molars.

835 Most later mammals had less dissimilar teeth, such as the common ancestor of
836 mouse and hamster or the present golden hamster. Yet the heritage of the mammalian
837 innovation remains visible in the transient developmental dynamics of lower and upper
838 molars. This also constitutes a case of “recapitulation” since early ontogeny of cusp
839 formation recapitulates phylogeny (Gould, 1977).

840

841 These hidden developmental specificities could serve as a basis for the independent
842 evolution of upper molar in the mouse lineage. It is interesting that some fossil rodents
843 close to mouse/hamster common ancestor carried a crest along the lingual basis of the
844 upper, but not the lower molar, which may be seen as an ancestral predisposition to
845 enlarge lingually and form lingual cusps (Charles et al., 2009; Tiphaine et al., 2013).

846

847 What does underlie the conserved morphogenetic identity of molars? Ancestral molecular
848 identity of molars

849 We identified several conserved specificities of upper and lower molars at the
850 developmental system level, yet such conserved specificities remain rather discrete at the
851 transcriptomic level. We found relatively few genes consistently biased in the two species,
852 and their temporal profiles were most often not conserved, except some highly relevant
853 transcription factors. This includes the two jaw-specific genes *Nkx2-3* and *Pou3f3*, and
854 several *Dlx* genes. The *Dlx* genes are homeobox transcription factors which specify jaw
855 identity at early stages of craniofacial development in jawed vertebrates and might have
856 been implicated in the transition from a reptilian to a mammalian jaw (Depew et al., 2005;
857 Gillis et al., 2013). The dose as well as the complement of *Dlx* genes (*Dlx1/2* in upper jaw;
858 *Dlx1/2/5/6* in the lower jaw) are important for normal jaw development in mouse (Depew et
859 al., 2005), and upper molars fail to develop without *Dlx1/2* (Qiu et al., 1997). *Dlx1/2*

860 showed an upper-bias in both species, and *Dlx5/6* a lower bias. Transcription factors known
861 to be essential to tooth development, such as *Msx1*, *Barx1*, *Pitx1* also showed a conserved
862 bias. It remains to be tested if this bias is directly controlled by identity genes.

863 Our results show that during evolution, the details of developmental interactions in serial
864 organs diverge extensively, but some developmental specificities of one organ with respect
865 to the other are conserved (e.g. the relative order and timing of appearance of the 3 first
866 cusps and the period of maximal transcriptomic divergence, the delayed development of
867 the upper molar). These specificities could be encoded in a conserved relative dose of the
868 key transcription factors specifying an organ (here a molar or a limb), and this conserved
869 relative dose could be controlled by identity genes. Altogether this forms an ancestral
870 molecular and developmental identity for the two teeth.

871

872 Reinforcement of the ancestral molecular and morphogenetic identity in mouse molars

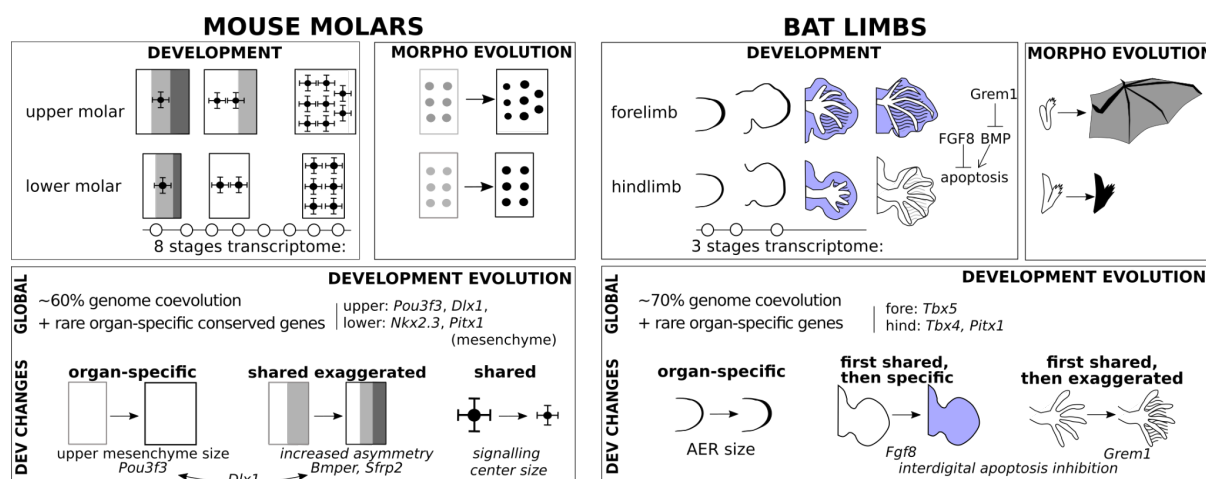

873 We found that the molecular identity was reinforced in mouse, in the upper molar but also
874 more surprisingly in lower molar. Expression levels doubled for the upper-molar specific TF
875 *Pou3f3* and the lower-molar specific TF *Nkx2-3*, and the ancestral bias of many genes was
876 exaggerated, whether in favor of upper or lower molar (e.g. *Barx1* and *Dlx1*; *Pitx1*,
877 respectively). Consistent with these changes in individual TFs, we found at genome-wide
878 scale that the temporal profiles in the mouse were exaggeratedly different from each other.
879 As for specific TF, divergence is seen both in upper and lower molar.

880

881 Mouse upper molar displays three morphogenetic changes favoring supplementary cusp 882 formation, one is building on ancestral upper molar specificities

883 The supplementary cusps form last, the most anterior one being the very last, just as
884 it happens in the fossil record (Lazzari et al., 2008; Tiphaine et al., 2013). This
885 “recapitulation” looks superficially like a case of “terminal addition”, a mechanism for
886 evolutionary change whereby development is incremented with one more step (Gould,
887 1977). However, species divergence peaks early in development and we point to three
888 features that concern mouse early upper molar development, but could pave the way for
889 the supplementary cusps (Figure 8).

890

891

892 Fig 8 | A summary of findings and working model from this study. For mouse molars and bat limbs,
 893 the "development" box shows key developmental stages with the time period covered by
 894 transcriptome data. The box "morphological evolution" represents the drastic morphological
 895 changes of the upper molar and forelimb as compared to the relative conservation of the lower
 896 molar and hindlimb. The "development evolution" box summarises the evolution of transcriptome
 897 and developmental mechanisms. Transcriptomes are dominated by co-evolution, with rare
 898 conservation of organ-specific expression besides identity genes. Organ-specific, shared, and shared
 899 but exaggerated developmental changes combine to achieve the organ-specific morphological
 900 change. For each change, the ancestral and derived state are represented, and candidate genes are
 901 indicated. In mouse molars, 3 changes (increased mesenchyme size, increased bucco-lingual
 902 asymmetry and smaller inhibitory signalling centres) combine to induce extra cusps on the lingual
 903 side of the upper molar only. In bat limbs, we took the example of early changes in AER size (apical
 904 ectodermal ridge, a signalling center) leading to altered digit patterning and late expression changes
 905 in *Fgf8* and *Grem1*, that efficiently combine to suppress interdigital apoptosis in the forelimb only. In
 906 our working model, shared changes are necessary but not sufficient. Combining them with more
 907 specific changes (e.g. mesenchyme size) and/or ancestral specific features (e.g. ancestral difference
 908 in molar Bucco/lingual axis) is necessary to achieve the morphological change. Related to Figure
 909 S12-13.

910

911 The first feature is the larger mesenchyme compartment of the mouse upper molar.
 912 Increasing mesenchyme proportion increases cusp number in tooth engineering studies (Hu
 913 et al., 2006), probably because the mesenchyme promotes epithelial growth, which

914 enlarges the field where activation-inhibition mechanisms act and pattern SEKs. The
915 observed difference seems however too modest to drive the formation of supplementary
916 cusps on its own and does not explain why the supplementary cusps would form on the
917 lingual side only.

918 The second feature is the stronger polarisation of the upper molar field along the
919 bucco-lingual axis, associated with a precocious transition from PEK to 1-SEK and a very
920 long 1-SEK stage. As a consequence, a larger undifferentiated field is present on the lingual
921 side, where activation-inhibition loops can pattern SEKs. This feature seems highly relevant
922 because it could explain why the increase in cusp number is focused on the lingual side of
923 the tooth, while the size of buccal cusps is reduced. It seems to exploit an ancestral
924 specificity of the upper molar as compared to the lower molar, which produces a longer 1-
925 SEK stage. This specificity could combine together with a novelty in mouse responsible for
926 shortening the PEK stage in both teeth, and produce an upper molar with a very long 1-SEK
927 stage and a large undifferentiated field, while change remains more modest in the lower
928 molar.

929 The third feature is the narrower range of expression of signaling molecules in
930 mouse signalling centres, which is especially obvious for *Bmp4*. Reducing the range of
931 these known cusp formation inhibitors should allow to squeeze more SEKs in an equivalent
932 field. In agreement with this idea, a mouse mutant where *Bmp4* is overexpressed in all the
933 epithelium loses the supplementary cusps (Meguro et al., 2019), hence reverting to the
934 ancestral phenotype.

935

936 Molecular mechanisms and candidate genes for the observed morphogenetic changes

937 Mapping mutations corresponding to these developmental phenotypes is out of the
938 scope of this study, but transcriptomics provided us with molecular mechanisms and some
939 candidate genes. No expression change was observed in two obvious candidates from the
940 literature (*Fgf3* and *Activin*2A, Figure S12, (Charles et al., 2009; Kwon et al., 2017).

941

942 In insects, the evolution of the dose of identity genes has been correlated with the
943 evolution of the size of serial organs (Paul et al., 2021). *Pou3f3* is expressed specifically in

944 the upper molar mesenchyme of both species and its dose is twice increased in mouse.
945 Hence *Pou3f3* is a good candidate to explain the larger proportion of mesenchyme
946 specifically in the mouse upper molar. *Pou3f3* loss-of-function mutants miss some skeletal
947 elements of the upper jaw, but their upper molars showed “no major defects” (data
948 unshown in (Jeong et al., 2008)). This may deserve re-examination, or study in sensitized
949 backgrounds. The causative mutation may also be upstream in the regulatory network, in
950 particular in *Dlx1/2*, since *Pou3f3* is regulated by *Dlx1/2* in the early jaw (Jeong et al., 2008)
951 and the dose of *Dlx1/2* genes are also twofold increased. Both *Dlx1/2* and *Pou3f3* are also
952 involved in cranio-facial development. Since mastication has changed together with tooth
953 morphology in the mouse lineage (Lazzari et al., 2008; Tiphaine et al., 2013), changes in the
954 dose of these genes could have had pleiotropic effects beyond the molar.

955

956 The reinforcement of the B/L polarity in the mouse upper molar likely involved
957 changes in or upstream of the BMP4/OSR2 network. Interestingly, mutations in this network
958 have very different consequences on lower and upper molar development of mouse (eg. a
959 tooth is normally formed *versus* arrested at a very early stage) (Jia et al., 2013, 2016; Kwon
960 et al., 2017; Lan et al., 2014). We show that the BMP4/OSR2 antagonism, which earlier in
961 development regulates the B/L polarization of the molar-forming region, persists in mouse
962 during the first steps of cusp formation. We found expression changes in two genes which
963 should modify the output of this BMP4/Ors2 network: *Sfrp2*, whose role in the network was
964 known in mouse (Jia et al., 2013, 2016; Kwon et al., 2017; Lan et al., 2014) and *Bmper*,
965 whose role in tooth development was unknown.

966 BMPER is a known modulator of the BMP4 pathway, which seems to be pro- or anti-
967 BMP4 in different contexts (Correns et al., 2021; Ikeya et al., 2010; Kelley et al., 2009; Serpe
968 et al., 2008). Because the molars of the *Bmper* loss-of-function mutant are “hypo-
969 buccal/hyper-lingual”, we deduce that *Bmper* is normally pro-BMP4 in the mouse
970 BMP4/OSR2 balance. In mouse, the strong buccal *Bmper* expression should favor BMP4
971 activity on the buccal side while the early lingual withdrawal should decrease BMP4 activity
972 on the lingual side. This sharper gradient of BMP4/OSR2 antagonism may link two
973 observations in mouse: on the buccal side, the earlier PEK/SEK transition; on the lingual

974 side, the larger undifferentiated field. Finally, we note that the teeth of the *Bmper* mutant
975 are strikingly similar to the molars of a mouse relative, *Mastacomys fuscus brazenori*. Its first
976 upper molars have very large supplementary cusps and have lost the same buccal cusp as
977 the *Bmper* mutant, and its lower molars have larger lingual cusps as compared to buccal
978 cusps (Museums Victoria Collections). Therefore, our data strongly suggest that
979 evolutionary changes in the BMP4/OR2 network might be responsible for both the
980 evolution of the murine dental plan and its further diversification.

981 Where could be the mutation which impacted this BMP4/Osr2 network? From the
982 present data, we envision at least three possibilities. 1) A cis-regulatory change in the
983 *Bmper* gene could have led to its new asymmetric profile, and feedback on *Sfrp2*
984 expression through the network. In cichlids, a QTL containing *Bmper* is associated with
985 variation in tooth number (Bloomquist et al., 2015). Species with more teeth have reduced
986 *Bmper* expression, as mouse with more lingual cusps have reduced lingual *Bmper*
987 expression (Bloomquist et al., 2015). 2) The mutation may lie in *Sfrp2*, and feedback on
988 *Bmper* expression. 3) The mutation might also lie in *Dlx1/2* genes, because they control
989 both *Sfrp2* and *Bmper* expression levels in the early mouse jaws (Jeong et al., 2008). It is
990 striking that these 3 genes show only a minor expression difference in favor of the upper
991 molar in hamster, but their expression is twice increased in mouse, together with a sharper
992 upper molar bias. By acting on both a buccal (*Bmper*) and a lingual (*Sfrp2*) gene with
993 antagonistic effects on the BMP4/Osr2 balance, the increased dose of *Dlx1/2* might have
994 converted the mild ancestral polarization of the tooth into the sharp bucco-lingual
995 polarisation seen in mouse. Future work focusing on the evolution of the cis-regulatory
996 regions of these genes could test these hypotheses.

997 Finally, we noticed clear changes in the expression patterns of *Bmp4*, *Wif1* and
998 *Dkk1*, three members of the BMP and Wnt pathways at the core of activation-inhibition
999 networks (O'Connell et al., 2012; Salazar-Ciudad, 2012). Given the many regulatory
1000 feedback in these networks, a mutation may lie in one of these genes and feedback on the
1001 expression of the others, or lie in another gene to be identified.

1002

1003

1004 Lower molar development evolved in a concerted manner with upper molar development

1005

1006 We show that the lower molar development has coevolved with the upper molar
1007 development. Temporal expression profiles coevolved massively and several features of
1008 cusp formation also evolved in a concerted manner: the precocious PEK to SEK transition,
1009 the narrow expression of inhibitors in signaling centers, the marked bucco-lingual
1010 asymmetry with persistence of some lingual naive tissue and the early *Bmp_{er}* withdrawal
1011 from the lingual side. Concerted evolution in bucco-lingual development is especially
1012 striking, since neither cusp number nor relative size along the B/L axis differs between
1013 mouse and hamster lower molars (Figure 1). The only derived features of the mouse lower
1014 molar are the connection between cusps (the crest connecting central and posterior cusps is
1015 lost) and their slightly more parallel arrangement (Lazzari et al., 2008).

1016 Why these concerted developmental changes translate into minor phenotypic change in the
1017 lower molar but major ones in the upper molar is an open question. Molar development has
1018 non-linear properties, characterized by threshold effects (Gjuvsland et al., 2013; Milocco &
1019 Salazar-Ciudad, 2020; Morita et al., 2020; Urdy et al., 2016). Since the lower molar can form
1020 supplementary lingual cusps when activation is boosted by adding ACTIVIN β A to the
1021 culture medium (Harjunmaa et al., 2012), it suggests that in wild type mouse, the lower
1022 molar remains below a threshold, while the upper molar passes it. There could be two
1023 different, non mutually exclusive reasons for that: 1) As mentioned above, there were
1024 ancestral differences in the regulation of the bucco-lingual axis in the common ancestor.
1025 When facing the same expression change (e.g. early *Bmp_{er}* withdrawal from the lingual
1026 side), its upper and lower molar might then have reacted very differently, passing or not the
1027 threshold. 2) The upper-specific increase in mesenchyme proportion may be just the small
1028 effect needed to pass the threshold in the upper molar, while the lower molar remains
1029 below it. Indeed, the mesenchyme is the endogenous source of ACTIVIN β A, whose
1030 supplementation produces lingual cusps in the lower molar (Harjunmaa et al., 2012).

1031

1032

1033

1034 A combinatory model to explain the independent phenotypic evolution of the upper molar
1035 with concerted developmental evolution in the lower molar

1036

1037 The three features that we observed hint at very complementary aspects of tooth
1038 development (Figure 8). The tooth literature shows it is difficult to increase cusp number in
1039 mouse molars: *in vitro* experiments have shown it can be necessary to play on multiple
1040 pathways, and mouse mutants show, at best, small accessory cusps, but no supplementary
1041 main cusps (Harjunmaa et al., 2012). None of these three changes should be sufficient on its
1042 own to induce the major changes in cusp size and proportions seen in mouse as compared
1043 to its ancestor. We therefore propose that the new phenotype involves combining
1044 mutations in at least two or three different genes, corresponding to these three features
1045 (Figure 8). Such a model with additive changes is also coherent with the stepwise addition
1046 of the supplementary cusps in the fossil record. Stem murine rodents had a single small
1047 extra cusp. Enlargement of this cusp, addition of a second extra-cusp, and size reduction of
1048 the buccal cusps came later (Tiphaine et al., 2013).

1049 The 3 mutations which could lie behind the observed developmental phenotypes
1050 represent three different categories, with respect to their consequences for the lower molar
1051 (Figure 8).

1052 i) mutation with organ-specific developmental effects - A mutation in the upper-
1053 molar specific *Pou3f3* gene which was part of the ancestral lower/upper code could have
1054 molecular effects specific to the upper molar. Such a mutation and effect are expected from
1055 the abundant literature on homeotic genes and serial appendage evolution.

1056 ii) mutation with shared effects, but exaggerated in the upper molar - Another
1057 mutation could have the same molecular effects on the development of both molars (e.g. a
1058 mutation making *Bmper* expression asymmetric) but with a stronger expressivity in upper
1059 molar (e.g. larger lingual field) because the ancestral lower/upper code determines a
1060 different developmental context between the two teeth.

1061 iii) mutation with fully shared effects on lower and upper molar development - A
1062 third mutation could have the same molecular effects and the same expressivity on the
1063 developmental phenotype (range of inhibitor expression in the signaling centers of the two

1064 teeth), but because it cannot combine with other effects in the lower molar as it does in the
1065 upper molar, it might have a very limited impact on the lower molar phenotype.

1066

1067 Such a genetic model is consistent with findings in butterflies' wings. Indeed,
1068 combinatory effects of mutations and context-dependency on the ancestral homeotic code
1069 have been proposed to explain the evolution of eyespot patterns in the fore and hind-wings
1070 (Monteiro 2007, 2021, 2022).

1071

1072 The patterns of transcriptome evolution seen in teeth resemble patterns observed in other
1073 serial organs

1074

1075 Comparative transcriptomics in embryos may be confounded by methodological effects
1076 that could inflate interspecies differences in expression levels. This includes estimating
1077 expression levels with RNA-seq data from different species and sampling a few stages in a
1078 continuous developmental window in species with different developmental rates. We
1079 controlled for this by estimating expression levels on orthologous portions of the
1080 transcripts, by matching the time window with homologous stages, by sampling many time
1081 points, and working on temporal profiles instead of individual stages.

1082

1083 To the best of our knowledge, there are only two other studies using interspecies
1084 transcriptomics in serial organ evolution, in similar settings: at least two species, one
1085 representing ancestral morphologies, and another one where a single organ strongly
1086 diverged from the ancestral morphology. One study compares bones from fore/hind limbs
1087 in mouse and jerboa at a single timepoint (Saxena et al., 2022). The other compares
1088 limbs/wings in mouse and bat at three timepoints (Maier et al., 2017) which allowed us to
1089 reanalyse the data with our methods.

1090 Similar patterns are seen in all these datasets. 1) Only a small set of genes, enriched in
1091 transcription factors, showed an organ-specific expression conserved between species (our
1092 tooth data, reanalyzed limbs dataset, and (Maier et al., 2017; Saxena et al., 2022)). 2) The
1093 expression of large numbers of genes co-evolved in the two organs (tooth and reanalyzed

1094 limb data, (Saxena et al., 2022)). 3) Expression differences between serial organs are
1095 increased in species with the morphological innovation (tooth and reanalyzed limbs data,
1096 (Saxena et al., 2022)) 4) but the serial organ which kept the most ancestral morphology
1097 does not show better expression conservation (tooth and reanalyzed limbs data, and
1098 (Saxena et al., 2022).

1099

1100 Co-evolution is also pervasive in bat limbs, where adaptation combines organ-specific with
1101 shared gene expression changes.

1102

1103 Our comparative analysis of early mouse and bat development revealed that
1104 developmental dynamics of gene expression is largely shared by the two bat limbs, despite
1105 their drastically different morphologies. This concerted evolution was largely overlooked so
1106 far (e.g. *Shh* gene), because attention was mainly given to wing-specific developmental
1107 features, which seem more logically susceptible to explain wing evolution. We however
1108 realized that gene expression changes, previously pointed for their role in bat wing
1109 evolution, are in fact accompanied by concerted expression changes in the hindlimb. The
1110 bat wing membrane is achieved by suppressing the apoptosis which normally defines the
1111 digits. Functional tests showed that this is achieved by simultaneously activating the anti-
1112 apoptotic FGF pathway and downregulating the pro-apoptotic BMP pathway (Weatherbee
1113 et al., 2006). *Fgf8* and the BMP inhibitor *Grem1* coevolved in our analysis (Figure S12), with
1114 a new mesenchymal expression in both bat limbs (Figure 8, drawn from Figure 3 A-C, E-G in
1115 (Weatherbee et al., 2006)). At later stages, *Fgf8* mesenchymal expression persists in the
1116 interdigital area in the wing, but not in the foot (from Figure 3H in (Weatherbee et al.,
1117 2006)). In contrast, the BMP inhibitor *Grem1* expression persists in both limbs, with higher
1118 levels in the wing (from their Figure 3D, note the blue staining remaining around digits
1119 whereas more proximal parts of the limb are not stained at all). Thus, at this stage, specific
1120 and exaggerated shared gene expression changes seem to combine to pass the threshold
1121 for apoptosis suppression in the wing, but not in the foot (Figure 8). This evolutionary
1122 scenario of independent evolution is thus very similar to teeth, involving a combination of

1123 specific, shared, and exaggerated shared expression changes and differential threshold
1124 effects.

1125

1126 Concerted evolution with Developmental System Drift is a mechanism facilitating
1127 independent evolution of serial organs

1128

1129 We observed incongruent patterns of transcriptome and morphologies in molar evolution :
1130 transcriptomes diverged equally in the upper and lower molars, while the morphology of
1131 the lower molar remains largely conserved. This unexpected level of developmental
1132 divergence as compared to morphological conservation is called Developmental System
1133 Drift (DSD, (Cutter & Bundus, 2020; Félix, 2012; True & Haag, 2001)).

1134

1135 There is now accumulating evidence that cryptic changes in developmental systems are
1136 frequent in evolution (Félix, 2007; Guignard et al., 2020; Torres Cleuren et al., 2019; Wotton
1137 et al., 2015). Because natural selection mainly acts on the final product of development,
1138 divergent developmental paths may be taken to reach the same final phenotype and drift in
1139 development is neutral with respect to natural selection. Further taking into account that
1140 genomes are constantly mutating, DSD appears as a likely alternative to developmental
1141 conservation (Félix & Wagner, 2008; Peter & Davidson, 2011).

1142

1143 The situation here seems different from this classical definition of DSD since at least part of
1144 lower molar and hindlimb DSD is not random: it is concerted with developmental
1145 innovation in the other organ, and therefore likely induced by the adaptation of this other
1146 organ. Because the lower molar and the hindlimb developmental systems could evolve
1147 while robustly maintaining the final phenotype during evolutionary times, mutations with
1148 shared effect could be used by adaptation. This is unexpected since it is commonly thought
1149 that adaptive mutations need to be modular at the DNA level to have organ-specific effects
1150 and thereby circumvent gene pleiotropy. The capacity of developmental systems to
1151 undergo DSD is another way of circumventing gene pleiotropy, and thus appears as a
1152 mechanism by which non-modular mutations can be selected in adaptation. We propose

1153 this is the reason why independent evolution can be so frequently seen in nature despite
1154 gene pleiotropy.

1155

1156 Pleiotropy, concerted evolution and DSD

1157 Serial organs such as molars and limbs have a heavy pleiotropy load and for this reason,
1158 they are possibly especially prone to developmental co-evolution and DSD. We
1159 nevertheless believe that our results in serial organs illustrate a much more general
1160 correlation between pleiotropy and DSD at the organismal level, as suggested previously
1161 (Félix, 2007; Pavlicev & Wagner, 2012).

1162 The link between pleiotropy and DSD has been observed in experiments of *in silico*
1163 evolution (Johnson & Porter, 2007; Tulchinsky et al., 2014). It has also been observed in
1164 nematode genetics with a mutation increasing the fitness in laboratory conditions that has
1165 induced DSD in the vulva (Duveau & Félix, 2012). Finally, a link between pleiotropy and
1166 concerted transcriptomic evolution has already been suggested. In most multispecies
1167 transcriptomic analyses, samples of different organs tend to group by species (like molar
1168 samples in Figure 1C). This pattern, so-called “species signal”, often dominates in samples
1169 of adult tissues (e.g. kidney, brain, liver... (Brawand et al., 2011)) as well as in individual
1170 embryonic timepoints (Liang et al., 2018; Tschopp et al., 2014). This has been reinterpreted
1171 as a conspicuous concerted evolution, possibly driven by the pleiotropy of gene networks,
1172 repeatedly used in different organs (Liang et al., 2018; Musser & Wagner, 2015).

1173

1174 We further suggest that pleiotropy-induced DSD may explain another observation
1175 concerning genes involved in human diseases and pleiotropic genes. It was expected that
1176 the embryonic expression profiles of these important genes would evolve slowly, but they
1177 evolve as fast as the rest of the genome (Cardoso-Moreira et al., 2019, 2020). Further work
1178 may reveal which part of sequence and expression divergence which is usually attributed to
1179 genetic drift (divergence by random chance) could in fact be attributed to “pleiotropy-
1180 induced DSD”.

1181

1182

1183 MATERIAL AND METHODS

1184

1185 Data analysis

1186 R scripts corresponding to the main methods and processed data are available on GitHub
1187 (<https://github.com/msemon/DriftHamsterMouse>).

1188

1189 Rodent breeding and embryo sampling

1190 CD1 (CD1) adult mice and RjHan:AURA adult hamsters were purchased from Charles River
1191 (Italy) and Janvier (France) respectively. Females were mated overnight and the noon after
1192 morning detection of a vaginal plug or sperm, respectively, was indicated as ED0.5. Other
1193 breeding pairs were kept in a light-dark reversed cycle (12:00 midnight), so that the next
1194 day at 16:00 was considered as ED1.0.

1195 The *Bmper*^{tm1Emdr} strain (Zakin et al., 2008) was kept in a C57/BL6N background by crossing
1196 heterozygotes with wild types, as homozygotes die at birth. To avoid suffering at birth, we
1197 generated homozygotes and wild type samples for X-ray by crossing heterozygotes and
1198 sacrificing pregnant mice at 19.5 days (1 day before delivery). Pregnant mouse females
1199 were killed by cervical dislocation. Hamster females were deeply anesthetized with a
1200 ketamine-xylazine mix administered intraperitoneally before being killed with pentobarbital
1201 administered intracardially. All embryos were harvested and thereby anesthetized on
1202 cooled Hank's or DMEM advanced medium, weighted as described in (Peterka et al., 2002)
1203 and immediately decapitated.

1204 This study was performed in strict accordance with the European guidelines 2010/63/UE
1205 and was approved by the Animal Experimentation Ethics Committee CECCAPP (Lyon,
1206 France, APAFIS#27308-2020092210045896 v1).

1207

1208 Estimating embryonic age from embryo weight

1209 Embryo weight is well correlated with developmental age, allowing us to use it as a proxy in
1210 mouse and hamster, following (Pantalacci et al., 2009). We fitted age of development
1211 according to weight (in mg) for hamster and mouse data separately, based on 1047 mouse

1212 embryos and 636 hamster embryos respectively, collected over more than 15 years of
1213 research. We fitted generalised additive models (GAM) to the data after Box-Cox
1214 transformation of weight (libraries mgv version 1.8-35 for GAM and MASS 7.3-53.1 for Box-
1215 Cox). These models were preferred to log transformations and linear models, because they
1216 allow to treat the data homogeneously between species, and because the relationship is
1217 not perfectly linear between weight and age (Figure S1). These models were then used to
1218 predict developmental age, based on weight, for all samples used in this study (RNA-seq
1219 analysis, cusp patterning analysis, and *in situ* hybridizations for several genes).

1220

1221 Epithelium dissociations and *in situ* hybridizations

1222 Complete or hemi mandibles and maxillae were dissected in Hank's medium and treated
1223 with Dispase (Roche) 10mg/ml in Hepes/KOH 50mM pH7.7; NaCl 150 mM at 37 °C for 30
1224 min to 1h depending on embryonic stage. Epithelium and mesenchyme were carefully
1225 separated and fixed overnight in PFA 4% at 4 °C. DIG RNA antisense mouse *Fgf4*, *Shh*,
1226 *Fgf10* (Bellusci et al., 1997), *Bmper/Cv2* probes were prepared from plasmids described
1227 elsewhere (Coffinier et al., 2002). Mouse *Dkk1*, *Wif1*, hamster *Bmper* probes, Mouse and
1228 hamster *Bmp4* probes were newly cloned following RT-PCR or DNA synthesis (Table S1). *In*
1229 *situ* hybridizations were done according to a standard protocol (DIG mix, DIG antibody and
1230 BM purple were purchased from ROCHE). Photographs were taken on a Leica M205FA
1231 stereomicroscope with a Leica DFC450 digital camera (Wetzlar, Germany) or on a Zeiss
1232 LUMAR stereomicroscope with a CCD CoolSNAP camera (PLATIM, Lyon, France).

1233

1234 Immunolocalisation and 3D reconstructions

1235 Tooth germs dissected from litter-mate embryos of RNA-seq samples were fixed overnight
1236 in PFA4% and dehydrated through a methanol series. In toto immunolocalization protocol
1237 was adapted from (Ahnfelt-Rønne et al., 2007). Following incubation in H2O2 5%, DMSO
1238 10% in methanol for 4 hours, they were rehydrated, blocked and incubated successively
1239 with a pan-cytokeratin antibody (overnight, 1/200, Novus Biologicals) and a Dylight 549
1240 conjugated Donkey Anti-rabbit antibody (overnight 1/200, Jackson immunoresearch) and
1241 finally with Hoechst (overnight , 50µg/ml). Following methanol dehydration, they were

1242 clarified and mounted in BABB as described in (Yokomizo & Dzierzak, 2010). They were
1243 imaged with a Zeiss LSM710 confocal microscope at the PLATIM (Lyon, France). The outline
1244 of the epithelium labelled by the pan-cytokeratin antibody and the outline of the tooth
1245 germ labelled with hoechst were delineated manually and reconstructed in 3D in the
1246 AMIRA software.

1247

1248 X-ray scanning and 3D reconstruction of *Bmper* and wild type tooth shape at 19.5 days

1249 We obtained 14 homozygote (Ho) and 19 wild type (Wt) samples from a total of 14 different
1250 19.5 dpc litters, out of which we selected for reconstruction of the first molar morphology 7
1251 Ho and 4 Wt with matching body weights (homozygotes: 1174-1329 mg; wt: 1227-1310
1252 mg). At 19.5 dpc, female embryos are more developmentally advanced than male embryos
1253 of a similar weight, therefore sex was also recorded. This was necessary to control for
1254 differences in growth advancement, since we anticipated (and confirmed) that
1255 supplementary cusps are still growing rapidly at this stage, due to their late formation.
1256 Heads freed of skin were fixed in PFA, dehydrated in ethanol, stained with 0,3% PTA in 70%
1257 ethanol for 2 weeks-1 month and scanned at 40kV on a Phoenix Nanotom S
1258 microtomography for a voxel size of 4 μm . Semi-automatic reconstruction of the enamel-
1259 dentin junction was performed with ITK-snap. Reconstructions were oriented for
1260 comparison in MeshLab 2021.05. Due to variations in staining efficiency and advancement
1261 of mineralization, only a total of 4 Ho and 4 Wt upper molars and 3 Ho and 4 Wt lower
1262 molars were finally successfully reconstructed and considered to be directly comparable.
1263 The aberrant upper molar morphology was obvious on microCT sections in 7/7 samples.
1264 The loss of one cusp was observed in 4 Ho/4 3D reconstructions. The larger lingual cusps
1265 were observed in all Ho 3D reconstructions when paired with a wt of corresponding age.
1266 This (as well as cusp loss) was also confirmed by comparing epithelial dissociations of
1267 *Bmper* Ho and Wt embryos at 19.5 dpc.

1268

1269 Modelling and comparing cusp patterning dynamics

1270 To compare the dynamic of crown morphogenesis in four teeth (lower and upper molars in
1271 hamster and mouse) we need to establish the sequence of primary and secondary signalling

1272 centres formation (respectively, PEK and SEK). In mouse, this could be done with time lapse
1273 imaging of fluorescent lines (Harjunmaa et al., 2014). To integrate non-model species like
1274 hamster, we had to set up a new method that infers the dynamic based on fixed embryos.
1275 We hybridised developing molars against a *Fgf4* probe to reveal PEK and SEKs. The
1276 patterns we observed among samples are consistent with a stereotypic and specific
1277 sequence of SEK patterning in each tooth and species (Figure 1B, schemas on the sides).
1278 We name each stage by the number of signalling centres (PEK stage then 1-SEK stage, 2-
1279 SEK stage etc).

1280 Cusp patterning can be seen as a succession of irreversible stages representing step-wise
1281 cusp additions. Transition rates between these stages were modelled through continuous
1282 time Markov modelling as in (Pantalacci et al., 2017). The rationale is that if sampling is
1283 uniform over the time course of tooth morphogenesis, stages that are rarely sampled are
1284 very transient (with high exit rate), while stages that are often sampled last for a longer
1285 period of time. In continuous Markov models, the duration of each state follows an
1286 exponential distribution, which is not realistic for the stage lengths. So, to have a more
1287 realistic stage length distribution, each stage was modelled by several consecutive states,
1288 so that its length followed an Erlang distribution, which has a mode different from zero. We
1289 built independent models for each species and tooth types. Models are estimated on 121
1290 embryos for the hamster lower molars, 113 for hamster upper, 217 for mouse lower, 187 for
1291 mouse upper.

1292 We estimated the duration of each stage in a complete model, with different transition rates
1293 for all stages. We also fitted several simpler, nested models, with constraints on the number
1294 of different transition rates, up to the most simple model with the same transition rate for all
1295 stages. We retained models with three different rates in mouse, and two different rates in
1296 hamster, by comparing the fit of the models by likelihood ratio tests in each tooth. Markov
1297 models were built by custom scripts calling on R libraries `maxLik` and `expm` (`maxLik_1.4-8`
1298 and `expm_0.999-6`).

1299
1300
1301

1302 RNA-seq sample preparation

1303 A total of 32 samples per species, coming from eight individuals, were prepared for the
1304 time serie RNA-seq analysis, representing consecutive stages in mouse (ED14.5, 15.0, 15.5,
1305 16.0, 16.5, 17.0, 17.5, 18.0) and nine stages in hamster (ED11.8, 12.0, 12.2, 12.5, 13.0,
1306 13.25, 13.5, 13.75, 14.0). Each sample contained two whole tooth germs, the left and right
1307 first molars (M1) of the same female individual, and for a given stage, the upper and lower
1308 samples came from the same individual. Harvesting and dissection were performed in a
1309 minimal amount of time in advanced DMEM medium. The M1 lower and upper germs were
1310 dissected under a stereomicroscope and stored in 200 uL of RNA later (SIGMA). Similarly
1311 dissected tooth germs from the same litter and same weight were fixed overnight in PFA
1312 4% for immunolocalization and 3D reconstruction, to check for dissection leaving almost no
1313 non-tooth tissue. Examples of dissection are visible in (Pantalacci et al., 2017). Another
1314 embryo of the same litter and same weight was processed as indicated above for *Fgf4 in*
1315 *situ* hybridization to check the exact developmental stage. Total RNA was prepared using
1316 the RNeasy micro kit from QIAGEN following lysis with a Precellys homogenizer. RNA
1317 integrity was controlled on a Bioanalyzer (Agilent Technologies, a RIN of 10 was reached for
1318 all samples used in this study). PolyA+ libraries of the large-scale dataset were prepared
1319 with the Truseq V2 kit (Illumina, non stranded protocol), starting with 150 ng total RNA and
1320 reducing the amplification step to only 12 cycles and sequenced on an Illumina Hi-seq2000
1321 sequencer (100 bp paired end reads) at the GENOSCOPE (Evry, France).
1322 For the bucco-lingual dataset, we dissected the 4 first molars (left/right, lower/upper) from a
1323 unique mouse E15.0 embryo (weight: 359 mg) as above, except that tooth germs were cut
1324 in two halves to isolate buccal and lingual side. Replicates were thus obtained by
1325 comparing the right and left side of this same embryo. Total RNAs were extracted and
1326 libraries were prepared as above, starting with 50-70 ng total RNAs, where an equal
1327 amount of AmbionR ERCC RNA Spike-In Mix1 had been added according to the AmbionR
1328 protocol (e.g. 1µL og a 1 :1000 dilution for each tube). A total of 8 libraries were sequenced
1329 (50bp single-end reads) by the Genomeast Sequencing platform, a member of the France
1330 Genomique program.

1331 For the epithelium-mesenchyme dataset, lower and upper mouse and hamster first molars
1332 were dissected as above and treated for 15 minutes at 37°C with Dispase (Roche) 10mg/ml
1333 in Hepes/KOH 50mM pH7.7 ; NaCl 150 mM to separate the epithelial from mesenchymal
1334 parts which were stored in RNAlater. For the mouse data, we generated samples for 2
1335 stages in 2 replicates, using embryos from the same litter (stage 15.0 dpc, weight: 350 and
1336 370 mg; stage 16.5 dpc: weight: 788 and 808 mg). Left and right epithelium or
1337 mesenchyme were pooled. For the hamster data, we generated samples for a single stage
1338 without replication. We pooled the left epithelial or mesenchymal parts from 2 embryos
1339 from the same 12.5 dpc litter (413 and 427mg). A total of respectively 16 and 4 libraries
1340 were generated with Truseq V2 kit and sequenced (50bp single-end reads) by the
1341 Genomeast Sequencing platform.

1342

1343 Multivariate analyses

1344 Multivariate analyses were performed using the ade4 package (ade4_1.7-18; (Dray &
1345 Dufour, 2007)). We performed principal component analyses on normalised counts (DESeq
1346 basemean), and between groups analyses on the resulting components, which allowed us
1347 to quantify the proportion of variance associated with each factor.

1348 We used RAPToR (RAPToR_1.1.4, (Bulteau & Francesconi, 2021)) to estimate the offset
1349 between upper and lower molar development. We staged upper molar samples on
1350 reference made from lower molar samples conjointly for both species. Interpolations were
1351 done with gam models fit on 5 components of an ICA.

1352

1353 Expression levels estimation using RNA-seq and differential expression analysis

1354 For the whole tooth germ data (64 samples) we obtained 100 bp paired-end sequences,
1355 with on average 46.2M (millions) reads per sample. For epithelium/mesenchyme and
1356 bucco/lingual data (respectively 20 and 8 samples), we obtained 50 bp single-end
1357 sequences, with on average 93.7M and 48.6M reads per sample respectively. Raw data are
1358 publically available in ENA with project accession number: PRJEB52633.

1359

1360 These reads were mapped by using Kallisto (version 0.44.0, (Bray et al., 2016)) to custom
1361 reference sequences for hamster and mouse transcriptomes. To generate them, we
1362 retrieved mouse and hamster cDNAs from Ensembl (release 93, July 2018, assemblies
1363 GRCm38.p6 and MesAur1.0 (Howe et al., 2021)), selected 14536 pairs of one-to-one
1364 orthologous transcripts, realigned pairs of sequences with Macse (macse_v2.01, (Ranwez et
1365 al., 2011)) and cropped the alignments to get orthologous segments by using custom
1366 scripts to make expression levels comparable between species.

1367

1368 Differential gene expression analysis (DE analysis) was performed on smoothed expression
1369 profiles over developmental age. Developmental age was estimated with embryo weight
1370 (GAM models above) and stages were homologized based on morphological criteria at
1371 early cap stages and late bell stage (14.5/18.0 days in mouse; 12.2/14.5 days in hamster).
1372 These boundaries, confirmed by PCA analysis of the transcriptome data (Figures 1 and S1)
1373 were used to convert days of development into relative development age (0-10).

1374

1375 Expression profiles were fitted by third degree polynomial splines with 2 interior knots, for
1376 each tooth and species (bs function of spline R package (W. Wang & Yan, 2021),
1377 independently or jointly within tooth and/or species, as explained below. Nested models
1378 were tested by DESeq2 (Love et al., 2014) and the best model was chosen for each gene by
1379 comparing the fit of these nested models (FDR adjusted p-value < 0.05 from DESeq2 LRT
1380 tests). When we compared temporal profiles between species, we accounted for the
1381 average level of expression in each species. This is to focus on changes in regulation over
1382 development, and to discard potential remaining artefacts in species-specific
1383 quantifications. Several tests were performed and are described below with the
1384 corresponding figure number.

1385

1386 To model temporal expression profiles in each species separately (Related to Figure 2A), we
1387 compared a “simple” model with a single curve for both time series to a “complex” model
1388 with one specific curve per tooth. This procedure does not directly provide the sense of the
1389 bias. To estimate it in each species, we computed the values predicted by the upper and

1390 lower models for 100 equally distributed points (i) on the timeline, and measured the
1391 distance point by point as follows : $\text{sum}((\text{up}(i)-\text{low}(i))/(\text{up}(i)+\text{low}(i)))$ (Mus.dist.sign or
1392 Ham.dist.sign in Table S2). This measure evaluates whether overall, expression levels in
1393 upper molar are above or below lower molar's.

1394

1395 To model the divergence of temporal expression profile in each tooth type separately
1396 (Related to Figure 6D), we compared a "non-divergent" model with a single curve to fit
1397 both time series (with a species-specific offset to only consider the temporal dynamic), to a
1398 "divergent" model with one specific curve per species (with a species-specific offset).

1399

1400 To model temporal expression profiles in the 4 tooth types with tooth-specificity in one
1401 species (related to Figure 3B), the four time series were modelled as in the
1402 "hamster/mouse", plus "mouse tooth-specific" and "hamster tooth-specific" models, which
1403 correspond to distinct curves for upper and lower molars in one species, but not in the
1404 other. Genes were selected by comparison with the "hamster/mouse" model above.

1405

1406 Selection of the temporal expression profile in the 4 tooth types was done as follows
1407 (related to Figure 6A). The "simple" model fits a single curve for the four time series. The
1408 "complex" model fits 4 different curves, one per tooth type. The "hamster/mouse" model
1409 has 2 different curves, one per species. The "upper/lower" model has one curve per tooth,
1410 including the species-specific offset. The best model was selected for each gene by using a
1411 bottom-up approach with the results of four independent tests: t1 compares
1412 "hamster/mouse" versus simple model; t2: "upper/lower" versus simple; t3: complex vs
1413 "upper/lower"; t4: complex vs "hamster/mouse". If t1 and t2 are not significant, then the
1414 simple model is chosen. If t1 is significant and not t2, the gene is assigned to:
1415 "hamster/mouse". If t2 but not t1: "upper/lower". Finally, if "lower/upper" or
1416 "hamster/mouse" and t4: complex.

1417 From this selection procedure, percentage of coevolution among genes was computed as
1418 the proportion of selected "hamster/mouse" models among the selected models as follows
1419 (related to Figure 6A): $\text{"hamster/mouse"}/(\text{"hamster/mouse"} + \text{"upper/lower"} + \text{"complex"})$.

1420

1421 We then computed the intersection of the results with several lists of genes important for
1422 tooth development: 259 genes from the bite-it database (retrieved in July 2019), 187 genes
1423 with a phenotype in tooth development (100 “dispensable” genes, 87 “keystone” genes,
1424 (Hallikas et al., 2021)), and 295 genes belonging to 8 pathways active in tooth development
1425 (17 genes in ACTIVIN pathway, 81 in BMP, 10 in EDA, 69 in FGF, 32 in SHH, 9 in NOTCH,
1426 11 in TGFB, 96 in WNT, courtesy Jukka Jernvall).

1427

1428 Gene Ontology analysis

1429 Gene ontology (GO) analysis was performed and visualised with gprofiler2 (gprofiler2_0.2.0,
1430 (Kolberg et al., 2020)), clusterProfiler (clusterProfiler_3.18.1, (Wu et al., 2021)), and
1431 simplifyGO (simplifyEnrichment_1.2.0 (Gu & Hübschmann, 2021)) using the full list of genes
1432 expressed in the corresponding dataset as a background.

1433

1434 Measure of pathway activation in RNAseq samples

1435 ROMA was used to quantify activation of WNT, BMP and SHH pathways in the bucco-
1436 lingual samples (version rRoma_0.0.4.2000, <https://github.com/Albluca/rRoma> and
1437 (Martignetti et al., 2016)). ROMA is designed to compare pathway activity in transcriptomic
1438 samples based on expression levels of a list of targets for the pathway. Genes for the SHH
1439 modules were retrieved from GSEA ((Mootha et al., 2003), 41 genes present in our dataset).
1440 Because BMP and WNT pathways are active both in the mesenchyme and the epithelium
1441 and they target different genes in each tissue (O’Connell et al., 2012), we used two
1442 separate lists of targets to estimate both an epithelial and a mesenchymal activity, adapted
1443 from a “regulatory evidence” dataset established for first lower molar development
1444 (O’Connell et al., 2012). Building on literature and their own transcriptomic analysis, the
1445 authors had defined target genes based on their up or downregulation following activation
1446 or inactivation of each pathway. For data consistency, we selected only targets established
1447 in the study from transcriptome analysis, in 13.5 and 14.5 dpc epithelium and 10.5 dpc
1448 mesenchyme. Different modules were built for activities in the mesenchyme and epithelium
1449 compartments. For BMP in the mesenchyme, we considered 15 genes as positive targets

1450 and 4 as negative targets (further noted 15:4). In the epithelium, the numbers of
1451 positive:negative targets were respectively 32:34. For WNT, we built modules with 4:31
1452 positive:negative targets in the mesenchyme, and 33:45 in the epithelium. These in-silico
1453 quantifications were consistent with many known aspects of tooth development. Buccal
1454 compartments all show high levels of pathway activity, consistent with the presence of the
1455 first SEK acting as a source of WNT, BMP and SHH signals. Lingual compartments show
1456 much lower levels of signalling activities than buccal compartments, consistent with their
1457 distance to the first SEK. The lower lingual compartments show BMP and WNT activities
1458 that are higher in epithelium than in mesenchyme, consistent with the fact that epithelial
1459 activation predates mesenchymal activation in tooth development.

1460

1461 Estimating tissue proportions from RNA-seq data by deconvolutions

1462 We used the R package DeconRNASeq (DeconRNASeq_1.32.0 (Gong & Szustakowski,
1463 2013)) to estimate the relative proportions of epithelium and mesenchyme compartments in
1464 bulk tooth germ transcriptomes. We defined lists of marker genes for each compartment by
1465 pairwise differential analysis of tissue-specific transcriptomes (DESeq2, log2 fold change >
1466 3, adjusted p-value < 0.05). We used 1025 mesenchyme and 621 epithelium marker genes
1467 found by comparing 10 epithelium and 10 mesenchyme RNAseq samples, mixing tooth,
1468 stages and species. We estimated the accuracy of the prediction by bootstrapping 1000
1469 times the marker lists. The relative proportions of buccal and lingual compartments was
1470 inferred by a similar procedure. We used 414 buccal and 235 lingual marker genes, from
1471 the differential analysis of 8 samples (DESeq2, log2 fold change > 1, adjusted p-value <
1472 0.05).

1473

1474 Expression levels and transcriptome dynamics in bats

1475 We downloaded all bats and mouse raw RNA-seq samples from a published dataset
1476 (SRP061644, Maier et al. 2017), totalizing 17 samples in mouse and 16 in bat (*Carollia*
1477 *Perspicillata*) at three consecutive stages: ridge (CS13), bud (CS14) and paddle (CS15)
1478 stage. Bat reads were assembled *de novo* with Trinity v2.14.0 (Grabherr et al., 2011), by
1479 using single end mode and *in silico* normalisation. Bat expression levels were quantified by

1480 Salmon (Patro et al., 2017) with the script provided by Trinity
1481 (align_and_estimate_abundance.pl). Mouse reads were directly mapped with Salmon to the
1482 GENCODE mouse transcriptome reference (gencode.vM29.pc, (Frankish et al., 2021)). Bat
1483 transcripts were assigned to mouse orthologs by blastn (Altschul et al., 1990). Blast and
1484 Trinity were run with prebuilt dockers. Differential analysis was run over smoothed
1485 expression profiles like in the method section “Expression levels estimation using RNA-seq
1486 and differential expression analysis”. Code is available here:
1487 <https://github.com/msemon/DriftHamsterMouse>

1490

1491 ACKNOWLEDGEMENTS

1492

1493 We acknowledge the contribution of several platforms of SFR Biosciences Gerland-Lyon Sud
1494 (UMS344/US8): the Plateau de Biologie Expérimentale de la Souris (PBES) (many thanks
1495 especially to Jean-Louis Thoumas, Tiphaine Dorel, Céline Angleraux, Marie Teixeira, Myriam
1496 Prudent), the Plateau Technique Imagerie/Microscopie (PLATIM) and the ANIRA/IMMOS
1497 platform with Mathilde Bouchet; as well as the computer resources from PSMN (ENS Lyon).
1498 We acknowledge the technical help of Anne Lambert, Alain Rubod, Mathilde Estevez-Villar,
1499 Claudine Corneloup and the contribution of many students including Coraline Petit, Alice
1500 Lorenc, Margaux Pillon, Ludivine Rotard and Asma Benahmed. We are grateful to several
1501 colleagues and their staff for sending plasmid probes: Irma Thesleff (*Fgf4*), Hiko Ogura
1502 (*Cv2/Bmper*), D. Duboule (*Fgf10*). We are grateful to Pamela Lockyer, Cam Patterson and
1503 Xinchun Pi for collecting our very first *Bmper* embryos. We are grateful to Jennifer Esser for
1504 kindly providing the *Bmper* strain and advice on genotyping. We kindly thank Mirko
1505 Francesconi, Marie Delattre, Michaelis Averof, Pascal Hagolani for their feedback on the
1506 manuscript.

1507

1508 This work was supported by the Agence Nationale pour la Recherche (ANR 2011 JSV6 00501
1509 “Convergdent”), a grant from the GENOSCOPE - Centre National de Séquençage and a
1510 grant from IDEX Lyon ANR-16-IDEX-0005. Salaries were supported by the Centre National
1511 de la Recherche Scientifique, the Ecole Normale Supérieure de Lyon and the Université de
1512 Lyon, Université Lyon 1. Klara Steklikova benefited from a Barrand Fellowship program.
