## Abstract

The removal of the non-steroidal anti-inflammatory drug (NSAID) Naproxen (NAX) in water by hydroxyl radicals ( $\cdot\text{OH}$ ) was performed by electrochemical advanced oxidation processes either with Pt or BDD anodes and a 3D carbon felt cathode. The degradation of NAX by ( $\cdot\text{OH}$  vs. electrolysis time) was well fitted to a pseudo-first-order reaction rate kinetic. The detected reaction intermediates (aromatic compounds and carboxylic acids) were experimentally monitored during the process via LC, while density functional theory (DFT) was applied to uncover undetected intermediates, some for the first time in literature. The formation of toxic intermediates with higher toxicity than NAX were identified, such as IMS4b (6-Methoxy-1-[1-(6-methoxynaphthalen-2-yl) ethyl] naphthalen-2-ol), catechol, and glycolic acid. Based on these data, a detailed oxidation pathway of NAX by  $\cdot\text{OH}$  was proposed. The evolution of solution toxicity indicated that formed toxic intermediates were subsequently removed during the TOC removal process. Finally, almost complete mineralization of NAX was achieved in simulated urine or wastewater, by the electro-Fenton treatment with an optimized dose of iron as catalyst, showing the EAOPs' potential to efficiently remove NAX even from challenging matrices. In extension, the strategies developed can be applied to the treatment of other NSAIDs.

**Keywords:** Naproxen, Electro-Fenton, Reaction intermediates, Mineralization pathway, Density functional theory, Toxicity

## 1. Introduction

The global pharmaceutical market has experienced a significant growth over the recent decades, with thousands of tons of pharmaceuticals consumed worldwide [1]. Among these pharmaceuticals, non-steroidal anti-inflammatory (NSAIDs) are used by more than 30 million people every day. Naproxen (NAX 6-methoxy- $\alpha$ -methyl-2-naphthalene acetic acid) is found in the list of popular pharmaceuticals consumption (Table S1). It was monitored in environmental samples globally as frequently as Diclofenac [2], at concentrations in waters from ten to five hundred-fold greater than the threshold value suggested by the European Medicine Agency (EMA) [3].

Nearly 60% of NAX is excreted as metabolites and 10% as unchanged form leave our bodies via urine. Researchers have considered NAX to be an emerging contaminant, considering its trace levels in the bile of fish of lakes receiving treated wastewater from municipal WWTPs [4]. Several works have proved that long-term exposure of NAX can increase the potential of heart attack in humans [5, 6]. Furthermore, the by-products of NAX pose a chronic toxicity higher than its acute toxicity levels by bioassay tests, which may be due to the stability of the NAX chemical structure (i.e., the naphthalene ring) [4, 7, 8].

It is accepted that the effluents (96% of occurrence) play an important role as pollutant sources to surface water [9]. Unfortunately, the pharmaceutical compounds and their metabolites, usually treated by WWTPs, reach the environment without undergoing any changes [10], since conventional treatment methods are unable to remove them. Even more, their ecotoxicity, as well as their metabolites or mixture of compounds, are still poorly investigated, raising public concern on their potential risk for the organisms living in terrestrial and aquatic environments [2, 11, 12]. The physicochemical properties of NAX limit its biodegradation by traditional wastewater treatment

processes leads to appeal for more effective treatment methods such as the advanced oxidation processes (AOPs) [13].

A variety of advanced oxidation processes, including UV photolysis of chemical oxidants (e.g., H<sub>2</sub>O<sub>2</sub>, chlorine, peracetic acid, etc.) [14-16], semiconductor photocatalysis, Fenton, photo Fenton and electro-Fenton have been described [15, 17-19]. Despite the high degradation of recalcitrant contaminants of these AOPs, each method has its own drawbacks; the UV light penetration maybe obstructed by water turbidity, chlorine oxidation may induce higher toxic by-products, new pollutants released into environment, high cost of storage of reagents (e.g., H<sub>2</sub>O<sub>2</sub>) or extra iron sludge generated as Fenton reactions [20, 21]. Electro-Fenton (EF) process has been developed as electrochemical advanced oxidation process (EAOP) where the reaction between electrogenerated the H<sub>2</sub>O<sub>2</sub> from dissolved O<sub>2</sub> on a carbonaceous cathode and externally added catalyst (iron II salt) leads to the in-situ generation of strong oxidants hydroxyl radical ( $\cdot\text{OH}$ ) via the Fenton's reaction [22, 23]. Anodic oxidation (AO) process is another EAOP where  $\cdot\text{OH}$  are produced at the surface of anode [24].  $\cdot\text{OH}$  is able to oxidize the organic pollutants in a non-selective oxidation way, causing, among others, ring opening and other significant transformations in a short timescale. Moreover, EF reacts till conversion of organics to final products of H<sub>2</sub>O, CO<sub>2</sub> and inorganic ions [25]. Due to the potential safety risks in storage and transportation of H<sub>2</sub>O<sub>2</sub>, and presence of wasting reactions decreasing process efficiency, EAOPs are considered as more environmentally friendly technologies for the removal of persistent organic pollutants [26]. The main benefit is the significantly lower input of catalyst in EF, due to the regeneration of Fe<sup>2+</sup> from electroreduction of Fe<sup>3+</sup> at the cathode, or generation of  $\cdot\text{OH}$  in AO without adding any chemicals, conducting to the effective elimination of refractory organics.

In EAOPs, in situ generated  $\cdot\text{OH}$  react with organic compounds at a high rate, of around 10<sup>6-9</sup> M<sup>-1</sup> s<sup>-1</sup>

[26]. However, the lifetime of important “transition” pollutants’ intermediates of pollutants is less than  $10^{-2}$  s, rendering their detection challenging. Besides, the detailed mechanisms of degradation, specifically, to locate the  $\cdot\text{OH}$  attack sites of the target molecules, are still not available by current analytical technologies. In this case, quantum chemical studies are applied to predict the kinetic behaviours of organic compounds in advanced oxidation technologies [27]. Recently, the by-products in the first step of the oxidation reaction between NAX and  $\cdot\text{OH}$  in water were modeled on molecular level using a density functional theory (DFT) approach [28]. Initially, it was proposed that decarboxylation of NAX was performed by deprotonation [29], and most DFT investigations on the intermediates’ oxidation by  $\cdot\text{OH}$  were attributed at the “side-chain” reaction of NAX [30]. However, significantly less work has been dedicated on the “ring-opening” reaction, hence important parts of the mechanism of NAX degradation mechanism by  $\cdot\text{OH}$  oxidation systems are missing. At the same time, deep investigations of the contribution of these intermediates to the toxicity evolution during  $\cdot\text{OH}$ -mediated oxidation of NAX are also missing.

Therefore, in our work, the main focus was the experimental and theoretical investigation on the degradation of NAX and the intermediates produced during its electrochemical advanced oxidation, and its toxicity evolution. To this end, we monitored the evolution of the toxicity of intermediates produced during processes by Microtox, while following the decay kinetics and mineralization of NAX, as well as the generated carboxylic acids. In this novel approach, our methods aimed at clarifying the dominant mechanism of NAX mineralization by identifying the most important intermediates, assessing the safety of the NAX oxidized by  $\cdot\text{OH}$ , and allowing to set up a valid intermediates-toxicity correlation. Based on the experimentally determined by-products and theoretically obtained ones (DFT calculation results), we proposed a plausible reaction sequence for NAX degradation. Finally,

based on the present understanding on the EAOPs effect on NAX elimination, our treatment methods were assessed in a more complex matrix of high relevance to NAX, such as urine and wastewater, validating the high efficiency of these technologies in a more realistic setting.

## 2. Materials and methods

### 2.1 Chemicals and Reagents

Naproxen (NAX), sodium sulfate ( $\text{Na}_2\text{SO}_4$ ) and iron (II) sulphate heptahydrate ( $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ ) were purchased from Sigma-Aldrich. *p*-hydroxybenzoic acid (*p*-HBA,  $\text{C}_7\text{H}_6\text{O}_3$ ) was used as competition substrate in the kinetic experiments. NAX solution was prepared in tap water (4.56 mg/250 mL corresponding to the final concentration of 0.198 mM). The pH of the solutions was adjusted using analytical grade sulfuric acid and/or sodium hydroxide. The main intermediates and short chain carboxylic acids were all obtained from Alfa Aesar Co, whose detailed information were listed in Table S12. For synthetic wastewaters preparation, urea ( $\text{CH}_4\text{N}_2\text{O}$ ), sodium acetate ( $\text{NaC}_2\text{H}_3\text{O}_2$ ), sodium dihydrogen phosphate ( $\text{NaH}_2\text{PO}_4$ ), potassium dihydrogen phosphate ( $\text{KH}_2\text{PO}_4$ ), potassium chloride (KCl), sodium hydroxide (NaOH), magnesium chloride hexahydrate ( $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ), calcium chloride dihydrate ( $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ ) and ammonium chloride ( $\text{NH}_4\text{Cl}$ ) were purchased from Merck. All other materials were purchased with purity higher than 99%.

### 2.2 Electrolytic experiments

Experiments were performed at room temperature ( $23 \pm 2^\circ\text{C}$ ), controlled by water flow in an open, cylindrical and one-compartment cell of inner diameter of 7.5 cm, with a working volume of 250 mL. A 3D carbon-felt (18.00 cm  $\times$  6.00 cm  $\times$  0.60 cm, from Carbone-Lorraine, France) was placed on the inner wall of the electrochemical as cathode. Pt (4.5 cm<sup>2</sup> Pt cylindrical mesh) or boron-doped diamond (BDD) thin-film on niobium substrate (24 cm<sup>2</sup> from Condias, Germany) were used as anode. Anodes were placed in the center of the cell. 1 L min<sup>-1</sup> of compressed air bubbled through the solution to saturate it in O<sub>2</sub> and the reaction medium was agitated continuously by a magnetic stirrer (800 rpm)

to ensure mass transfer during the experimental process. An AMEL 2055 potentiostat/galvanostat was used to apply a constant current. Electrolysis was conducted in 50 mM Na<sub>2</sub>SO<sub>4</sub> solution as supporting electrolyte (Fig. S1). The pH of the medium was adjusted to 3 by H<sub>2</sub>SO<sub>4</sub> with a CyberScan pH 1500 meter. An adequate dose of FeSO<sub>4</sub>·7H<sub>2</sub>O was added into initial solutions as catalyst for EF process. The experiments were conducted in triplicate in tap water, simulated urine and hospital wastewater (Table 1).

**Table 1. Composition of the simulated urine and hospital wastewater.**

### 2.3 Apparatus and analytical procedures

Concentration of NAX and its aromatic intermediates were monitored by high performance liquid chromatography (HPLC). The experiments were conducted at a lower current intensity of 50 mA, which allows slow reactions to proceed and ease the monitoring of the by-products produced during the degradation. The mobile phase for analyses was a mixture of methanol/water/acetic acid (69:29:2 (v/v/v)) at a flow rate of 0.20 mL min<sup>-1</sup>. Measurements were carried out by a Merck/Hitachi LaChrom chromatograph equipped with a Purospher RP-18 column (5 μm, 25 cm×3 mm (i.d.)), coupled with

an L-2400 UV detector set at 240 nm and 40°C. The identification and quantification of carboxylic acids as terminal by-products were performed by ion-exclusion HPLC with a Supelcogel H column (4.60 mm × 25.00 cm) using a mobile phase formed of 1% H<sub>3</sub>PO<sub>4</sub> solution at the detection wavelength set at 210 nm. The identification and quantification of by-products were achieved by comparison of retention time and area of peaks with that of pure products. The injection volume was 20 µL. Measurements were controlled through EZChrom Elite 3.1 software. The mineralization degree of samples was determined on a Shimadzu VCSH TOC analyzer by determining the abatement of total organic content. Reproducible total organic content (TOC) values with ±2% accuracy were obtained using the non-purgeable organic carbon (NPOC) method.

The mineralization current efficiency (MCE in %) is an indicator for assessment of the capacity of current intensity application. It can be calculated according to the Eq. (1) at a given electrolysis time *t* (h) [26, 31]:

$$\text{MCE} = \frac{n F V_s \Delta(\text{TOC})_{\text{exp}}}{4.32 \times 10^7 m I t} \times 100 \quad (1)$$

where *n* is the number of electrons consumed per molecule mineralized (i.e. 64), *F* is the Faraday constant (96487 C mol<sup>-1</sup>), *V<sub>s</sub>* is the solution volume (L), Δ(TOC)<sub>exp</sub> is the experimental TOC decay (mg L<sup>-1</sup>), 4.32 × 10<sup>7</sup> is a homogenization factor (3600 s h<sup>-1</sup> × 12,000 mg mol<sup>-1</sup>), *m* is the number of carbon atoms of NAX (14) and *I* is the applied current intensity (0.10 - 0.75 A).

The assessment of the potential toxicity of NAX and its intermediates was conducted following the international standard process (DIN 11348-3), by the inhibition of the luminescence (%) of bioluminescent marine bacteria *V. fischeri* (Lumistox LCK 487, Hach Lange France SAS), known as the Microtox® method. The value of the inhibition of the luminescence (%) was measured after 15 min of exposure of bacteria to treated solutions at 15 °C. The bioluminescence measurements were

performed on solutions electrolyzed at different constant current intensities ( $I = 0.10$  and  $0.30$  A). The inhibition toxicity of the samples was expressed as a percentage inhibition compared to the blank ( $C_0 = 0 \text{ mg L}^{-1}$  of NAX).

## 2.4 Computational methods

The optimized theoretical calculations were implemented using the Gaussian 16-A03-AVX2 (09 D.01 program) package based on density functional theory (DFT) [32]. Molecular geometries of all intermediates and transition states (TS) were optimized by M05-2X/6-31+G\*\* level of theory (Fig. S2) [28]. The single point energy was calculated by B2PLYPD3 functional and def2TZVP basis set with higher accuracy. The energy calculations of all structures were thermodynamically corrected [33, 34]. The solvent effects were taken into consideration by using the solvation model of density (SMD) [35]. Vibrational analysis was carried out to confirm that each structure is a true minimum or a saddle point. Intrinsic reaction coordinate (IRC) calculations were performed to assure the transition states connected the reactants and products for each elementary reaction [36].

Conventional TS theory was used to predict the rate of reaction between molecular and  $\cdot\text{OH}$  at 298 K in water with the standard state [37] through Eqs. 2 and 3:

$$k = \sigma \Gamma(T) \frac{k_B T}{h} e^{-(\Delta_{\ddagger}^{\ddagger} G)/RT} \quad (2)$$

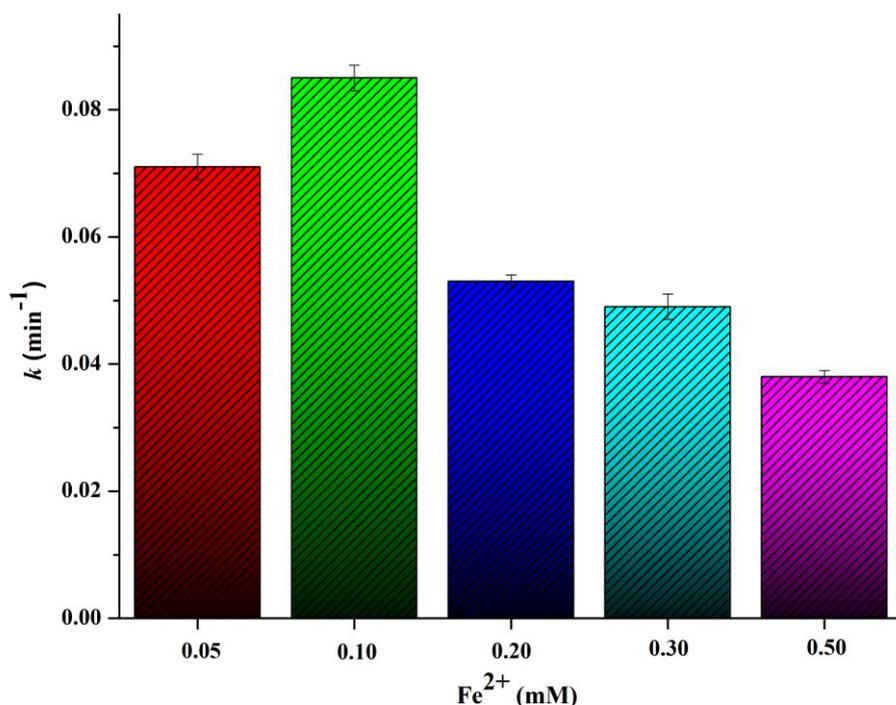

$$\Gamma(T) = 1 + \left(\frac{1}{24}\right) \left[1.44 \frac{v_i}{T}\right]^2 \quad (3)$$

Where  $\sigma$  presents the degeneracy of the reaction pathway,  $\Gamma(T)$  is the tunneling correction factor approximated by Wigner approach [38],  $k_B$  is the Boltzmann's constant,  $T$  is the temperature,  $h$  represents the Planck's constant, and  $\Delta_{\ddagger}^{\ddagger} G$  is the Gibbs free energy of activation and  $v_i$  is the imaginary frequency, whose vibrational motion is the direction of the reaction.

### 3. Results and discussion

#### 3.1 Determining optimal values of electrochemical parameters on NAX removal

The catalyst concentration is an important parameter in the EF processes that strongly influences organic pollutants removal efficiency [22]. The optimized concentration of ferrous iron was varied from 0.05 to 0.5 mM (Fig. 1) in the EF process with Pt anode (EF-Pt). The maximum degradation rate of NAX was obtained for a catalyst concentration of 0.10 mM. Interestingly, the NAX oxidation rate catalyst led to increase in the rate of the competitive reaction between  $\text{Fe}^{2+}$  and  $\bullet\text{OH}$  (Eq. (4)) causing a lower NAX degradation efficiency [39, 40].

**Fig. 1. Apparent rate constant of naproxen oxidation by  $\bullet\text{OH}$  at different concentration of ferrous ion (catalyst) in tap water medium by EF-Pt process.  $[\text{NAX}]_0 = 0.198 \text{ mM}$ ;  $[\text{Na}_2\text{SO}_4] = 50 \text{ mM}$ ;  $V = 0.25 \text{ L}$ ;  $\text{pH} = 3.0$ ; current intensity: 0.10 A.**

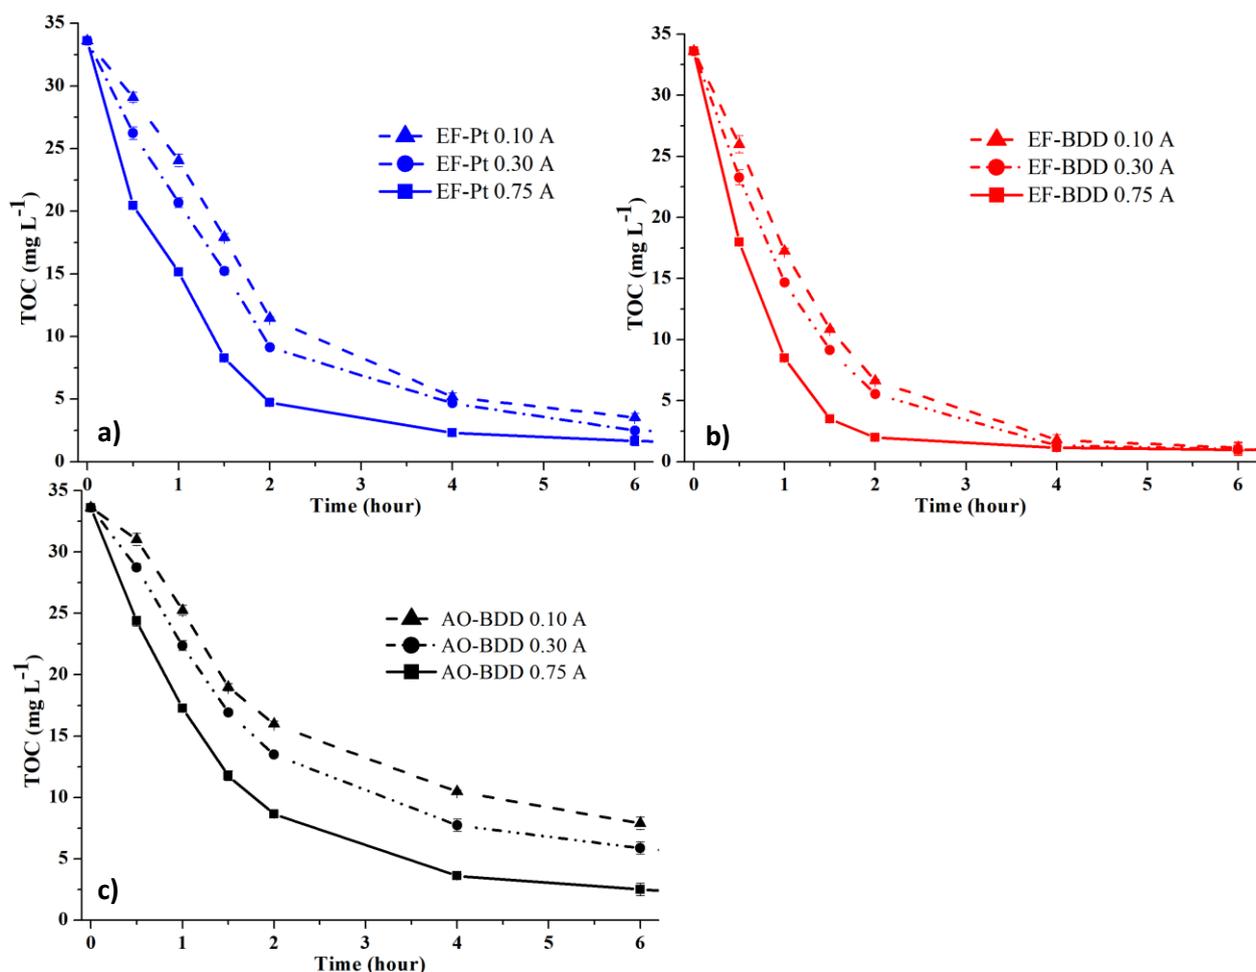

NAX mineralization was found to be dependent to the applied current value as its TOC removal rate. For instance, TOC abatement rate after 4 h of electrolysis was 84.60%, 94.60% and 68.80% at 0.10 A for EF-Pt, EF-BDD and AO-BDD, respectively (Fig. 2). The current is a main parameter for EAOPs since it governs the electrochemical reaction generating  $\bullet\text{OH}$  in the bulk and on the anode surface. Thus, an applied current intensity ranging from 0.10 to 0.75 A was tested in the EAOPs processes with Pt BDD anodes vs. carbon felt cathode to monitor the degradation and/or mineralization of 0.198 mM NAX. The degradation rates of NAX increased with increasing current values (Fig. 3a). NAX degradation fits well the both pseudo-first order reaction kinetics -  $k_{app}$  ( $R^2 > 0.981$ , Table S3) and retarded first-order model (Eq. (5)) kinetics -  $k_a$  ( $R^2 > 0.940$ , Table S3) [41].

core-shell particles

$$\frac{dC_t}{dt} = \frac{k_a}{1+\alpha t} C_t \text{ or } C_t = C_0 (1 + \alpha t)^{-k_a/\alpha} \quad (5)$$

where  $C_0$  and  $C_t$  are NAX concentration ( $\text{mg L}^{-1}$ ) at time 0 and  $t$  (min), respectively,  $k_a$  is the apparent rate constant ( $\text{min}^{-1}$ ), which is analogous to the initial pseudo-first-order rate constant, and retardation factor  $\alpha$  describes the decline of the reaction rate with time.

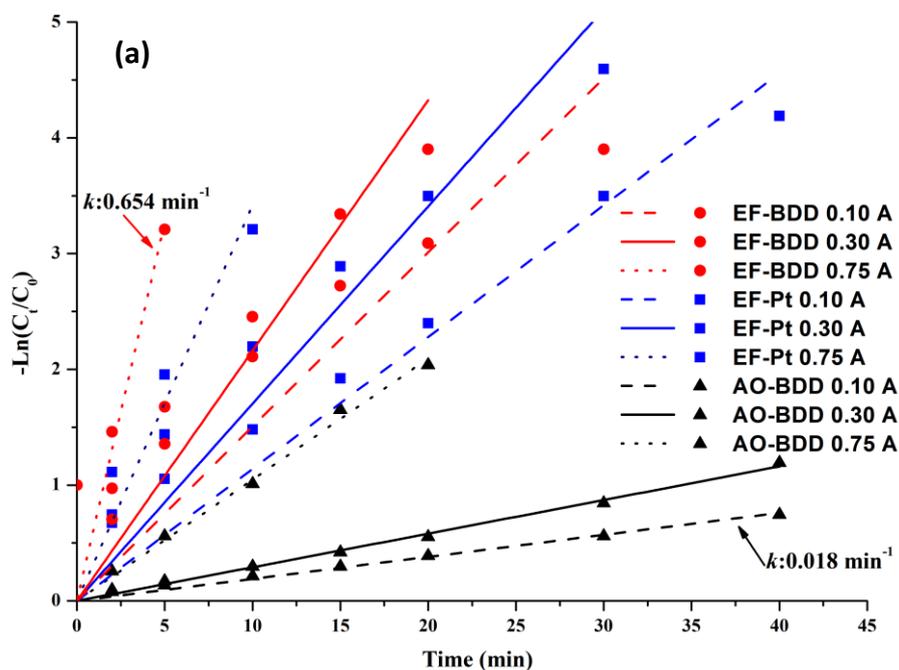

Higher  $k_{app}$  and  $k_a$  values were found for EF when compared with AO; specifically, the  $k_{app}$  of EF-BDD was about 7-fold higher than that of AO-BDD at same current intensity. The  $k_{app}$  values of EF-Pt were lower than that of EF-BDD (Table S2), which is related to the production of supplementary, highly reactive  $\bullet\text{OH}$  on the surface the BDD ( $\text{BDD}\bullet\text{OH}$ ), compared with the Pt anode [42]. Pt anodes have a lower  $\text{O}_2$  evolution overpotential, with relatively less  $\text{Pt}(\bullet\text{OH})$  which are chemisorbed, thus are less reactive. Meanwhile, the higher current values accelerate  $\text{H}_2\text{O}_2$  and  $\text{Fe}^{2+}$  formation kinetics and consequently promote  $\bullet\text{OH}$  generating rate, resulting in higher degradation efficiency of NAX [43].

**Fig. 2. Effect of applied current intensity on mineralization of naproxen by  $\bullet$ OH in tap water during its oxidative degradation by EAOPs.**

Then, TOC removal rate become very low indicating a significantly lower current efficiency. The mineralization current efficiency (MCE) follows the order: EF-BDD > EF-Pt > AO-BDD as shown in Fig. 3b. The lower MCE value decelerated at higher current values can be attributed to: (i) decrease of organic matter in the solution, (ii) the competition between the formation of  $H_2O_2$  with the side reaction of the hydrogen gas evolution (Eq. (6)), (iii) promotion of parasitic reactions consuming  $\bullet$ OH (Eqs. (7) and (8)) [44] and (iv) the formation of hard-to-oxidize intermediates, such as carboxylic acids, due to their lower reaction rates with  $\bullet$ OH [45]. Therefore, a lower current intensity should be used,

for NAX removal in aqueous systems to avoid adverse effect such low current efficiency and high-energy consumption (Figs. 3b and 3c).

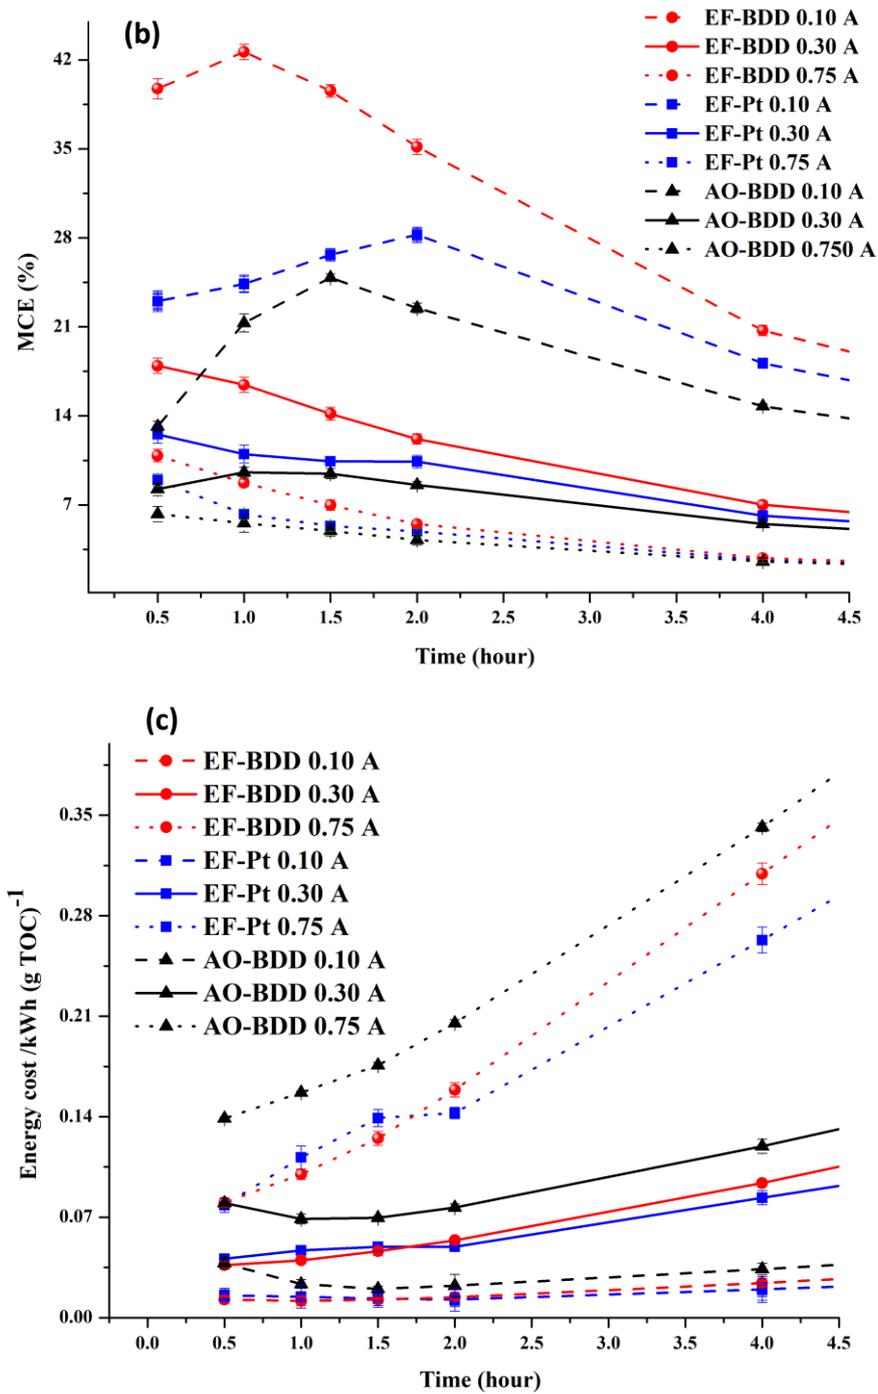

Fig. 3. (a): Linear relationship of  $-\ln(C_t/C_0)$  and operation time; (b): MCE value (%) of mineralization of NAX by  $\cdot\text{OH}$  and (c): Energy cost of mineralization of NAX under different current intensities in EAOPs.  $[\text{NAX}]_0 = 0.198$  mM;  $[\text{Na}_2\text{SO}_4] = 50$  mM;  $V = 0.25$  L; for EF:  $[\text{Fe}^{2+}] = 0.10$  mM;  $\text{pH} = 3.0$ ; for AO:  $\text{pH} = 7.5$ .

For the consideration of economic aspect of the treatment, the energy cost (EC) for the tests was

calculated using Eq. (9) [22]:

$$\text{Energy cost [kWh (g TOC)}^{-1}] = \frac{VIt}{\Delta(\text{TOC})_{\text{exp}} Vs} \quad (9)$$

in which, V is the cell voltage (V), t is the electrolysis time (h), and all other parameters are the same as for Eq. (1). The EC values ranged from 0.012 and 0.036, 0.012 and 0.047, 0.02 and 0.057 kWh (g TOC)<sup>-1</sup>, at 0.10 A, for EF-Pt, EF-BDD and AO-BDD, respectively.

As expected, the EC increases with increasing current intensity (Fig. 3c). Application of AO results in higher costs compared to the EF process, which indicates that trace catalyst iron addition could remarkably reduce the energy input. The lower EC was obtained around 1 to 2 h at 0.10 and 0.30 A, however, with an obvious increase at 0.75 A in all EAOPs. Hence, considering the degradation, mineralization and energy costs we show that the removal of NAX solution could be processed under lower current intensity within the first 2 h.

### 3.2 Toxicity analysis

The intermediates produced from oxidation of NAX have been often reported to manifest a higher toxicity than the parent molecule itself [46]. Hence, in order to understand the evolution of the toxicity of NAX solution during treatment, bioluminescence measurements were conducted after 15 min exposure to marine bacteria *V. fischeri* with solutions electrolyzed at different constant current intensities (I= 0.10 and 0.30 A) with BDD and Pt anodes at different electrolysis time (Fig. 4). The toxicity evolution of a blank sample ( $C_0 = 0 \text{ mgL}^{-1}$ ) was also assessed as reference and used for correction of the presented results.

As it can be seen from the curves of this figure, there was a significant increase of luminescence inhibition peaks within 20 min of electrolysis, which clearly showed that highly toxic intermediates

were produced during this interval of treatment. The research showed higher toxic intermediates than the parent molecule (NAX) produced in a different treatment process (i.e., photo-transformation) [47]. Similar results were also obtained by Jallouli et al. [46]. Compared to the initial toxicity level, all the samples displayed a lower percentage of bacteria luminescence inhibition after about 20 min of treatment, indicating that toxic intermediates were eliminated during the treatment.

The luminescence inhibition was higher with lower current intensity values, which is attributed to the lower formation rates of  $\bullet\text{OH}$  in these processes. At the same current intensity, a higher inhibition was obtained by the application of Pt anode, due to the lower oxidation power of Pt and the slower degradation of the organic matter in solutions, as indicated by the lower TOC abatement. Afterwards, the curves continuously decreased and there was a convergence between the curves of different anodes application, most possibly due to the similar products in the medium for the different processes, i.e., the short-chain carboxylic acids (*vide infra*, section 3.3). These compounds are relatively recalcitrant to  $\bullet\text{OH}$  but are all biodegradable. A high efficiency on removal of NAX and a decreased toxicity of the treated NAX solution makes EF-BDD process an applicable treatment at high pollutants' concentration from industrial wastewaters.

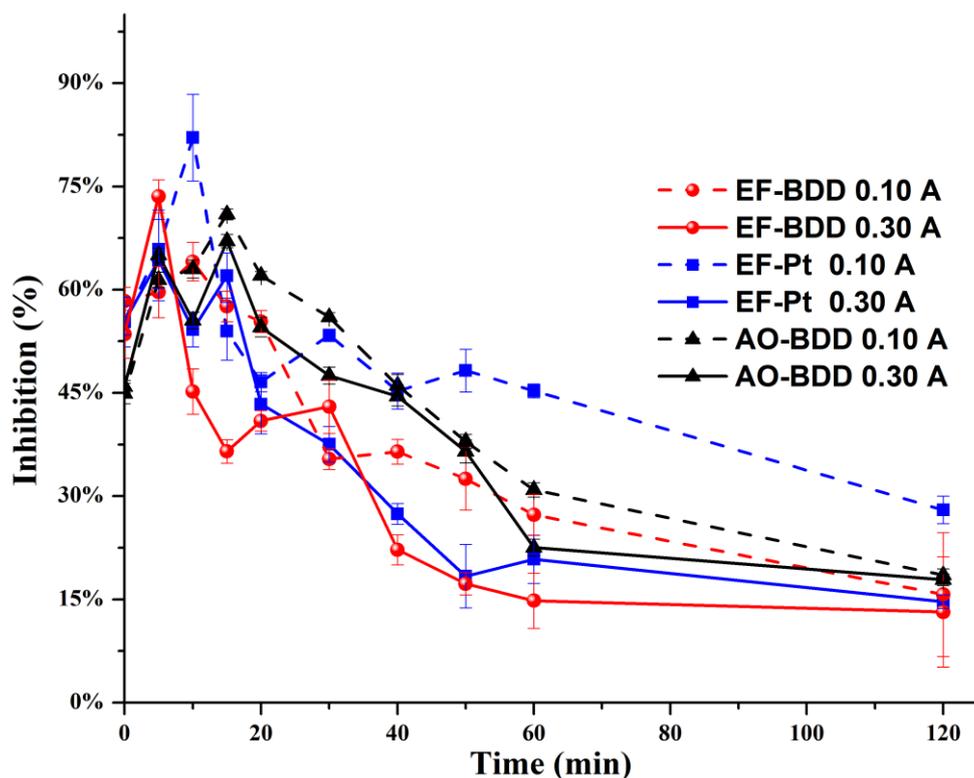

Fig. 4. Evolution of the inhibition of *Vibrio fischeri* luminescence (*Microtox*<sup>®</sup> test) during EAOPs.  $[NAX]_0 = 0.198$

mM;  $[Na_2SO_4] = 50$  mM;  $V = 0.25$  L; for EF:  $[Fe^{2+}] = 0.10$  mM; pH = 3.0; for AO: pH = 7.5.

### 3.3 Evolution of the detected mineralization intermediates of naproxen

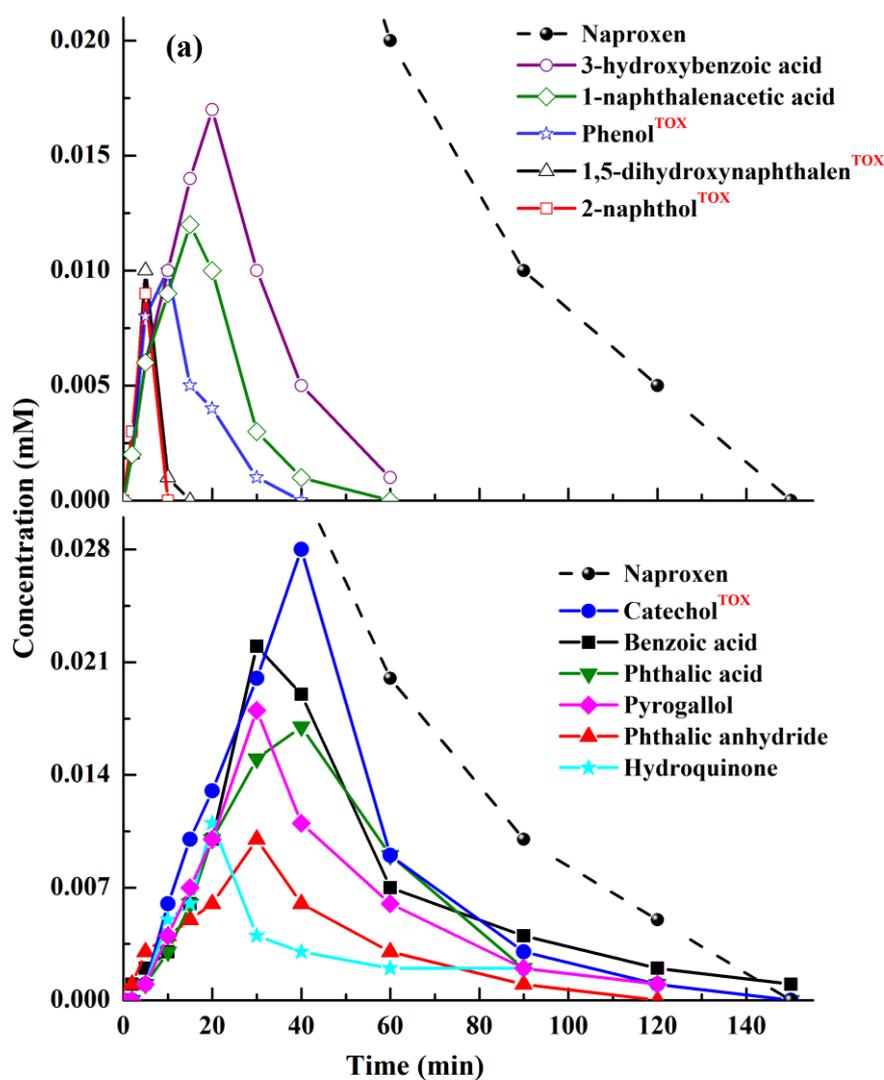

To investigate the mineralization mechanism of NAX by  $\cdot OH$  during EAOPs treatments, the experiments were conducted in deionized water and the resulting intermediates (i.e., aromatic by-products and short-chain carboxylic acids) were identified and quantified by comparison of retention time ( $t_R$ ) of standards compounds. The intermediates were identified as benzoic acid, hydroquinone, catechol, 3-hydroxybenzoic acid, pyrogallol, phthalic anhydride, phthalic acid, phenol, 1,5-dihydroxynaphthalene, 1-naphthaleacetic, and 2-naphthol, at  $t_R$  (min) of 2.97, 3.53, 4.7, 5.0, 5.3, 6.3, 6.9, 7.5, 8.0, 8.7, and 9.8, respectively (Fig. S3a).

Fig. 5a shows that high molecular-weight aromatic intermediates were formed at the early stage of

the electrolysis simultaneously with the disappearance of the parent molecule. 1,5-dihydroxynaphthalene, 2-naphthol, and phenol were first produced; it is well-known that these three compounds have high acute toxicity to aquatic life [48, 49], which explains the higher toxicity occurred in the former processes depicted in Fig. 4. Then, non-toxic compounds as 1-naphthalenacetic and 3-hydroxybenzoic acids appeared. The concentration of most of the aforementioned intermediates was less than 0.017 mM. Following, intermediates such as catechol, benzoic acid, phthalic acid, pyrogallol, phthalic anhydride and hydroquinone reached their highest concentration, then decreased gradually within the electrolysis time. These by-products were all formed in small quantities. However, compounds such as catechol, with a higher concentration at late stages of NAX elimination, pinpointed the second peak of luminescence inhibition. All the detected intermediates, except benzoic acid, were completely removed before the total elimination of NAX. Considering that persistent intermediates containing polar functional moieties were formed in Fenton-based reactions, such as hydroxyl and carboxyl groups, they are expected to be highly mobile in environmental systems, despite their high molecular weight.

The concentrations of the produced carboxylic acids were higher than that of aromatics (Fig. 5b), indicating that short-chain carboxylic acids were quickly generated from the oxidative breaking of the aryl moiety of aromatics in the EF process [50, 51]. The elution time for each acid was shown in Fig. S3b. Oxalic and formic acids persisted for longer, being the terminal carboxylic acids that are directly converted into CO<sub>2</sub> [42]. Glycolic and malic acid were identified at the beginning of electrolysis time and disappeared gradually, among which glycolic acid contributed the latter peak of inhibition % of bacteria shown in Fig. 4. Formic acid got to its maximum peak concentration of 0.08 mM after 1 h of electrolysis and then decreased gradually. Glyoxylic acid constantly appeared in the electrolysis time,

below 0.004 mM. Acetic acid was formed as the largest amount acid with its highest amount of 0.076 mM formed after 2 h electrolysis time. Oxalic acid gradually increased to its maximum peak concentration 0.197 mM after 2 h, meaning it can be produced from other carboxylic acids oxidized by  $\cdot\text{OH}$  (Fig. 5b). The glyoxylic acid may also derive from the oxidation of aryl moieties and then converted to oxalic acid [44]. Oxalic and acetic acids were persistent as the final intermediates during the whole processes. The lack of complete mineralization of NAX by the EF processes can be explained by the ferric-oxalate complexes, which are formed by terminal intermediates reaction with the ferric iron and are resistant to oxidation [52, 53].

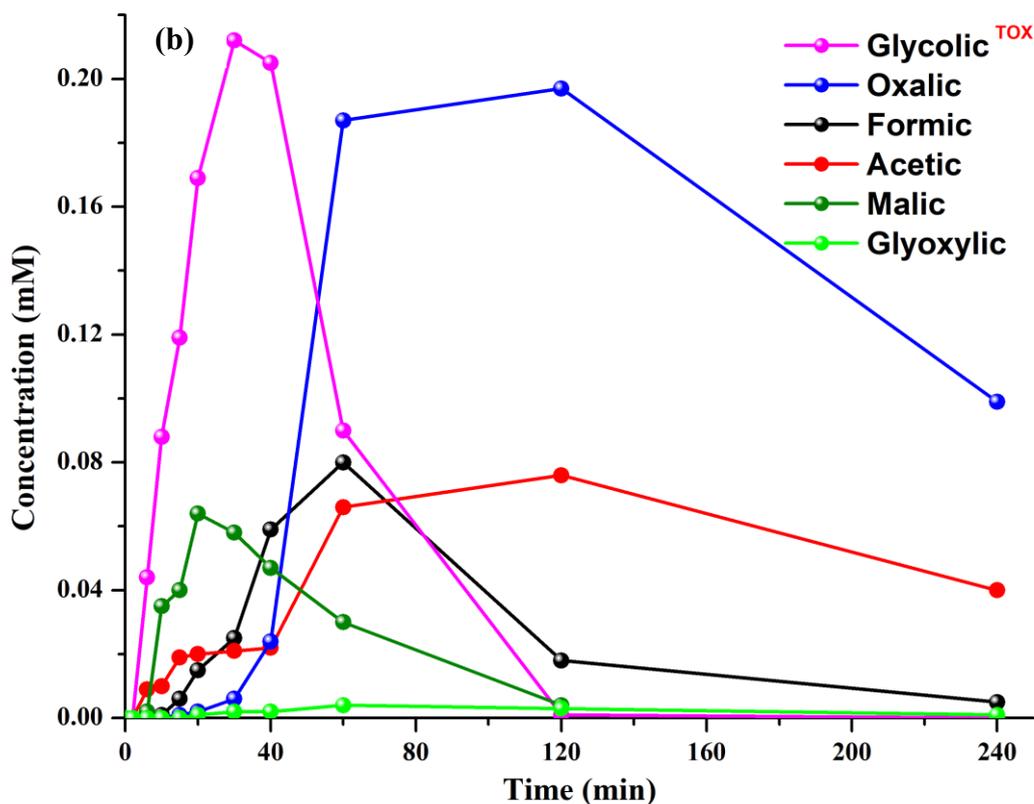

Fig. 5. Time course of the concentration of the main aromatic intermediates (a), and short chain carboxylic acids (b) accumulated during degradation of NAX in tap water medium: electro-Fenton process with Pt as anode.

$[NAX]_0 = 0.198 \text{ mM}$ ;  $[Na_2SO_4] = 50 \text{ mM}$ ;  $V = 0.25 \text{ L}$ ;  $[Fe^{2+}] = 1 \text{ mM}$ ;  $pH = 3.0$ ; current intensity = 50 mA.

### 3.4 DFT calculation of undetected intermediates oxidized by $\bullet OH$

DFT calculations were used to systematically compute the intermediates of NAX produced by  $\bullet OH$  in the separate pathways of “ring-opening” and “side-chain”. The optimized structure of NAX is represented in Fig. S4.

The intermediate and transition states of the first step reaction between NAX and  $\bullet OH$  at branched chain have been well investigated in the study of Luo [30]. The “side-chain” reaction by  $\bullet OH$  were investigated in our research at first part at possible site of NAX or intermediates of NAX.

### 3.4.1 Reaction at C<sub>7</sub>, C<sub>12</sub>, and C<sub>17</sub> of NAX

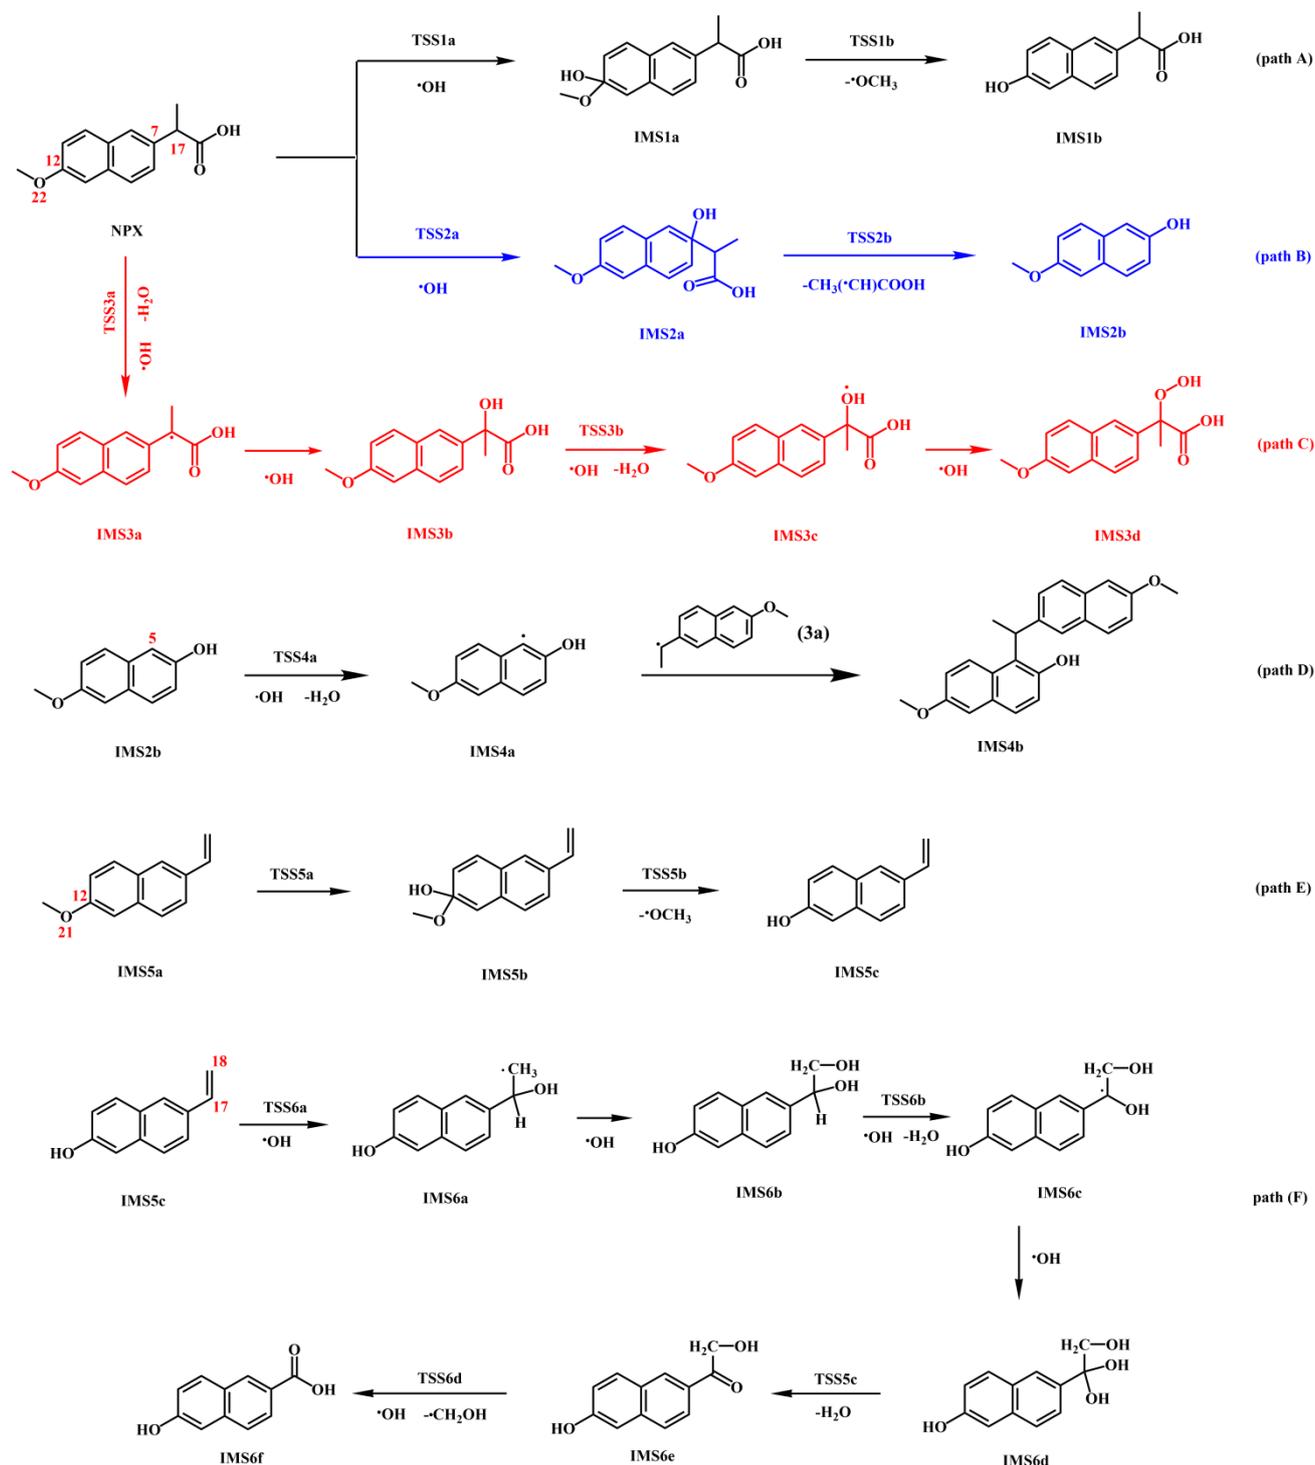

Fig. 6. "Side-chain" reaction of  $\cdot\text{OH}$  and NAX with calculated intermediates at C<sub>7</sub>, C<sub>12</sub>, and C<sub>17</sub> (path A-C); C<sub>5</sub>

**(path D); C<sub>12</sub> and C<sub>22</sub> (path E); and C<sub>17</sub> and C<sub>18</sub> (path F).**

<sup>•</sup>OH attacked C<sub>12</sub> (black) and C<sub>7</sub> (blue) of naphthalene, leading the formation of IMS1a and IMS2a, forming the new C<sub>12</sub>-O and C<sub>7</sub>-O at branched chain in NAX separately (Fig. 6 path A & B), the corresponding Gibbs free energy change  $\Delta G$  of IMS1a and IMS2a are  $\Delta G_{S1a} = 5.78 \text{ Kcal mol}^{-1}$  and  $\Delta G_{S2a} = 9.46 \text{ Kcal mol}^{-1}$  (Fig. S5a & b), respectively, which are consistent with Luo [30]. The corresponding second-order rate constants  $k_{S1a} = 3.58 \times 10^{10} \text{ s}^{-1}\text{m}^{-1}$ , and  $k_{S2a} = 7.21 \times 10^7 \text{ s}^{-1}\text{m}^{-1}$ .

IMS1a was further oxidized at C<sub>12</sub>-O<sub>22</sub> with -O-CH<sub>3</sub> broken off, of  $\Delta G_{S1b} = 11.21 \text{ Kcal mol}^{-1}$ , and  $k_{S1b} = 3.80 \times 10^4 \text{ s}^{-1}$ , forming IMS1b- 6-Desmethylnaproxen [11]; IMS2a oxidized at C<sub>7</sub>-C<sub>17</sub> with -CH-CH<sub>3</sub>-COOH off, of  $\Delta G_{S2b} = 12.16 \text{ Kcal mol}^{-1}$ , and  $k_{S2b} = 7.58 \times 10^3 \text{ s}^{-1}$ , forming IMS2b - 6-Methoxy-2-naphthol (Fig. S5a & b) [54].

<sup>•</sup>OH attacked C<sub>17</sub> of the branched chain of NAX, producing IMS3a radical (Fig. 6 path C & Fig. S5c), of  $\Delta G_{S3a} = 21.04 \text{ Kcal mol}^{-1}$ , and  $k_{S3a} = 2.12 \times 10^{-1} \text{ s}^{-1}\text{m}^{-1}$ . Furthermore, one <sup>•</sup>OH added in the C<sub>17</sub> with the formation of IMS3b, which is dehydrated to produce active IMS3c, of  $\Delta G_{S3b} = 1.54 \text{ Kcal mol}^{-1}$ , and  $k_{S3b} = 4.58 \times 10^{13} \text{ s}^{-1}\text{m}^{-1}$ . The generated IMS3c radical combines with <sup>•</sup>OH at the active O to form IMS3d. It has been well illustrated that IMS3d - 2-hydroperoxy-2-(6-methoxynaphthalen-2-yl) propanoic acid, produced the Ketone derivatives by further dehydration and decarboxylation, as an important intermediate in the oxidative degradation of NAX.

The results show that the de-methoxylation reaction rate ( $k_{S1a}$ ) of NAX oxidized by <sup>•</sup>OH is significantly faster than that of de-propionylation reaction rate ( $k_{S2a}$ ). That is due to the difference of electronegativity of the O atom of -O-CH<sub>3</sub> and that of the C atom of -CH-CH<sub>3</sub>-COOH, implying that -O-CH<sub>3</sub> connecting the naphthalene ring has higher electron-donating ability. Therefore, the path A is considered as a primary channel.

### **3.4.2 Reaction at C<sub>5</sub> of intermediates of NAX**

Following, IMS2b produced in the reaction of “path B” was oxidized to active IMS4a, and H<sub>2</sub>O, under the activation of •OH with the extraction of H at C<sub>5</sub> (Fig. 6 path D), of  $\Delta G_{S4a} = 3.53 \text{ Kcal mol}^{-1}$ , and  $k_{S4a} = 1.60 \times 10^{12} \text{ s}^{-1}\text{m}^{-1}$  (Fig. S5d). Immediately, IMS4a reacts with molecular named as 3a identified in the oxidation process of NAX in other literature [28], and transfers into a macro-molecular IMS4b (6-Methoxy-1-[1-(6-methoxynaphthalen-2-yl) ethyl] naphthalen-2-ol). IMS4b was detected in the study of Yang [55] and Jallouli [46], proved to be more toxic than the parent NAX, leading to increased toxicity in the early stage of the oxidation process.

### **3.4.3 Reaction at C<sub>12</sub> and O<sub>22</sub> of intermediates of NAX**

IMS5a formed by •OH oxidation of NAX was confirmed by Tu [28]. In this paper, the following oxidants produced of IM5Sa by •OH reaction were calculated (Fig. 6 path E & Fig. S5e). IMS5b was formed of one -OH added at C<sub>12</sub> of IM5Sa, of  $\Delta G_{S5a} = 6.45 \text{ Kcal mol}^{-1}$ , and  $k_{S5a} = 1.16 \times 10^{10} \text{ s}^{-1}\text{m}^{-1}$ . Owing to the change of electron-donating ability, •OH attacked the same position, C<sub>12</sub>-O<sub>22</sub> bond was broken and demethoxylation reaction happened. IMS5c - 6-Vinylnaphthalen-2-ol [56] was produced in the hydroxylation process of NAX, of  $\Delta G_{S5b} = 14.54 \text{ Kcal mol}^{-1}$ , and  $k_{S5b} = 1.37 \times 10^2 \text{ s}^{-1}$ .

### **3.4.4 Reaction at C<sub>17</sub> and C<sub>18</sub> of intermediates of NAX**

IMS5c obtained above was further oxidized by •OH (Fig. 6 path F & Fig. S5f). •OH firstly attacked the double bond of C<sub>18</sub> to form pre-intermediate IMS6a<sub>0</sub>, leading to the reduction of energy, then transfers into C<sub>17</sub> to have active IMS6a generated, of  $\Delta G_{S6a} = 29.45 \text{ Kcal mol}^{-1}$ , and  $k_{S6a} = 1.63 \times 10^{-7} \text{ s}^{-1}\text{m}^{-1}$ . •OH continues to attack active C<sub>18</sub> to form IMS6b and then reacts with H connected of C<sub>17</sub>, leading to dehydration reaction, i.e. one molecular H<sub>2</sub>O was off from IMS6b, of  $\Delta G_{S6b} = 7.59 \text{ Kcal mol}^{-1}$ , and  $k_{S6b} = 1.70 \times 10^9 \text{ s}^{-1}\text{m}^{-1}$ , forming the active IMS6c. The active IMS6c reacts with •OH, forming one -OH added at C<sub>17</sub>-IMS6d, that significantly reduces the energy barrier, of  $\Delta G_{S6d} = 37.41 \text{ Kcal mol}^{-1}$

<sup>1</sup>, and  $k_{S6d} = 2.41 \times 10^{-15} \text{ s}^{-1}$ . The -OH group connected to C<sub>17</sub> undergoes intermolecular dehydration to form IMS6e. Under the oxidation of <sup>•</sup>OH, IMS6f -6-Hydroxy-2-naphthoic acid, was formed by one <sup>•</sup>CH<sub>2</sub>OH off from IMS6e, of  $\Delta G_{S6e} = 0.22 \text{ Kcal mol}^{-1}$ , and  $k_{S6e} = 4.22 \times 10^{12} \text{ s}^{-1}$ . IMS6f obtained is an important oxidation product in the degradation of NAX as previous works indicated [12, 57].

#### **3.4.5 Reaction at C<sub>9</sub>-C<sub>12</sub>, C<sub>12</sub>-C<sub>14</sub> and C<sub>2</sub>-C<sub>7</sub>, C<sub>5</sub>-C<sub>7</sub> of “ring-opening” of NAX**

<sup>•</sup>OH has strong oxidization ability as its element O reacted with the C of naphthalene ring, opening the “ring” of NAX. The ortho- methoxy- group in NAX makes the “opening” process easier [58]. In the calculation of branched chain reaction, it is proved that  $\Delta G$  of attacking C<sub>12</sub> was lower than that of C<sub>7</sub> by <sup>•</sup>OH. The sites near methoxy group were calculated as the reacted sites at 3.4.1. Hence, ortho-position of C<sub>12</sub> as C<sub>9</sub> and C<sub>14</sub>, and of C<sub>7</sub> as C<sub>2</sub> and C<sub>5</sub>, that connect to methoxy group of IMS1a, were calculated.

<sup>•</sup>OH attacked C<sub>12</sub>, making the whole naphthalene ring becoming a large active free radical group, forming C-O bond IMS1a. The calculated results demonstrated that the formation of IMS1a is no energy barrier. <sup>•</sup>OH attacked sites of adjacent C<sub>9</sub> and C<sub>14</sub> to C<sub>12</sub> and then generated the corresponding stable intermediates IMR1a and IMR2a (Fig. 7 path G & H). These intermediates continued being oxidized by <sup>•</sup>OH, form coupled structures IMR1a<sub>0</sub> and IMR2a<sub>0</sub>, respectively. IMR1a<sub>0</sub> reacted with <sup>•</sup>OH at C<sub>9</sub>, with one hydroxylic hydrogen extracted, IMR1b generated, of  $\Delta G_{R1a} = 16.23 \text{ Kcal mol}^{-1}$ , and  $k_{R1a} = 7.97 \times 10^2 \text{ s}^{-1}\text{m}^{-1}$ ; the same reaction occurred at C<sub>14</sub> of IMR2a<sub>0</sub>, to formed IMR2b, of  $\Delta G_{R2a} = 33.11 \text{ Kcal mol}^{-1}$ , and  $k_{R2a} = 3.40 \times 10^{-10} \text{ s}^{-1}\text{m}^{-1}$  (Fig. S5 g & h).

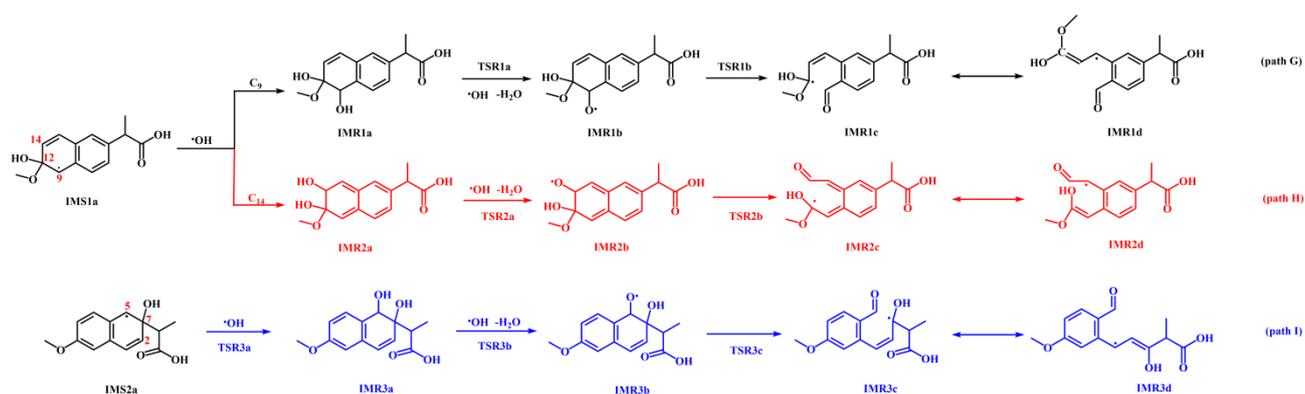

Following, the bond-breaking reaction of C<sub>9</sub>-C<sub>12</sub> and C<sub>12</sub>-C<sub>14</sub> bonds implied that “ring-opening” of NAX occurred, with the generation of IMR1c and IMR2c, of  $\Delta G_{R1b} = 0.66 \text{ Kcal mol}^{-1}$ , and  $\Delta G_{R2b} = 6.33 \text{ Kcal mol}^{-1}$ , respectively. The corresponding reaction rates are  $k_{R1b} = 2.05 \times 10^{12} \text{ s}^{-1}$  and  $k_{R1b} = 1.43 \times$

$10^8 \text{ s}^{-1}$ , IMS2a was formed after  $\cdot\text{OH}$  attacked the  $\text{C}_7$  (Fig. 7 path I). The calculated  $\Delta G$  of  $\text{C}_2$  reaction with  $\cdot\text{OH}$  was so high that further research ended. On the contrary, a coupling IMR3a0 was formed from the reaction of IMS2a and  $\cdot\text{OH}$  firstly, and then,  $\cdot\text{OH}$  attacked  $\text{C}_5$  to form IMR3a, of  $\Delta G_{\text{R3a}} = 6.80 \text{ Kcal mol}^{-1}$ , and  $k_{\text{R3a}} = 4.13 \times 10^9 \text{ s}^{-1}\text{m}^{-1}$ . Hydroxyl hydrogen connected with  $\text{C}_5$  was extracted through the reaction of  $\cdot\text{OH}$  and TSR3b, to produce the IMR3b and  $\text{H}_2\text{O}$ , of  $\Delta G_{\text{R3b}} = 0.78 \text{ Kcal mol}^{-1}$ , and  $k_{\text{R3b}} = 1.64 \times 10^{14} \text{ s}^{-1}\text{m}^{-1}$ . TSR3c was formed under the continuous oxidation of IMR3b. Then the bond of  $\text{C}_5$ - $\text{C}_7$  was broken in the oxidative reaction of TSR3c, forming the IMR3c, of  $\Delta G_{\text{R3c}} = 2.63 \text{ Kcal mol}^{-1}$ , and  $k_{\text{R3c}} = 7.35 \times 10^{10} \text{ s}^{-1}\text{m}^{-1}$ . (Fig. S5i)

By using Becke method of the multiwfn program, the spin population is obtained:

- (1) IM1R1c, the spin population of  $\text{C}_{12}$  and  $\text{C}_{16}$  are 0.26 and 0.38 respectively, which are the higher of all atoms. Based on this data, the optimal resonance formula of IM1R1c is obtained;
- (2) IMR2c, the spin population of  $\text{C}_{16}$  and  $\text{O}_{34}$  are as high as 0.46 and 0.21, respectively. Based on the spin population, the optimal resonance formula of IMR2c structure is achieved;
- (3) Similarly, for IMR3c, the spin population of  $\text{C}_4$  and  $\text{C}_7$  are 0.39 and 0.31, respectively, the optimal resonance formula of IMR3c is got.

It is clear that the “ring-opening” molecules as IMR1c, IMR2c and IMR3c occurred at the  $\cdot\text{OH}$  oxidation process of NAX were all of such lower  $\Delta G$  and short time (nanoseconds level). The three “ring opening” pathways of NAX provide a feasible degradation mechanism.

**Fig. 7. "Ring-opening" reaction of  $\bullet\text{OH}$  and NAX at  $C_{17}$  and  $C_{18}$  with calculated intermediates (path G-I).**

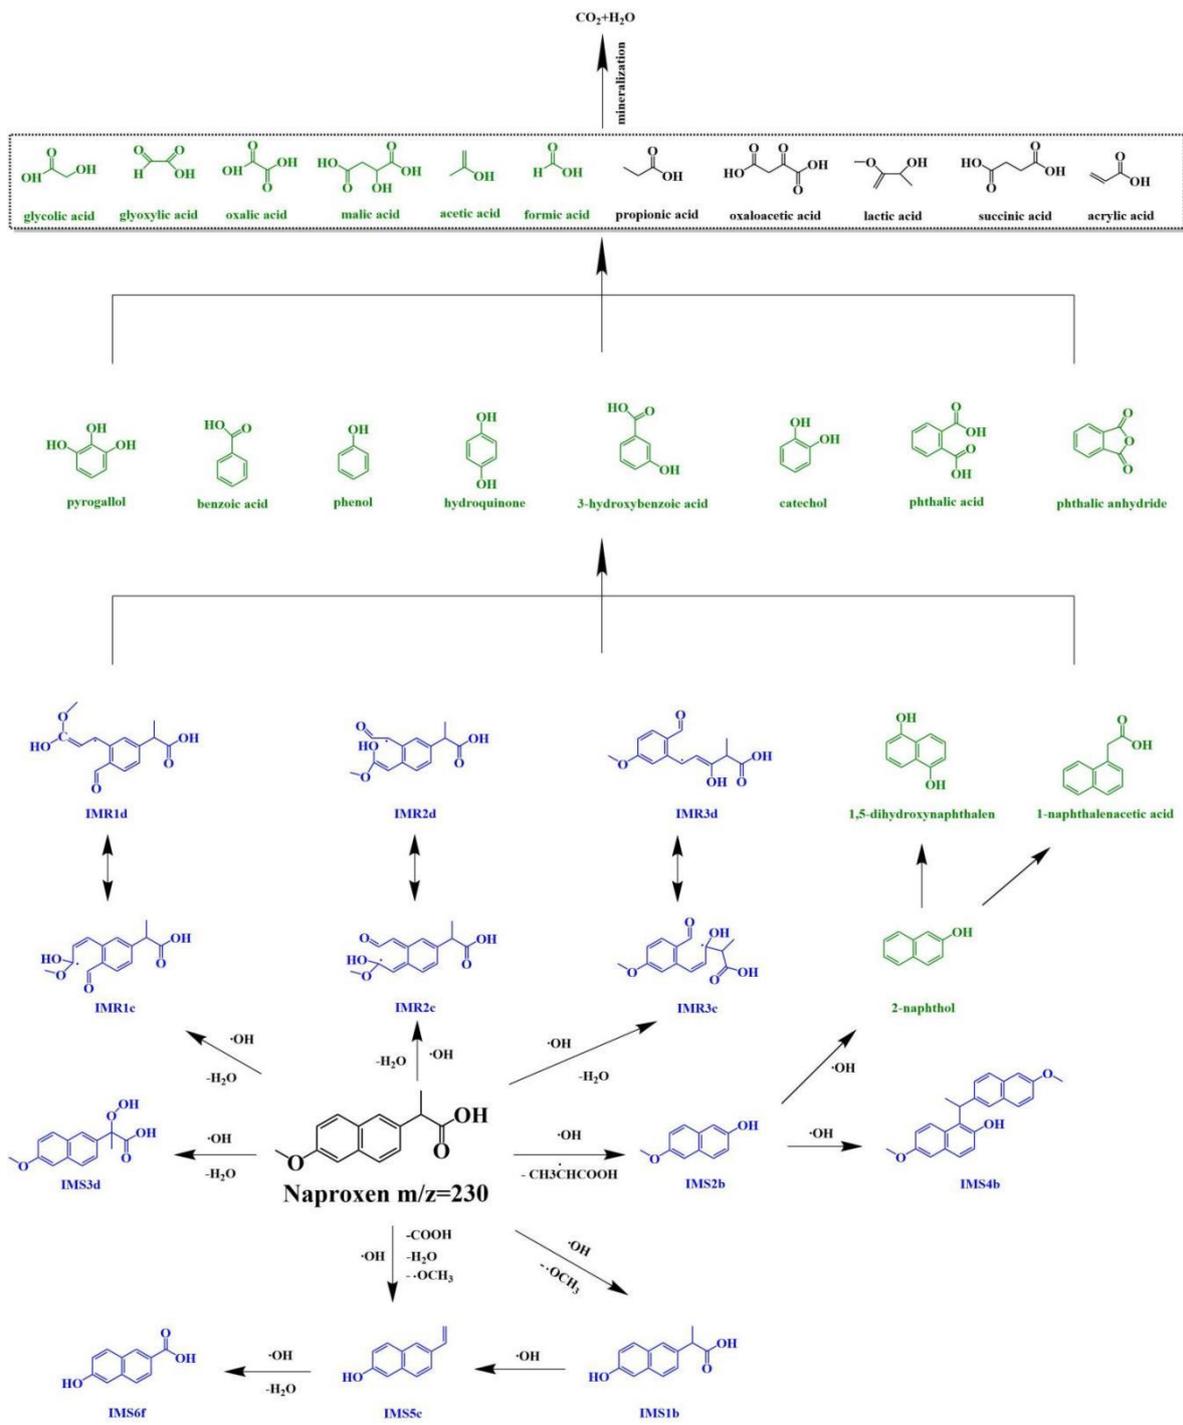

With the electron-donating methoxy group, the  $C_{12}$  reacted with  $\bullet\text{OH}$  of an obviously lower  $\Delta G$  in path A, leading a primary reacted intermediate. All data of  $\Delta G$  show that each path of NAX can occur under the attack of  $\bullet\text{OH}$ . It is worth noting that  $\Delta G$  of TSS6d in path F and TSR2a in path H are  $37.41 \text{ Kcal mol}^{-1}$  and  $33.11 \text{ Kcal mol}^{-1}$ , respectively. However, free radicals are coupled in the former step of the reaction, releasing a large amount of energy to overcome the reaction requirements. At the same time, the change of  $\Delta G$  indicates the rationality of the reaction and the feasibility of theoretical calculation.

### 3.5 The mechanism of Naproxen removal by $\bullet\text{OH}$

Based on the intermediates (aromatic and carboxylic acids) detected by experimental analysis, the main intermediates substantiated by computation in our work, as well as the intermediates formed upon oxidation of NAX on related literature published [59], the detailed degradation pathway of NAX oxidized by  $\bullet\text{OH}$  was illustrated in Fig. 8.

The reactions of  $\bullet\text{OH}$  on NAX happen as decarboxylation, hydroxylation, demethylation, yielding the molecular as other literature illustrated and DFT calculated (mostly black and blue ones). It was clear that the naphthalic acid and "ring-opening" molecule were formed at the early stage of the

electrolysis. Aromatic intermediates are generated concomitantly with the disappearance of the parent molecule. Side chain on the C( $\beta$ )-atom of polycyclic aromatic hydrocarbons was oxidized to form intermediates. In parallel, hydroxylation led to hydroxyl-rich polycyclic aromatic hydrocarbons. The attack of  $\bullet\text{OH}$  on NAX happened by addition of  $\bullet\text{OH}$  on the benzoic ring (hydroxylation) or by losing side chain. These intermediates were then oxidized to form polyhydroxylated products that finally underwent oxidative ring opening reactions, leading to the formation of aliphatic compounds. Further reaction with the cleavage of the aromatic ring in the electron-rich benzene formed hydroxylated benzenes as di/tri-hydroxybenzenes of corresponding as 3-hydroxybenzoic acid, phenol, catechol, benzoic acid, phthalic, pyrogallol, phthalic anhydride and hydroquinone etc. (mostly top green ones). Finally, these intermediates were mineralized to carbon dioxide by further reactions with  $\bullet\text{OH}$ , as acetic, oxalic, formic, glycolic, malic and succinic acids, which originate from the oxidative breaking of the benzenes' moiety of aromatic intermediates. In the end, the final carboxylic acids were oxidized to carbon dioxide and water, or oxalic acid which formed hardly oxidizable iron complexes.

**Fig. 8. General reaction pathway proposed for the mineralization of naproxen in aqueous medium by  $\cdot\text{OH}$ . Blue: DFT calculated; Green: detected in this research; Black: carboxylic acids validated by other research works.**

### 3.6 Application of EAOPs on removal of Naproxen in relevant water matrices

To evaluate the applicability of the EAOPs to degrade NAX in matrices more complex than tap water, the pollutant treatment was carried out in simulated urine and wastewater (Table 1). These matrices were considered as the main excretion way of this pharmaceutical in humans is the urine [60, 61], and hospital wastewater is a recognized source of anti-inflammatories discharge into municipal treatment plants [62, 63]. Moreover, the application at primary sources of pollution by NAX (as urine and hospital wastewaters) could contribute to mitigate the negative environmental impact of this pharmaceutical [64].

The  $k_{app}$  value of all the experiments were shown in Table S4, in which curves of 0.30 A were selected to present the degradation of NAX in artificial urine and wastewater in Fig. 9. The degradation of NAX in both urine and wastewater was slower than in tap water. This is most likely associated to the presence of competing substances in these matrices. Urine contains urea, acetate, chloride, sulfate, phosphate anions at high concentrations, which can react with electro-generated  $\cdot\text{OH}$  [65], producing less powerful and more selective oxidizing agents (e.g.,  $\text{Cl}\cdot$ ,  $\text{SO}_4\cdot^-$ ,  $\text{H}_2\text{PO}_4\cdot^-$ ) than the hydroxyl radical. Also, wastewater has urea, peptone, chloride, sulfate and phosphate anions in higher concentrations than NAX. This explains why the removal in urine and wastewater required more treatment time than in tap water.

However, the EAOPs were able to reach 100% of degradation even in these complex matrices (which have elevated concentrations of competing substances) after 2 h of treatment, compared with 30~60 min in tap water. As the experimental parameters show, the naturally occurring iron contents in wastewater can efficiently remove NAX; this phenomenon indicates that extra iron sludge is not expected in a potential real application. A moderate hydraulic retention time (2 h), and a low current

intensity applied (0.3 A) were sufficient to eliminate pollutants from complex matrices.

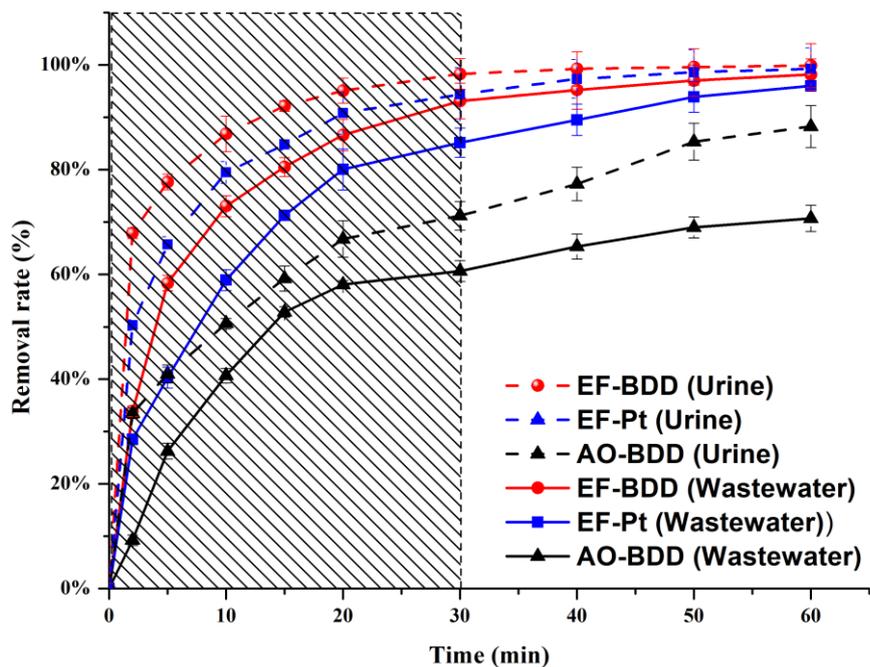

Fig. 9. Degradation of NAX by  $^{\bullet}\text{OH}$  in urine and wastewater.  $C_0 = 0.198 \text{ mM}$ ;  $[\text{Na}_2\text{SO}_4] = 50 \text{ mM}$ ;  $V = 0.25 \text{ L}$ ;

current intensity:  $0.30 \text{ A}$ ; for EF:  $[\text{Fe}^{2+}] = 0.2 \text{ mM}$ ;  $\text{pH} = 3.0$ ; for AO:  $\text{pH} = 7.5$ .

## 4. Conclusions

In this work, the removal of NAX in aqueous solution was carried out with BDD/Pt as anode and carbon-felt as cathode at lab-scale. It has been found out that 0.198 mM NAX could be almost completely eliminated in all EAOPs, with an optimized ferrous ion concentration at natural level in EF processes. In addition, the increasing current intensity accelerates the degradation and mineralization processes. The degradation curves of NAX by hydroxyl radicals within electrolysis time followed pseudo-first order reaction kinetics. EF with BDD anode showed higher removal ability as additional  $\cdot\text{OH}$  due to the Fenton reaction, a large surface area and higher ability of the BDD anode, compared with AO-BDD and EF-Pt, separately.

The “ring-opening” intermediates of NAX were firstly proposed by theoretical DFT calculation. Based on the intermediates identified during the treatment and DFT calculation, an oxidation pathway of NAX by  $\cdot\text{OH}$  was proposed. The evolution of intermediates and toxicity is summarized as: the aromatic intermediates were oxidized at the early stage by addition of  $\cdot\text{OH}$  on the benzoic ring (hydroxylation) or by losing side chain, which cause the increase of the inhibition of the luminescence of bacteria *Vibrio fischeri* by phenol, 1,5-dihydroxynaphthalen, 2-naphthol, catechol and IMS4b. Then, the short chain carboxylic acids were produced from the cleavage of the aryl moiety, such as glycolic, malic, succinic acids. The non-electrolyzed solution explained the remaining TOC observed within the electrolysis time. This explained why a high MCE value was obtained at low current intensity, where the side reaction and energy loss occurred on the persistent small byproducts produced. EAOPs were able to reach 100% of NAX degradation in artificial urine and hospital wastewater in 2 hours of treatment with a low current intensity applied.

Considering the energy input, removal efficiency and toxicity evaluation, less than a 2-h application

is necessary for NAX elimination in different water matrices. Hence, it can be concluded that the EF with BDD anode process could efficiently and quickly eliminate NAX and aromatic intermediates, while AO-BDD can be applied at neutral pH and with no catalyst input. Therefore, except the efficiency, economic input, duration of treatment or other requirements need to be taken into account when making the choice of EAOPs in real applications.

In overall, our results point out that i) EAOPs can be great in NAX removal, ii) even challenging matrices can be properly treated, iii) oxidation of NAX can lead to the generation of more toxic by-products, but prolonged treatment decreases this effect, iv) partial treatment can be risky, according to the expected intermediates formed, v) high-degree mineralization always ensures toxicity loss, and vi) DFT is a powerful tool to predict the intermediates and their toxicity, since complete mineralization is not always feasible and partially treated matrices are often discharged. Further assessment of the elicited toxicity phenomena must be performed; we should underline that despite the utility of *V. fischeri* as a model bacterium indicator of acute toxicity, generalization of the results should be made with caution, and the employment of higher order or more complex organisms should be tested before extrapolating these results towards expressing human toxicity concerns.

## Summary

Table S1. Basic physico-chemical information of naproxen. (3)

Table S2. Basic information of intermediates. (3)

Table S3. Apparent rate constants ( $\text{min}^{-1}$ ) for oxidative degradation of naproxen at various current intensities by EAOPs. (3-4)

Table S4. Apparent rate constants ( $\text{min}^{-1}$ ) for oxidative degradation of naproxen at various current intensities by EAOPs in urine and wastewater. (4)

Figure S1. Schematic diagram for EAOPs experiment set-up. (5)

**Figure S2.**  $\Delta G$  for the formation of IMS1a to IMS1b in path A calculated by M06-2X/6-311g\*\* and M05-2X/6-31+g\*\*. This indicates that the results obtained by M05-2X and M06-2X are basically consistent. (5)

**Figure S3.** Elution profiles for all the standard substances by HPLC. a: methanol/water/acetic acid (69:29:2 (v/v/v)) for aromatic intermediates; b: 1%  $\text{H}_3\text{PO}_4$  as eluent for short chain carboxylic acid. (6)

**Figure S4.** Optimized structure of NAX under DFT. (7)

**Figure S5.**  $\Delta G$  for the formation of a-c: IMS1a to IMS3d for path A-C; d: IMS4a to IMS4b for path D; e: IMS5a to IMS5c for path E; f: IMS6c to IMS6f for path F; g-i: IMS1a to IMS3c path G-I. (8-9)

Table S1. Basic physico-chemical information of naproxen.

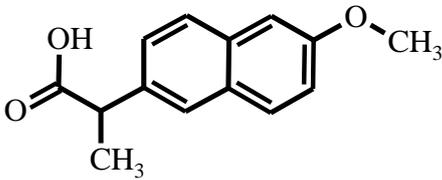

Naproxen	Formula: C <sub>14</sub> H <sub>14</sub> O <sub>3</sub>	Structure
Molecular weight (g mol <sup>-1</sup> ): 230.3	Solubility (at 20°C): 15.9 mg·L <sup>-1</sup>	
pKa (25°C): 4.15	Log Kow: 3.18	

Table S2. Basic information of intermediates products.

Intermediates	Formula	Molecular weight (g mol <sup>-1</sup> )	Log Kow	pKa (25°C)
Catechol	C <sub>6</sub> H <sub>6</sub> O <sub>2</sub>	110	0.88	pK <sub>a1</sub> : 9.45; pK <sub>a2</sub> : 12.8
Phthalic acid	C <sub>8</sub> H <sub>6</sub> O <sub>4</sub>	166	0.73	pK <sub>a1</sub> : 2.76; pK <sub>a2</sub> : 4.92
Hydroquinone	C <sub>6</sub> H <sub>6</sub> O <sub>2</sub>	110	0.59	9.96
Benzoic acid	C <sub>7</sub> H <sub>6</sub> O <sub>2</sub>	122	1.87	4.204
Phenol	<a href="#">C<sub>6</sub>H<sub>6</sub></a>	94	1.46	9.99
Phthalic anhydride	C <sub>8</sub> H <sub>4</sub> O <sub>3</sub>	148	1.60	-
Pyrogallol	<a href="#">C<sub>6</sub>H<sub>6</sub>O<sub>3</sub></a>	126	0.97	9.01
3-hydroxybenzoic acid	<a href="#">C<sub>7</sub>H<sub>6</sub>O<sub>3</sub></a>	138	-	4.06
2-naphthol	<a href="#">C<sub>10</sub>H<sub>8</sub>O</a>	144	2.70	9.51
1-naphthalene acetic acid	<a href="#">C<sub>12</sub>H<sub>10</sub>O<sub>2</sub></a>	186	2.24	4.23
1,5-dihydroxynaphthalene	C <sub>10</sub> H <sub>8</sub> O <sub>2</sub>	160	1.96	-
Glycolic	C <sub>2</sub> H <sub>4</sub> O <sub>3</sub>	76.05	-1.11	3.83
Oxalic	C <sub>2</sub> H <sub>2</sub> O <sub>4</sub>	90	-0.81	pK <sub>a1</sub> : 1.46; PK <sub>a2</sub> : 4.40
Formic	CH <sub>2</sub> O <sub>2</sub>	46	-0.54	3.75
