PREFACE

For this 14th iteration of the International Conference on Educational Data Mining (EDM 2021), the conference was held completely online. EDM is organized under the auspices of the International Educational Data Mining Society and was meant to happen in Paris, France. The conference, held June 29th through July 2nd, 2021, follows thirteen previous editions (Online, 2020, Montreal 2019, Buffalo 2018, Wuhan 2017, Raleigh 2016, Madrid 2015, London 2014, Memphis 2013, Chania 2012, Eindhoven 2011, Pittsburgh 2010, Córdoba 2009, and Montreal 2008).

The official theme of this year's conference was Shifting Landscape of Education: Improving Blended and Distance Learning. This theme focused on identifying learning or teaching strategies that can be used to improve learning in various formats, such as partially or fully online, synchronous or asynchronous, and centralized or federated. In addition to the general topics, we welcomed research in the following areas: receiving implicit and explicit feedback from learners in BDL environments, interacting with students to ensure no learner is left behind, integrating and utilizing learning analytics in BDL environments to cope with switching between in-person and online modes, and addressing emerging privacy and ethical challenges in the new learning setting. This year's conference featured three invited talks: Cristina Conati, Professor at University of British Columbia; Sidney D'Mello, Associate Professor at University of Colorado Boulder; and Pierre Dillenbourg, Professor at École Polytechnique Fédérale de Lausanne.

Building on the policy started in 2019, EDM 2021 continued using a double-blind review process. To continue EDM 2020 efforts, the conference's Program Committee was significantly expanded by inviting new committee members from the past authors of the EDM community and the PC members of the related conferences. In total, 33 senior and 74 ordinary program committee members, in addition to the conference and track chairs, contributed to the reviewing process. This year, we received a total of 100 full-paper submissions and 84 short-paper submissions. From the full-paper submissions, 22% were accepted as full papers, 25% were accepted as short papers, and 16% were accepted as posters. From the short-paper submissions, 23% were accepted as short papers and 23% were accepted as posters.

Review & Decision Processes: For transparency and possible benefit of future EDM conferences, we are providing a detailed description of the paper

review and decision processes for the Full and Short paper tracks at EDM 2021:

1. After all papers were submitted, the Program Committee (PC) and Senior Program Committee (SPC) members directly bid on which papers they would like to review.

2. If committee members did not bid on papers after several reminders, bids were assigned to them. This was done automatically via the EasyChair conference management system.

3. Given the PC and SPC bids, the Program Chairs assigned papers to reviewers using EasyChair's automatic assignment option. This assignment maximizes the total score of the assignment, with high weight on matches where the bid was a "yes", medium weight on matches where the bid was a "maybe", and low weight on matches where the bid was a "no". The assignments were checked by the program chairs to ensure review restrictions of the program committee members and the number of reviews they would have preferred, if they had any. Each paper was assigned to one SPC member and two PC members. Considering the increased number of submissions and the review limitations of PC members, each PC member received on average 5.2 papers, and each SPC member received on average 4.1 papers. The maximum number of papers assigned to a program committee member was 6 papers. The automated reviewing assignment was manually checked to ensure fairness to reviewers in being primarily assigned papers for which they had entered positive bids, fairness to papers in being primarily assigned reviewers who had bid positively on that paper, and that automatic conflict detection had accurately detected conflicts. A set of changes was made based on this manual check, either due to assigning a paper to all reviewers that had bid "no" on it or due to assigning multiple papers to a reviewer who had assigned a "no" bid on all of them.

4. In an effort to increase the mean and decrease the variance in review quality, the Program Chairs defined reviewing guidelines, both for the PC and the SPC. These guidelines were posted to the EDM 2021 website and also linked in emails sent to reviewers.

5. At the end of the review period, the Program Chairs identified papers that received fewer than 3 reviews, as well as papers whose reviews were clearly lacking (e.g., just 1-2 sentences). Emergency reviewers (including the Program Chairs) were identified, and papers were assigned to them.

6. The Program Chairs examined the meta-reviews and acceptance/rejection recommendations for all papers. For any papers lacking a meta-review, the Program Chairs read the reviews and the paper, wrote a meta-review, and arrived at a recommendation for acceptance/rejection.

7. Papers were ranked by their weighted average review scores. The Program Chairs then manually identified and examined papers in "critical regions" of the ranking in which there was large variance in the meta-reviewers' decision recommendations (Accept as Full, Accept as Short, Accept as Poster, Reject) or

there was large difference between the weighted and unweighted average review scores. The goal here was to ensure that, in the opinions of both Program Chairs, all papers accepted as either Full or Short exhibited sufficient rigor for publication as such. When in doubt, the more conservative outcome (i.e., Accept as Short rather than Full, or Accept as Poster rather than Short) was chosen. In particular:

(a) For the Full paper track, the following range was calculated: Let m_f be the lowest score of any paper recommended by its meta-reviewer for "Accept as full", and let n_s be the highest score of any paper recommended by its meta-reviewer for "Accept as short". For any paper recommended for "Accept as full" whose score was in $[m_f, n_s]$, the Program Chairs discussed the paper and decided jointly whether to Accept as Full or Short. This deliberation focused on the question: "Do the reviewers point out important methodological or other fundamental problems that could significantly threaten validity?"

(b) The analogous process (both for papers submitted as Full, and for papers submitted as Short) was applied to papers whose weighted or unweighted average review scores were in the range $[m_s, n_p]$, where m_s is the lowest score of any paper recommended for Accept as Short and n_p is the highest score of any paper recommended for Accept as Poster.

(c) All other papers – i.e., those whose unweighted average review scores were outside the ranges described above – were accepted/rejected according to the recommendation of their assigned meta-reviewer.

During all aspects of both the Review and Decision processes, no Program Chair examined or handled any paper on which she was a co-author; any such paper was seen and handled exclusively by the other Chair to avoid a conflict of interest. (No papers were co-authored by both Program Chairs.)

Note that papers submitted to the Industry, Doctoral Consortium, Poster/Demo, and Workshop components of EDM 2021 had their own reviewing processes that were defined by the corresponding chairs in consultation with the Program Chairs. Papers published in the Poster/Demo track are the union of those submitted & accepted as Posters/Demos, and those submitted as either the Full or Short tracks that were accepted as Posters.

Posters/Demos: In addition to the Full or Short paper submissions that were accepted as posters mentioned above, there was a dedicated Poster/Demo track to which papers could be submitted directly. This track accepted 10 contributions out of 20 submissions.

JEDM: Together with the Journal of Educational Data Mining (JEDM), the EDM 2021 conference held a JEDM Track that provides researchers a venue to

deliver more substantial mature work than is possible in a conference proceeding and to present their work to a live audience. The papers submitted to this track followed the JEDM peer review process. Three JEDM papers are featured in the conference's program.

Industry: The main conference invited contributions to an Industry Track in addition to the main track. The EDM 2021 Industry Track received 5 submissions, of which 4 were accepted.

Doctoral Consortium: The EDM conference continues its tradition of providing opportunities for young researchers to present their work and receive feedback from their peers and senior researchers. The doctoral consortium this year features 4 such presentations.

Paper Topics: In terms of topics of all submitted papers, the tables (Table 1 & Table 2) below list the top 20 popular keywords associated with papers created by the EasyChair system:

Keyword	**Weight**
Educational Data Mining	1000
Knowledge Tracing	624
Machine Learning	494
Neural network	426
Learning Analytics	397
Higher education	305
Student performance	299
Intelligent Tutoring System	284
Computer Science	278
Data Mining	259
Self-regulated learning	235
Deep Knowledge Tracing	209
Deep Learning	174
Natural Language Processing	167
Response time	164
Research question	161
Automated Essay Scoring	155
Artificial Intelligence	154
Peer assessment	149

Keyword	Weight
Learning environment	142

Table 1. Top 20 keywords associated with submitted papers

Also, the table below lists the top 20 popular keywords associated with the accepted papers:

Keyword	Weight
Educational Data Mining	300
Knowledge Tracing	163
Causal inference	124
Machine Learning	96
Neural network	90
Learning Analytics	88
Educational social network	74
Computer Science	70
Learning Agency	68
Hidden Markov Model	67
Intelligent Tutoring System	66
Knowledge State	66
Data Mining	65
Student performance	58
Stack Overflow	53
Student knowledge state	49
Computational linguistic	46
Problem solving	45
Curricular pattern	42
Student success	38

Table 2. Top 20 keywords associated with accepted papers

Best Paper, Presentation, and Reviewer Awards

Following the past EDM traditions, one best full paper, one best short paper,

and one best student paper were selected and awarded. The selection process included the program chairs reviewing the papers with praised and consistently high rated papers by the program committee and the recommended papers by the senior program committee members. After selecting four nominees from all the full and short papers, a committee of senior EDM members voted, met, and conferred to select the awardees. The best student paper was selected from the list of full paper nominees, since all of them has student first-authors. The list of best paper awardees are:

The best full paper:

Just a Few Expert Constraints Can Help: Humanizing Data-Driven Subgoal Detection for Novice Programming. By Samiha Marwan, Yang Shi, Ian Menezes, Min Chi, Tiffany Barnes and Thomas Price

The best student paper:

Early Prediction of Conceptual Understanding in Interactive Simulations. By Jade Cock, Mirko Marras, Christian Giang and Tanja Käser

The best short paper:

Do Common Educational Datasets contain Static Information? A Statistical Study. By Théo Barollet, Florent Bouchez-Tichadou and Fabrice Rastello

As the conference moved to the online setting, the program chairs decided to add best paper presentation and best poster presentation awards to encourage high-quality presentations by paper authors and engagement and attendance of the community. These awards were selected by the EDM conference community and attendees in a rank-based voting system. The attendees could select rank paper and poster presentations separately via two online Google forms, by selecting the best, second-best, and third-best presentations during the conference. To avoid memory availability bias, the forms were extensively advertised in the daily emails sent to the attendees by the general chairs, and at the end of each session. The votes were tallied before the closing session to announce the awardees.

The best poster presentation:

Are Violations of Student Privacy "Quick and Easy"? Investigating the Privacy of Students' Images and Names in the Context of K-12 Educational Institution's Posts on Facebook. By Macy Burchfield, Joshua Rosenberg, Conrad Borchers, Tayla Thomas, Benjamin Gibbons and Christian Fischer

The best paper presentation:

Early Prediction of Conceptual Understanding in Interactive Simulations. By Jade Cock, Mirko Marras, Christian Giang and Tanja Käser

In addition to the above, as a way to thank the current program committee members and to encourage serving as a program committee member and providing high-quality reviews in the future EDM conferences, the program chairs added the best reviewer award to the list of awards. These reviewers were selected

by the program chairs after carefully reading all the reviews and meta-reviews of all papers, focusing on the reviewers providing extraordinary reviews, such as suggestions on how to improve the authors' works and mentioning relevant literature to them, and the ones who have been on-time or volunteering to review more papers than average. The list of the best reviewers is:

Agathe Merceron, Beuth University of Applied Sciences Berlin

Andrew Olney, University of Memphis

Anna Rafferty, Carleton College

Cheng-Yu Chung, Arizona State University

Christopher Brooks, University of Michigan

Dragan Gasevic, Monash University

Giora Alexandron, Weizmann Institute of Science

James Lester, North Carolina State University

Joshua Gardner, University of Michigan

Julio Guerra, Universidad Austral de Chile

Sébastien Lallé, The University of British Columbia, Department of Computer Science

Sergey Sosnovsky, Utrecht University

Shalini Pandey, University of Minnesota

Stephen Fancsali, Carnegie Learning, Inc.

Tanja Käser, EPFL

Vincent Aleven, Human-Computer Interaction Institute, Carnegie Mellon University

Test of Time Award: Following in the footsteps of last year's conference, EDM 2021 also includes an invited talk by the authors of the 2020 winner of the EDM Test of Time Award. This year's talk is delivered by Cristóbal Romero.

Workshops: In addition to the main program, there are six workshops accepted, including Reinforcement Learning for Education: Opportunities and Challenges; Causal Inference in Educational Data Mining; Workshop for Undergraduates in Educational Data Mining and Learning Engineering; A Workshop on Process Analysis Methods For Educational Data; The Second Workshop of The Learner Data Institute: Big Data, Research Challenges, & Science Convergence in Educational Data Science; The 5th Educational Data for Mining in Computer Science Education (CSEDM).

Coronavirus: This year's conference was originally arranged to take place in Paris, France. Due to the SARS-CoV-2 (coronavirus) epidemic, EDM 2021, as

well as most other academic conferences in 2021, had to be changed to a purely online format. This presented some difficulties, especially of how to engage and encourage interaction among participants using just Zoom and other online tools (i.e. Gather Town, SpeakUp, Whova, etc.) rather than face-to-face meetings. However, it also significantly reduced the costs of conducting and attending the conference since physical meeting spaces, air travel, and on-site lodging were no longer necessary – and this arguably increased our conference's accessibility. To facilitate efficient transmission of presentations, especially given that not everyone's Internet connection could be guaranteed to be stable, we required all paper presenters to pre-record their presentation as a video and then to host it online.

Thanks: We thank Direction du numérique pour l'éducation (French MoE), Pix, CNRS, Inria, Eedi, EvidenceB, Educational Testing Service (ETS), Duolingo as sponsors of EDM 2021 for their generous support, especially during this financially difficult time of the coronavirus. We are also grateful to the individual conference chairs, the senior program committee, regular program committee members, subreviewers, emergency reviewers, and IEDMS board members, without whose expert input and hard work this conference would not be possible. Finally, we thank the entire organizing team and all authors who submitted their work to EDM 2021.

Abstract

Educational data mining involves the application of data mining techniques to student activity. However, in the context of computer programming, many data mining techniques can not be applied because they require vector-shaped input whereas computer programs have the form of syntax trees. In this paper, we present ast2vec, a neural network that maps Python syntax trees to vectors and back, thereby enabling about a hundred data mining techniques that were previously not applicable. Ast2vec has been trained on almost half a million programs of novice programmers and is designed to be applied across learning tasks without re-training, meaning that users can apply it without any need for deep learning. We demonstrate the generality of ast2vec in three settings: First, we provide example analyses using ast2vec on a classroom-sized dataset, involving two novel techniques, namely progress-variance-projection for visualization and a dynamical systems analysis for prediction. In these examples, we also explain how ast2vec can be utilized for educational decisions. Second, we consider the ability of ast2vec to recover the original syntax tree from its vector representation on the training data and two further large-scale programming datasets. Finally, we evaluate the predictive capability of a linear dynamical system on top of ast2vec, obtaining similar results to techniques that work directly on syntax trees while being much faster (constant- instead of linear-time processing). We hope ast2vec can augment the educational data mining toolbelt by making analyses of computer programs easier, richer, and more efficient.

Affect, Support and Personal Factors: Multimodal Causal Models of One-on-one Coaching

Lujie Karen Chen

Joseph Ramsey Carnegie Mellon University
jdramsey@andrew.cmu.edu

Artur Dubrawski Carnegie Mellon University
awd@cs.cmu.edu

Abstract

Human one-on-one coaching involves complex multimodal interactions. Successful coaching requires teachers to closely monitor students' cognitive-affective states and provide support of optimal type, timing, and amount. However, most of the existing human tutoring studies focus primarily on verbal interactions and have yet to incorporate the rich aspects of multimodal cognitive-affective experiences. Meanwhile, the research community lacks principled methods to fully exploit the complex multimodal data to uncover the causal relationships between coaching supports and students' cognitive-affective experiences and their stable individual factors. We explore an analytical framework that is explainable and amenable to incorporating domain knowledge. The proposed framework combines statistical approaches in Sparse Multiple Canonical Correlation, causal discovery and inference methods for observations. We demonstrate this framework using a multimodal one-on-one math problem-solving coaching dataset collected at naturalist home environments involving parents and young children. The insights derived from our analyses may inform the design of effective technology-inspired interventions that are personalized and adaptive

Abstract

Adaptive spacing algorithms are powerful tools for helping learners manage their study time efficiently. By personalizing the temporal distribution of retrieval practice of a given piece of knowledge, they improve learners' long-term memory retention compared to fixed review schedules. However, such algorithms are generally designed for the pure memorization of single items, such as vocabulary words. Yet, the spacing effect has been shown to extend to more complex knowledge, such as the practice of mathematical skills. In this article, we extend three adaptive spacing heuristics from the literature for selecting the best skill to review at any timestamp given a student's past study history. In real-world educational settings, items generally involve multiple skills at the same time. Thus, we also propose a multi-skill version for two of these heuristics: instead of selecting one single skill, they select with a greedy procedure the most promising subset of skills to review. To compare these five heuristics, we develop a synthetic experimental framework that simulates student learning and forgetting trajectories with a student model. We run multiple synthetic experiments on large cohorts of 500 simulated students and publicly release the code for these experiments. Our results highlight the strengths and weaknesses of each heuristic in terms of performance, robustness and complexity. Finally, we find evidence that selecting the best subset of skills yields better retention compared to selecting the single best skill to review.

ABSTRACT

Research studies in Educational Data Mining (EDM) often involve several variables related to student learning activities. As such, it may be necessary to run multiple statistical tests simultaneously, thereby leading to the problem of multiple comparisons. The Benjamini-Hochberg (BH) procedure is commonly used in EDM research to address this issue, and it has proven to be a useful method. However, the main limitation of the procedure is that it requires the statistical tests to either be independent or satisfy certain dependency conditions. The Benjamini-Yekutieli (BY) procedure is an alternative that can be applied under arbitrary dependence assumptions, but this extra flexibility comes with a loss of statistical power; hence, the BH procedure is preferred whenever it can be properly applied. Based on these considerations, in this work we employ simulation studies to assess the validity of the BH procedure in two scenarios common to EDM research. The first scenario considers the evaluation and comparison of different classification models—such an analysis might occur, for instance, during the model tuning and validation stage of a study. Then, in the second scenario we look at experiments involving the study of state transitions in sequential data, examples of which occur in affect dynamics research. We find that the BH procedure performs as expected when used with simulated classification model predictions; however, when applied to simulated sequential data, it does not perform at the expected level. Based on these results, as well as previous studies evaluating the BH and BY methods, we discuss the appropriate usage of these procedures for the scenarios under examination.

Keywords

Multiple comparisons, false discovery rate, Benjamini-Hochberg, Benjamini-Yekutieli

1. INTRODUCTION

Consider a statistical analysis that tests several different null hypotheses, either on a single data set, or on related data sets. In such a scenario, the probability of making a *discovery*—i.e., rejecting a null hypothesis—is higher than in an analysis involving a single null hypothesis. Thus, it follows that the probability of rejecting a true null hypothesis increases as well; such errors are variously called *false positives*, *false discoveries*, or *type I errors*. This is known in the statistics literature as the multiple comparisons problem.

Studies in Educational Data Mining (EDM) and related fields are shaping the ongoing research and development of learning systems that are increasingly becoming part of everyday classrooms—thus directly impacting student lives. Greater attention is needed to ensure that the conclusions drawn from these studies are reliable. Along these lines, controlling for multiple comparisons is an important consideration, as it has been argued that addressing the issue is a major factor in ensuring the replicability of scientific results [2]. Additionally, many exaggerated or even incorrect results can be explained by the testing of multiple hypotheses without adjusting for the number of comparisons [34, 40]; while this issue commonly occurs with observational data, experimental studies are not immune to the problem [30].

The main focus of this study is the Benjamini-Hochberg (BH) procedure [3], a method that is commonly applied in EDM research to control the *false discovery rate* (FDR)—defined as the expected rate of false discoveries among all the discoveries made—when multiple statistical tests are used. One complication with using the BH procedure is that, in order for the theoretical guarantees on its performance to hold, the statistical tests must either be independent or satisfy certain dependency conditions [3, 4]. The Benjamini-Yekutieli (BY) procedure is an alternative method that can be used under arbitrary dependence assumptions among the statistical tests [4]. As the BY procedure is more generally applicable than the BH procedure, it is by necessity more conservative and thus less likely to classify a result as being statistically significant; in turn, this causes it to have lower statistical power compared to the BH procedure. Thus, the BH procedure is to be preferred over the BY procedure whenever it can be properly applied.

However, the difficulty is that verifying the conditions for applying the BH procedure is not always straightforward; while some scenarios have been mathematically proven to satisfy these conditions, many common examples have not been. For instance, as of 2010 the case of pairwise comparisons had not been mathematically proven to satisfy the

conditions for using the BH procedure [1], and to the best of our knowledge that has not changed in the interim. Because it's not always clear if the conditions for applying the BH procedure are satisfied, it is often used without any theoretical guarantees on its performance [15]. In other situations, researchers may resort to using both the BH and BY procedures and comparing the results [28]. Motivated by these issues, in this work we investigate two different scenarios that occur within EDM research, with the goal of understanding if the BH procedure is appropriate for each situation. In both scenarios, we assume that a researcher wants to control the FDR, ideally with the BH procedure, but is unsure if it will work as desired. As we are unable to provide mathematical proofs for these scenarios, we instead turn to simulation studies, a procedure that is commonly used to investigate the performance of multiple comparison procedures [1, 3, 14, 22, 31, 32, 38, 39].

The outline of the paper is as follows. We first discuss the specifics of the BH and BY procedures and how to apply them when performing multiple hypothesis tests; additionally, we also look at how multiple comparisons are handled in the EDM community by surveying the literature from the last five EDM conference proceedings. Then, in the remainder of the paper we evaluate the BH and BY procedures for two scenarios that EDM researchers may encounter in their work. The first scenario concerns the usage of these procedures for evaluating and comparing the performance of classification models. In this scenario, we make pairwise comparisons of simulated classifiers, using both accuracy and the area under the receiver operating characteristic curve (AUROC) to evaluate their performance; such a situation can occur, for example, when trying to find the best performing combinations of model algorithms and hyperparameters.

The next scenario we look at is the analysis of state transitions in sequential data. In such an analysis, researchers typically run several hypothesis tests to try and determine the importance of the various transitions between states. Examples of this occur in affect dynamics research, where the BH procedure is commonly used [18, 29]. Here, we run analyses on simulated sequences of transitions using two different statistical measures, and we then apply the BH and BY procedures and compare the results. Finally, based on the results of our numerical experiments, as well as the existing literature on controlling the FDR, we discuss the usage of the BH and BY procedures in these scenarios.

2. CONTROLLING FOR MULTIPLE COMPARISONS

2.1 Benjamini-Hochberg and Benjamini-Yekutieli Procedures

In this study we focus on procedures for controlling the false discovery rate (FDR). The FDR was introduced in [3], and it has since found widespread use in many scientific fields including education research [38], genetics [31, 35], and medical studies [4]. If we let $\mathbf{V}$ be the number of false discoveries and $\mathbf{S}$ be the number of true discoveries, as done in [3] we can define the quantity $\mathbf{Q}$ as

$$\mathbf{Q} = \begin{cases} \frac{\mathbf{V}}{\mathbf{V}+\mathbf{S}}, & \text{if } \mathbf{V}+\mathbf{S} > 0, \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

Then, the FDR is equal to $\mathbf{E}[\mathbf{Q}]$, the expected proportion of false discoveries among all the discoveries made.

The family-wise error rate (FWER), which is defined as the probability of making at least one false discovery when performing a set of hypothesis tests, is another measure commonly associated with the problem of multiple comparisons. Although the Bonferroni correction is probably the most famous procedure used to control the FWER, there exist many other alternatives. However, while such procedures can be useful in situations in which a false discovery must be avoided at all costs, such as clinical trials of new medical treatments [16], the downside to these methods is a loss of statistical power, resulting in an increased likelihood of missing true discoveries. While procedures for controlling the FWER are concerned with the occurrence of *any* false discoveries, FDR controlling procedures are slightly more permissive, as they allow a certain proportion of the discoveries to be false. Thus, the advantage of FDR controlling procedures is that they typically have greater statistical power and, as such, a better chance of correctly identifying true discoveries; the resulting trade-off is that false discoveries are more likely. However, this trade-off can be beneficial when a large number of hypothesis tests are being conducted,[1] or when the research is of a slightly more exploratory nature.

In addition to introducing the FDR to the scientific literature, the authors in [3] also outlined the BH procedure. As shown there, the BH procedure is mathematically proven to control the FDR at a given level when the statistical tests—or, equivalently, the test statistics—are independent. However, in many practical applications the statistical tests may have some underlying dependence between them. With these situations in mind, further important work on controlling the FDR appeared in [4], where the authors proved that, in addition to the independent case, the BH procedure is valid under certain dependency conditions between the statistical tests. Among other scenarios, it was shown that the BH procedure properly controls the FDR with multivariate normal test statistics having nonnegative correlations. Additionally, the authors in [4] introduced the BY procedure for situations in which the BH procedure is not valid, and they proved that the BY procedure controls the FDR regardless of the dependence between the tests.

In the remainder of this section we discuss the application of the BH and BY procedures. Consider a statistical analysis that involves the testing of m null hypotheses. Of these null hypotheses, $m_0 \leq m$ are true null hypotheses—these correspond to the hypotheses that we expect a statistical test to classify as not being significant—while the remaining $m - m_0$ hypotheses are the false null hypotheses. Note that, in practice, m_0 is an unknown value. Let $P_1, \ldots, P_m$ be the p-values for the m statistical tests, with these values being listed in ascending order; the corresponding null hypotheses are then represented by $H_1, \ldots, H_m$. The relationships

[1] As a relatively extreme example, statistical analyses in genetics research can involve thousands of hypothesis tests, and in such cases FWER controlling procedures can be overly restrictive [1].

between these various terms can be summarized as follows.

	Not significant	Significant	Total
True null	**U**	**V**	m_0
False null	**T**	**S**	$m - m_0$

(2)

- m = total number of hypotheses being tested
- m_0 = number of true null hypotheses
- **V** = number of false positives (i.e., false discoveries or type I errors)
- **S** = number of true positives
- **T** = number of false negatives (i.e., type II errors)
- **U** = number of true negatives

Let q represent our chosen threshold—or, level—for controlling the FDR, and define $\text{FDR}_{\max} = \frac{m_0}{m}q$. If the statistical tests are independent, or if they satisfy certain dependency conditions, it was shown in [4] that the FDR resulting from an application of the BH procedure is at most $\text{FDR}_{\max}$. Such an application works as follows. Assuming once again that the p-values are in ascending order, we find the largest integer k such that $P_k \leq \frac{k}{m}q$. Then, we simply reject all the null hypotheses H_i for which $i \leq k$.

Next, as the BY procedure controls the FDR under arbitrary dependence assumptions, it is necessarily more conservative when rejecting a null hypothesis. This takes the form of a lower threshold for the upper bound used to determine the "significance" of the p-values. Specifically, we find the largest integer k such that $P_k \leq \frac{k}{m \cdot c(m)}q$, where $c(m) = \sum_{i=1}^{m} \frac{1}{i}$. Using this procedure, it was shown in [4] that the resulting FDR is bounded above by $\text{FDR}_{\max} = \frac{m_0}{m}q$, regardless of the type of dependence between the statistical tests.

To see how these procedures work, we next look at an example. Suppose we run 10 separate statistical tests ($m = 10$) that return the following p-values.

$$0.002,\ 0.008,\ 0.011,\ 0.013,\ 0.023,$$
$$0.028,\ 0.092,\ 0.214,\ 0.647,\ 0.853$$

Next, we compare these p-values to the formulas used for the BH and BY thresholds, using a value of $q = 0.1$; for added context, we also include the results for the Bonferroni correction. For each method, the thresholds that correspond to statistically significant p-values are in bold.

k	P_k	BH $\frac{k}{m}q$	BY $\frac{k}{m\sum_{i=1}^{m}\frac{1}{i}}q$	Bonferroni $\frac{1}{m}q$
1	0.002	**0.01**	**0.003**	**0.01**
2	0.008	**0.02**	**0.007**	**0.01**
3	0.011	**0.03**	**0.010**	0.01
4	0.013	**0.04**	**0.014**	0.01
5	0.023	**0.05**	0.017	0.01
6	0.028	**0.06**	0.020	0.01
7	0.092	0.07	0.024	0.01
8	0.214	0.08	0.027	0.01
9	0.647	0.09	0.031	0.01
10	0.853	0.1	0.034	0.01

For the BH procedure, we can see that $k = 6$ is the largest value for which $P_k \leq \frac{k}{m}q$, as we have $0.028 < 0.06$. Thus, the BH procedure, using a value of 0.1, would reject the null hypothesis for the statistical tests corresponding to the lowest six p-values. Next, for the BY procedure we see that $k = 4$ is the largest value for which P_k is less than the corresponding threshold; in this case, we have $0.013 < 0.014$. It's worth noting that, in this example, even though both P_2 and P_3 are *not* below the corresponding thresholds, the BY procedure still classifies them as being statistically significant. This is a feature of FDR controlling procedures that, in many cases, allows them to be more permissive than procedures for controlling the FWER.

2.2 Applications in EDM Research

To understand how EDM research is controlling for multiple comparisons, we reviewed EDM conference proceedings from the last five years (2016–2020). We found that, among the 22 papers that reported controlling for multiple comparisons,[2] half used the Bonferroni correction and half used the BH procedure, with no studies using the BY procedure. Based on the method used to perform the comparisons, the studies can be partitioned as follows: group comparison (8), pairwise comparison (8; including pairwise model comparison), correlation (4), and regression analysis (2). The studies involving group comparisons used statistical methods such as the Mann-Whitney U test, chi-squared test, t-test, and ANOVA. The studies employing pairwise comparisons used methods such as the Kruskal-Wallis test, Mann-Whitney U test, McNemar's test, chi-squared test, and t-test. Overall, these 22 studies investigated diverse educational constructs in virtual learning environments including affect, student behavior in MOOCs, help-seeking, collaboration, and self-regulation.

The choice between the Bonferroni correction and the BH procedure varied in the studies, as the selection was not completely determined by the study methodology. For instance, an exploratory study used the more conservative Bonferroni method for a correlational analysis [61], while an experimental study with group comparisons used the less conservative BH procedure [46]. For EDM research, selecting between the Bonferroni correction and the BH procedure may not be universal and likely depends on the context of the study. As an example, consider that an analysis examining student demographic differences on an important educational construct—such as self-efficacy, affect, or learning—likely has fewer data samples from underrepresented minorities [20]. In such a case, penalizing the statistical power with a more conservative method like the Bonferroni correction may lead to missed opportunities for critical discoveries related to equity. On the other hand, contrast this with the evaluation of an expensive and large-scale educational technology intervention in a public school system; given the costs involved, both financially and otherwise, it could be argued that such an evaluation requires a more conservative approach to control for false discoveries.

More broadly, EDM research may not always involve large data sets. This is particularly true for educational constructs that require resource-intensive data collection procedures—

[2] See Section 8 for the full list of references.

e.g., training coders, gathering approvals, and conducting classroom studies. Hence, using the Bonferroni correction to control for multiple comparisons at the expense of losing statistical power may not always be affordable. In contrast, using the BH procedure in scenarios that violate its statistical assumptions may lead to invalid conclusions. Our review of EDM studies from the last five years also revealed that the field may not be taking advantage of the BY procedure, especially in scenarios where it is difficult to meet the assumptions of the BH procedure. These observations are what motivated us to investigate the use of the BH and BY procedures in research settings relevant to EDM.

3. METHODS

In this section we outline the general procedure we follow for our simulation studies. Since evaluating multiple comparison procedures requires knowledge of whether a null hypothesis is true, and as this isn't typically known with real data, simulations are commonly used for such analyses. In all of our experiments, we begin by generating simulated data according to a given probability distribution. While the specifics of this procedure vary for the two scenarios we consider, the common thread is that this must be done in a way as to have control over whether or not each null hypothesis is true. For example, in our comparisons of simulated classification models, the performance of each model is controlled by a single parameter; thus, when this parameter differs for two models, the null hypothesis that the models perform equally well is false.

Another important detail is that, as we are focusing on two particular scenarios, we can generate simulated data specific to these scenarios. That is, for the model comparison experiments we simulate both the classifier predictions and the ground truth labels; then, for the state transition analysis we generate simulated sequences of states. By simulating the underlying data for each scenario, we are attempting to evaluate the BH and BY procedures in conditions that are as realistic as possible. In comparison, other studies that are more general in nature may simulate the distribution of the test statistics, rather than the underlying data, when evaluating multiple comparison procedures.

After generating the data for a simulation run, we perform our statistical tests and compute the corresponding p-values. Once this is done, we then apply the BH and BY procedures for various threshold values q—specifically, we use 0.05, 0.1, and 0.15 in all our evaluations. While a value of 0.05 is commonly used, it's been argued that this threshold may be too low for some applications [26]; thus, we evaluate a range of values in our simulations. Based on the statistical significance results from our application of the BH and BY procedures, we can compute $\mathbf{Q}$, the proportion of false discoveries among all the discoveries made, using (1). To obtain our estimate of the FDR, we then compute the average of $\mathbf{Q}$ over a total of 10,000 simulation runs. For the various values of q, we compare these FDR estimates to the values of FDR_{max} as defined in Section 2.1.

At this point, it's worth mentioning that the value of $\mathbf{Q}$—and, hence, the estimated FDR value—can be very different from the false positive rate.[3] Using the notation in (2), the false positive rate can be written as $\frac{\mathbf{V}}{\mathbf{V}+\mathbf{U}}$. In comparison, $\mathbf{Q}$ is computed with the formula $\frac{\mathbf{V}}{\mathbf{V}+\mathbf{S}}$, which has a different denominator. Thus, while the FDR is the expected proportion of false discoveries among all the rejected null hypotheses, the false positive rate is the (expected) proportion of false discoveries among all the true null hypotheses. Consider the following example. Assume we are testing 20 total hypotheses, all of which are true null hypotheses ($m_0 = m = 20$). Furthermore, assume that one false positive is recorded. Then, the false positive rate for this set of tests would be equal to $\frac{1}{1+19} = 0.05$. However, applying (1) gives a value of $\mathbf{Q} = \frac{1}{1+0} = 1$. This discrepancy is something to keep in mind as we analyze the results from our simulation studies in subsequent sections.

4. MODEL COMPARISONS

The first scenario we study concerns the comparison of several classification models on a fixed set of test or validation data. A common example of this occurs during the model building process, where it may be necessary to evaluate the performance of many different combinations of classification models and hyperparameters. In such a case, it can be helpful for the researcher to run statistical tests to more precisely quantify the differences in performance. To that end, we focus on the pairwise comparisons of the classifiers, where we assume that the classifiers could have different underlying algorithms—e.g., logistic regression vs. random forest—or the same algorithm with different hyperparameters. We evaluate each pair of classifiers by looking at both the accuracy and the area under the receiver operating characteristic curve (AUROC). To measure the possible difference between the accuracy values of the models, we use McNemar's test [13, 27]. When conducting pairwise comparisons of classifier accuracy on a fixed set of test data—as opposed to a procedure such as k-fold cross-validation, where the test set varies—using McNemar's test is recommended [10]; for these evaluations we use the implementation in the `statsmodels` [33] Python library. Then, to compare the AUROC values we use DeLong's test [9], a method developed to statistically test for differences in AUROC values; specifically, we apply the fast version of the algorithm outlined in [36].[4]

Our simulations use the following procedure. We assume that we are evaluating the performance of a binary classifier on a test set containing n data points; for these simulations we use n-values of 500, 1000, and 5000. For each value of n, we sample n numbers uniformly at random from 0.01 to 0.99; we refer to this set of numbers as $\mathbf{U}_n$. In each simulation run, the numbers in $\mathbf{U}_n$ are used to generate the labels for our data using the following procedure. Let i be an integer from 1 to n, and let $p_i \in \mathbf{U}_n$. With probability p_i we assign a label of 1 to y_i; otherwise, with probability $1-p_i$ it is then given a label of 0. Note that the set $\mathbf{U}_n$ is generated once for each value of n, and this same set is then used repeatedly for all of our simulation runs with a test set of size n.

[3] That is, while "false discovery" and "false positive" are used interchangeably, the terms "false discovery rate" and "false positive rate" have different definitions.

[4] The code for our implementation of the algorithm in [36], as well as for running all of our experiments, is available at https://github.com/jmatayoshi/multiple-comparisons.

Table 1: Accuracy and AUROC values for an example simulation run using a test set of size $n = 1000$.

σ	0.1	0.1	0.1	0.5	1	2
Accuracy	0.733	0.724	0.732	0.706	0.651	0.606
AUROC	0.824	0.821	0.824	0.787	0.721	0.655

We next describe our procedure for simulating the classifier predictions. Let c_{ij} represent the predicted probability given by classifier j for the i-th data point in our test set. To generate c_{ij}, we begin by converting $p_i \in \mathbf{U}_n$ to a $\mathbf{z}$-score. Then, to add noise to the classifier's prediction we randomly sample a value, s_{ij}, from a normal distribution with mean 0 and standard deviation σ_j, add this to the $\mathbf{z}$-score, and then convert everything back to a probability; the resulting value is c_{ij}. The size of σ_j controls the performance of the classifier, with lower values giving predicted probabilities that are less noisy and more likely to align with the class labels. Let Φ denote the cumulative distribution function (CDF) of the standard normal distribution. Our procedure for generating the classifier predictions can be summarized as follows.

1. $z_i = \Phi^{-1}(p_i)$
2. Draw sample value s_{ij} from $\mathcal{N}(0, \sigma_j^2)$
3. $c_{ij} = \Phi(z_i + s_{ij})$

To get an idea of the effect of different values of σ on the performance of our simulated classifier predictions, in Table 1 we show the accuracy and AUROC values from one simulation run, using different values of σ and a test set size of $n = 1000$. The three classifiers with σ values of 0.1 have the best performance, with accuracy values from 0.72 to 0.73 and AUROC values around 0.82. The other classifiers, to varying degrees, perform worse, with the lowest accuracy and AUROC values at roughly 0.61 and 0.66, respectively. Our initial analysis simulates the pairwise comparison of six different classification models, where all the classifiers are assumed to perform equally; specifically, we use a value of $\sigma = 0.5$ for each model. Using our previously described procedure, we generate a total of 10,000 simulation runs for each value of n. Our experimental setup results in $\binom{6}{2} = 15$ pairwise comparisons ($m = 15$), and as there are no underlying differences between the simulated classifiers, we have 15 true null hypotheses ($m_0 = 15$). As such, if the conditions for the BH procedure are satisfied, we expect the FDR to be less than $\text{FDR}_{\text{max}} = \frac{15}{15}q = q$. The results are shown in Figures 1 and 2, where we display the estimated FDR rates for the BH and BY procedures, for different combinations of test set sizes and values of q. Using both McNemar's test and DeLong's test, the BH procedure appears to control the FDR by keeping it below the corresponding FDR_{max} value, shown by the dashed line, in all cases—that is, for all combinations of test set sizes and q. In comparison, the BY procedure is much more conservative, with each estimated FDR value far below the FDR_{max} line.

For our second set of simulations, we use the values of σ that appear in Table 1 to generate six different models. As there are three models with the same value of $\sigma = 0.1$, we have $\binom{3}{2} = 3$ true null hypotheses ($m_0 = 3$) out of 15 total comparisons ($m = 15$). Thus, under the appropriate conditions the BH procedure should keep the FDR at or below $\text{FDR}_{\text{max}} = \frac{3}{15}q = \frac{1}{5}q$. The results are given in Figures 3 and 4, where we can see that the estimated FDR values using the BH procedure are at or below the value of FDR_{max}, given by the dashed line, in all cases—that is, for all combinations of test set sizes and q. As before, the estimated FDR values from the BY procedure are very low, with each value again appearing far below the corresponding FDR_{max} line.

These results are seemingly consistent with previous works analyzing the performance of the BH procedure with pairwise comparisons [21, 38]. The findings from several of these studies are summarized in [39], where the author states that in "all the studies, for all configurations of true and false hypotheses simulated, for balanced and for non-balanced designs, normal and non-normal distributions, the BH procedure controlled the FDR." Thus, combining these previous results with our experiments from this section, there appears to be good evidence that the BH procedure properly controls the FDR in the case of pairwise comparisons of classification models. We return to this subject in the discussion.

5. TRANSITIONS IN SEQUENTIAL DATA

In our second scenario we look at data that are sequential in nature, as examples of such data appear in many areas of educational research. One particular focus with sequential data is the analysis of transitions between different states—or events—in these sequences. Researchers are often interested in understanding if transitions between certain pairs of states are significant, either because they happen often or because they rarely appear. Typically in such cases, many pairs of states are evaluated with statistical tests, thus necessitating a correction for multiple comparisons. For example, past studies have analyzed logs of student actions in learning systems, in an attempt to understand the differences between productive and unproductive transitions between activities within these systems [5, 6]. Another example is affect dynamics research, which studies sequences of student affective states, with the goal of understanding how students transition between these different states. Previous works in this area have used the BH procedure to control the FDR [18, 29], and as such the goal of our next analysis is to investigate the appropriateness of using this procedure when analyzing state transitions.

5.1 Experimental Setup

Our numerical experiments for sequential data evaluate the BH and BY procedures on simulated sequences of states. Each of these sequences could represent, for example, a student's affective states while working in a learning system. The states are randomly sampled according to the probability distribution given in Table 2; each entry in the table gives the probability of sampling the next state (column) based on the value of the previous state (row). For example, suppose that C is the previous state. In this case, A has a probability of 0.2 of being the next state, B has a probability of $0.2 - \gamma$ of being the next state, and so on.

For our simulations, we use two different values for γ: 0, which results in all 25 hypotheses being true null hypotheses; and 0.05, which results in 21 true null hypotheses, out of the 25. For each value of γ, we generate n sequences consisting of 20 states each. To generate these sequences, the first state in each sequence is sampled randomly from the five

choices, and then all subsequent states are sampled according to the probability distribution in Table 2. For each set of n sequences we evaluate our statistical tests (described in Sections 5.2 and 5.3) and then compute the resulting value for $\mathbf{Q}$; this constitutes one simulation run. We then perform 10,000 simulation runs for each value of n in order to obtain an estimate of the true FDR. For this analysis, we use the following values of n: 50, 100, and 200.

The L statistic, originally introduced in [12], is intended to be used as a measure of the significance of different pairs of transitions, and it has been widely applied in the study of affect dynamics [11, 12, 18]. Given two states A and B, it measures the likelihood of transitions from A to B while taking into account the overall frequency at which B occurs. However, several recent works have revealed issues with the use of the L statistic for the analysis of state transitions [7, 18, 19]. Thus, for our simulations we use two newer methods that have been developed in response to the problems with the L statistic. First, in Section 5.2 we look at the performance of the BH procedure when used in combination with the marginal model approach outlined in [25]. Then, in Section 5.3 we evaluate the BH procedure when it is used with the modified version of the L statistic from [24].

5.2 Marginal Model

To estimate the influence that starting in state A has on the probability of making a transition to B, in this section we use the marginal model regression procedure from [25]. In this approach, the regression model has a binary response variable, where the value of this variable is one if the next state is equal to B, and it is zero otherwise. Based on the binary response variable, we use the logit as our link function. Our predictor—or, independent—variable is also binary, with a value of one if the previous state is equal to A and zero otherwise. We can summarize this procedure as follows.

- $y = y_{it}$: one if B is the next state for student i at time t; zero otherwise
- $x = x_{it}$: one if A is the previous state for student i at time t; zero otherwise

Letting S represent the standard logistic function, the regression equation then has the form

$$P(y_{it} = 1 \,|\, x_{it}) = S(\beta_0 + \beta_1 x_{it}) = \frac{1}{1 + e^{-(\beta_0 + \beta_1 x_{it})}}. \quad (3)$$

When $x_{it} = 1$ the regression model returns an estimate for $P(B \,|\, A)$, the probability of a transition to B, given that the starting state is A. Then, when $x_{it} = 0$ it returns an estimate for $P(B \,|\, \overline{A})$, the probability of a transition to B, given that the starting state is not A. Thus, to measure the importance of starting in state A, we focus on testing if the value of β_1 is significantly different from zero. This is done using a two-tailed z-test on the value of β_1 for each individual fit of the regression model.

Finally, as the sequential data used in these analyses typically take the form of repeated measurements on a student,

the result is a set of dependent—or correlated—data. To account for this dependence, as outlined in [25] we use a marginal model, based on generalized estimating equations (GEE) [17, 23], to estimate the logistic regression coefficients; in particular, we use the GEE implementation from the `statsmodels` Python library.

As before, let m denote the total number of statistical tests, with $m_0 \leq m$ representing the number of true null hypotheses. Using the BH procedure with a value of $\gamma = 0$, we have $m_0 = m$; as such, we would expect the FDR to be less than $\text{FDR}_{\max} = \frac{25}{25}q = q$ if the BH conditions are satisfied. Then, for all values of $\gamma > 0$ we would expect the FDR to be less than $\text{FDR}_{\max} = \frac{21}{25}q$, assuming the BH conditions are satisfied, as $m_0 = 21$ of the tests are true null hypotheses.

The first set of results, using a value of $\gamma = 0$, is shown in Figure 5. Here, we can see that in all cases the estimated FDR values from the BH procedure are above the theoretical upper bound of $\text{FDR}_{\max}$, shown by the dashed line. The gap is particularly notable with smaller numbers of sequences. On the other hand, the BY procedure offers much more stringent control of the FDR, with all of the estimated values appearing below the $\text{FDR}_{\max}$ line. Figure 6 then shows the results from using a value of $\gamma = 0.05$. Overall, the picture appears similar to the $\gamma = 0$ case, with the estimated FDR values from the BH procedure always appearing above the $\text{FDR}_{\max}$ line, and with the difference again being more pronounced with smaller numbers of sequences.

5.3 Removing Self-Transitions

Our final set of experiments investigates a specific situation in sequential data analysis that occurs when researchers want to remove the influence of repeated states. To do this, many researchers in the affect dynamics community remove *self-transitions*—i.e., transitions where the same state is repeated for more than one step—before analyzing the data [18]. However, this procedure has been shown to overestimate the significance of transitions when used with the L statistic [19]. Thus, for this analysis we instead use a modified version of the L statistic, named L^* [24].

DEFINITION 1. *Let A and B be two states, and let*

$$T_{\overline{A}} = \{\textit{transitions where the next state is not } A\}. \tag{4}$$

Then, we define

$$L^*(A \to B) := \frac{P(B \mid A, T_{\overline{A}}) - P(B \mid T_{\overline{A}})}{1 - P(B \mid T_{\overline{A}})}, \tag{5}$$

where $P(B \mid A, T_{\overline{A}})$ is the probability of a transition to B in $T_{\overline{A}}$, given that the starting state is A, while $P(B \mid T_{\overline{A}})$ is the overall probability of a transition to B in $T_{\overline{A}}$.

The base rate of the state B, given by $P(B \mid T_{\overline{A}})$ in (5), can be computed either individually for each sequence, or averaged over the entire set of sequences. For the computations in the remainder of this work, we compute these rates individually per sequence.

Our analysis using L^* applies the statistic to the sequences from our experiments in Section 5.2. Specifically, we take each sequence and, for each pair of transition states, compute (5). To test for statistical significance, we follow the procedure outlined in [24] and apply a two-tailed t-test to the L^* values. The results for the $\gamma = 0$ and $\gamma = 0.05$ sequences are shown in Figures 7 and 8, respectively. While perhaps not quite as prominent as with the marginal model procedure, there are several examples where the estimated FDR values from the BH procedure are clearly above the $\text{FDR}_{\max}$ line. As with the marginal model procedure, the worst cases occur with the smallest number of sequences.

5.4 Dependence of the Statistical Tests

The experiments in this section provide evidence that, when used in combination with either the marginal model procedure or L^*, the BH procedure does not always control the FDR at the desired level; in turn, this may indicate that the conditions for applying the BH procedure are not satisfied. In the remainder of this section, we outline two arguments that show the assumption of independence is violated between the statistical tests used in these analyses. Note that these are not rigorous mathematical proofs; rather, our goal here is to simply give some intuition into the relationships between the statistical tests.

Consider a set of sequential data consisting of possible states A, B, C, D, and E. For states A and B, let $\beta_{A,B}$ represent the value of β_1 in (3) for transitions of the form $A \to B$. Suppose that the following inequalities hold.

$$\begin{aligned} \beta_{A,A} &> 0 & \beta_{A,B} &> 0 \\ \beta_{A,C} &> 0 & \beta_{A,D} &> 0 \end{aligned} \tag{6}$$

Consider, for example, $\beta_{A,B}$. The corresponding marginal model estimates the probability of a transition to B, depending on whether or not the starting state is A—these estimates correspond to $P(B \mid A)$ and $P(B \mid \overline{A})$, respectively. The inequalities in (6) can then be interpreted as follows.

$$\begin{aligned} P(A \mid A) &> P(A \mid \overline{A}) & P(B \mid A) &> P(B \mid \overline{A}) \\ P(C \mid A) &> P(C \mid \overline{A}) & P(D \mid A) &> P(D \mid \overline{A}) \end{aligned} \tag{7}$$

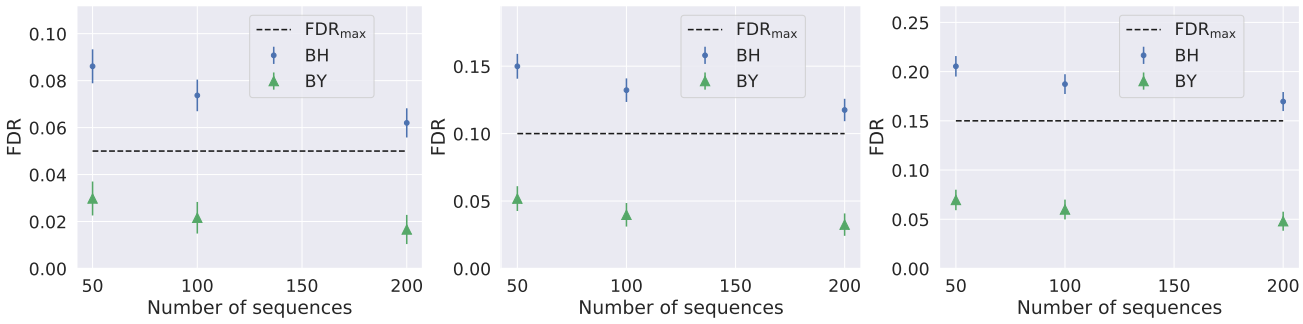
Next, consider the following two equalities.

$$\begin{aligned} P(E \mid A) &= 1 - P(A \mid A) - P(B \mid A) - P(C \mid A) - P(D \mid A) \\ P(E \mid \overline{A}) &= 1 - P(A \mid \overline{A}) - P(B \mid \overline{A}) - P(C \mid \overline{A}) - P(D \mid \overline{A}) \end{aligned} \tag{8}$$

Combining (7) and (8), it follows that $P(E \mid A) < P(E \mid \overline{A})$, or, equivalently, that $\beta_{A,E} < 0$. What this argument illustrates is that it's not possible—or, at least, it's highly unlikely—for $\beta_{A,E}$ to be positive when the other four coefficients are positive, which means that the corresponding statistical tests are not completely independent of each other.

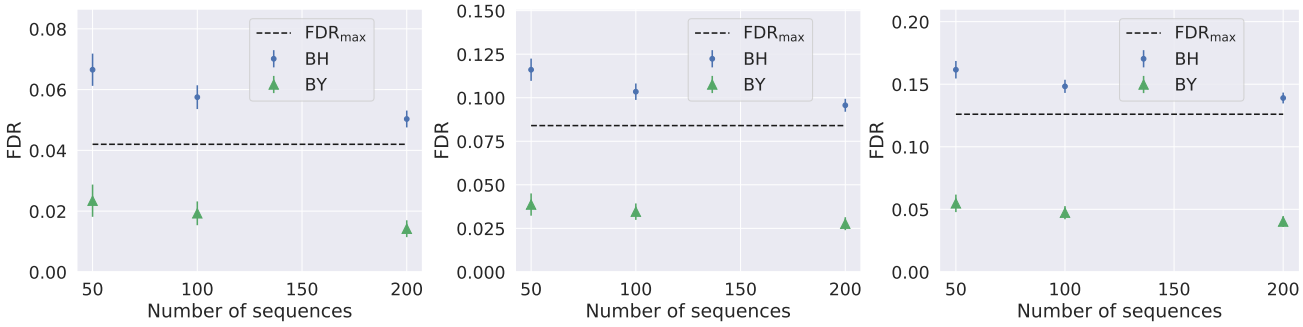
Next, suppose we are in the situation of removing self-transitions and applying L^*; thus, in what follows assume we are interested in transitions from A to B and that, following (4) in Definition 1, all transitions to A have been removed from our sequence. Suppose the following inequalities hold.

$$\begin{aligned} P(B \mid A) &> P(B) \\ P(C \mid A) &> P(C) \\ P(D \mid A) &> P(D) \end{aligned} \tag{9}$$



(a) $q = 0.05$ (b) $q = 0.1$ (c) $q = 0.15$

Figure 5: Comparison of the estimated FDR for the BH and BY procedures, using a value of $\gamma = 0$ and the marginal model method. Vertical lines represent the 99% confidence interval for each estimated FDR value.



(a) $q = 0.05$ (b) $q = 0.1$ (c) $q = 0.15$

Figure 6: Comparison of the estimated FDR for the BH and BY procedures, using a value of $\gamma = 0.05$ and the marginal model method. Vertical lines represent the 99% confidence interval for each estimated FDR value.

Consider the equalities

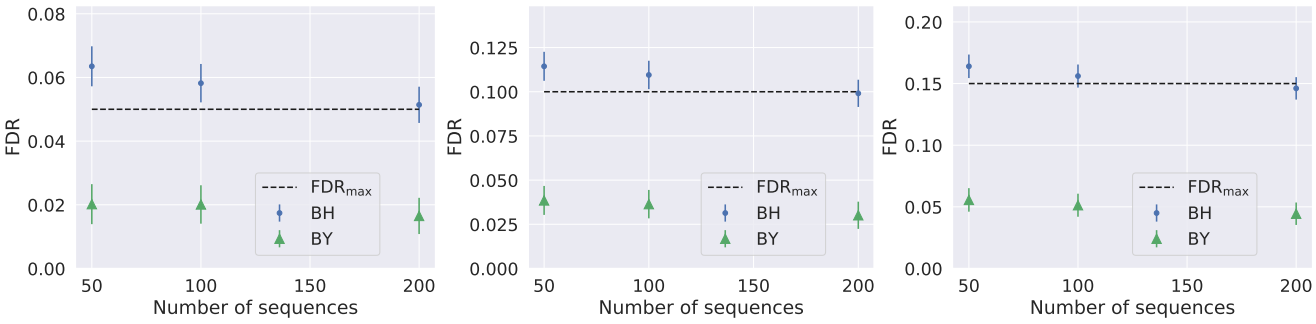
$$\begin{aligned} P(E \mid A) &= 1 - P(B \mid A) - P(C \mid A) - P(D \mid A) \\ P(E) &= 1 - P(B) - P(C) - P(D), \end{aligned} \tag{10}$$

where we're using the fact that, as we are removing transitions to A, $P(A \mid A) = 0$ and $P(A) = 0$. Combining (9) and (10), it follows that $P(E \mid A) < P(E)$. Thus, it's not possible for all four of the conditional probabilities to be larger than the base probabilities—in turn, this means that at least one of the L^* values must be negative. As such, it follows that the corresponding statistical tests are not completely independent of each other.

6. DISCUSSION

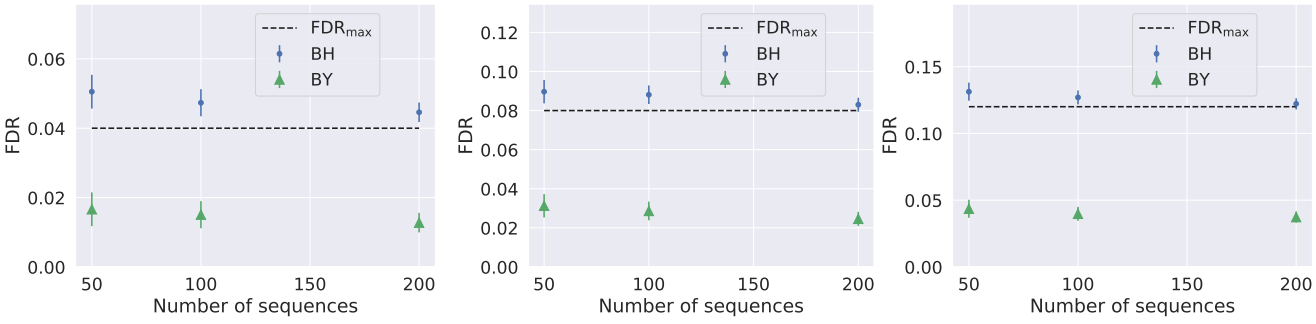
In this paper, we investigated the validity of methods used to adjust for false discoveries when performing multiple comparisons. In two scenarios relevant to EDM research, we evaluated the performance of the commonly used BH procedure in relation to an alternate method—the BY procedure—that is more general and is valid to use when the assumptions of the BH procedure cannot be met. Our first set of experiments looked at the performance of these procedures when used with pairwise comparisons of classification models on a fixed set of test data. In all our experiments, using both accuracy and AUROC as our performance metrics, the BH procedure controlled the FDR at the expected level. These results are consistent with previous studies investigating pairwise comparisons, where in all cases the BH procedure properly controlled the FDR [21, 38, 39]. Combining these previous results with the experiments in this study, our current view is that the usage of the BH procedures appears justified in this scenario—that is, one can reasonably expect the BH procedure to properly control the FDR when performing pairwise comparisons of classifiers on a fixed set of test data.

Contrast this with our investigation on sequential data, where we observed that the BH procedure, when combined with either the marginal model procedure or L^*, did not control the FDR at the expected level—this happened with various experimental conditions and for various threshold values q. The results could be an indication that the theoretical conditions for applying the BH procedure might not be satisfied in these situations. Combined with the fact that various issues involving the analysis of state transitions have recently come to light [7, 18, 19, 24, 25], we believe that using the more conservative BY procedure is justified, particularly when the analysis involves a small number of sequences. To compensate for the fact that it is more conservative, when applying the BY procedure we suggest the use of a larger value of q, such as 0.1.



(a) $q = 0.05$ (b) $q = 0.1$ (c) $q = 0.15$

Figure 7: Comparison of the estimated FDR for the BH and BY procedures, using a value of $\gamma = 0$ and the L^* statistic. Vertical lines represent the 99% confidence interval for each estimated FDR value.



(a) $q = 0.05$ (b) $q = 0.1$ (c) $q = 0.15$

Figure 8: Comparison of the estimated FDR for the BH and BY procedures, using a value of $\gamma = 0.05$ and the L^* statistic. Vertical lines represent the 99% confidence interval for each estimated FDR value.

More generally, it's worth noting that there are many examples where the BH procedure performs well without any theoretical guarantees [14, 22]. Thus, for situations in which the BH procedure has not been theoretically or empirically vetted, we offer a couple of suggestions. First, whenever possible, conducting a simulation study may be helpful; as seen in this work, the results could give evidence for or against the usage of the BH procedure. Failing that, and if there is good reason to doubt the validity of using the BH procedure, we suggest that the BY procedure be considered as a possible alternative. In these cases, a higher value for q may be justified in order to compensate for the more restrictive nature of the BY procedure, and this decision could be made based on the context of the study. For instance, in studies that are exploratory in nature or have small sample sizes, the loss of statistical power might be a larger concern; thus, the BY procedure using a threshold of 0.1 or larger may be appropriate. Whereas, in an experimental study looking for conclusive evidence, it may be preferable to use the BY procedure with a smaller value of q.

In regards to future work in this area, it would be of interest to more completely understand why the BH procedure fails to properly control the FDR in our simulations with sequential data. While we presented an argument in Section 5.4 that showed the statistical tests are not independent, it's an open question whether this argument can be extended to rigorously show that the assumptions of the BH procedure are violated—we are currently looking at this in more detail. Furthermore, it's possible that other elements may also be at play. For example, as discussed previously there are known issues with several existing methods commonly used to evaluate state transitions. While the methods we used in this study were originally developed in response to these problems [24, 25], it's possible that these existing issues, or perhaps even new ones, are a factor; thus, further adjustments to the marginal model and L^* methods could lead to improved control of the FDR with the BH procedure.

There exist other directions for future work that we are currently exploring. First, as the literature on multiple comparisons and controlling the FDR is actively growing, many methods have been developed over the years. Thus, while the BH and BY procedures are arguably the most notable of the FDR controlling procedures, it would be worthwhile to evaluate some of the newer alternatives, especially for the analysis of state transitions. Second, our analyses in this work focused exclusively on false discoveries (Type I errors) and did not consider false negatives (Type II errors). As such, in future work we aim to explicitly examine the interaction between these two types of errors with respect to the BH and BY procedures and EDM research.

ABSTRACT

We address the problem of predicting the correctness of the student's response on the next exam question based on their previous interactions in the course of their learning and evaluation process. We model the student performance as a dynamic problem and compare the two major classes of dynamic neural architectures for its solution, namely the finite-memory Time Delay Neural Networks (TDNN) and the potentially infinite-memory Recurrent Neural Networks (RNN). Since the next response is a function of the knowledge state of the student and this, in turn, is a function of their previous responses and the skills associated with the previous questions, we propose a two-part network architecture. The first part employs a dynamic neural network (either TDNN or RNN) to trace the student knowledge state. The second part applies on top of the dynamic part and it is a multi-layer feed-forward network which completes the classification task of predicting the student response based on our estimate of the student knowledge state. Both input skills and previous responses are encoded using different embeddings. Regarding the skill embeddings we tried two different initialization schemes using (a) random vectors and (b) pretrained vectors matching the textual descriptions of the skills. Our experiments show that the performance of the RNN approach is better compared to the TDNN approach in all datasets that we have used. Also, we show that our RNN architecture outperforms the state-of-the-art models in four out of five datasets. It is worth noting that the TDNN approach also outperforms the state of the art models in four out of five datasets, although it is slightly worse than our proposed RNN approach. Finally, contrary to our expectations, we find that the initialization of skill embeddings using pretrained vectors offers practically no advantage over random initialization.

Keywords

Student performance prediction, Recurrent neural networks, Time-delay neural networks, Dynamic neural models, Knowledge tracing.

1. INTRODUCTION

Knowledge is distinguished by the ability to evolve over time. This progression of knowledge is usually incremental and its formation is related to the cognitive areas being studied. The process of Knowledge Tracing (KT) defined as the task of predicting students' performance has attracted the interest of many researchers in recent decades [4]. The Knowledge State (KS) of a student is the degree of his or her mastering the Knowledge Components (KC) in a certain domain, for example "Algebra" or "Physics". A knowledge component generally refers to a learnable entity, such as a concept or a skill, that can be used alone or in combination with other KCs in order to solve an exercise or a problem [9]. Knowledge Tracing is the process of modeling and assessing a student's KS in order to predict his or her ability to answer the next problem correctly. The estimation of the student's knowledge state is useful for improving the educational process by identifying the level of his/her understanding of the various knowledge components. By exploiting this information it is possible to suggest appropriate educational material to cover the student's weaknesses and thus maximize the learning outcome.

The main problem of Knowledge Tracing is the efficient management of the responses over time. One of the factors which add complexity to the problem of KT is the student-specific learning pace. The knowledge acquisition may differ from person to person and may also be influenced by already existing knowledge. More specifically, KT is predominantly considered as a supervised sequence learning problem where the goal is to predict the probability that a student will answer correctly the future exercises, given his or her history of interactions with previous tests. Thus, the prediction of the correctness of the answer is based on the history of the student's answers in combination with the skill that is currently examined at this time instance.

Mathematically, the KT task is expressed as the probability $P(r_{t+1} = 1|q_{t+1}, X_t)$ that the student will offer the correct response in the next interaction x_{t+1}, where the students learning activities are represented as a sequence of interactions $X_t = \{x_1, x_2, x_3, ..., x_t\}$ over time T. The x_t interaction consists of a tuple (q_t, r_t) which represents the ques-

tion q_t being answered at time t and the student response r_t to the question. Without loss of generality, we shall assume that knowledge components are represented by skills from a set $S = \{s_1, s_2, ..., s_m\}$. One simplifying assumption, used by many authors [24], is that every question in the set $Q = \{q_1, q_2, ..., q_T\}$ is related to a unique skill from S. Then the knowledge levels of the student for each one of the skills in S compose his or her knowledge state.

The dynamic nature of Knowledge Tracing leads to approaches that have the ability to model time-series or sequential data. In this work we propose two dynamic machine learning models that are implemented by time-dependent methods, specifically recurrent and time delay neural networks. Our models outperform the current state-of-the-art approaches in four out of five benchmark datasets that we have studied. The proposed models differ from the existing ones in two main architectural aspects:

- we find that attention does not help improve the performance and therefore we make no use of attention layers
- we experiment with and compare between two different skill embedding types: (a) initialized by pretrained embeddings of the textual descriptions of the skill names using standard methods such as Word2Vec and FastText and (b) randomly initialized embeddings based on skill ids

The rest of the paper is organized as follows. Section 2 reviews the related works on KT and the existing models for student performance prediction. In Section 3 we present our proposed models and describe their architecture and characteristics. The datasets we prepared and used are present in Section 4 while the experiments setup and the results are explained in Section 5. Finally, Section 6 concludes this work and discusses the future works and extensions of the research.

2. RELATED WORKS

The problem of knowledge tracing is dynamic as student knowledge is constantly changing over time. Thus, a variety of methods, highly structured or dynamic, have been proposed to predict students' performance. One of the earlier methods is Bayesian Knowledge Tracing (BKT) [4] which models the problem as a Hidden Markov chain in order to predict the sequence of outcomes for a given learner. The Performance Factors Analysis Model (PFA) [14] proposed to tackle the knowledge tracing task by modifying the Learning Factor Analysis model. It estimates the probability that a student will answer a question correctly by maximizing the likelihood of a logistic regression model. The features used in the PFA model, although interpretable, are relatively simple and designed by hand, and may not adequately represent the students' knowledge state [23].

Deep Knowledge Tracing (DKT) [15] is the first dynamic model proposed in the literature utilizing recurrent neural networks (RNN) and specifically the Long Short-Term Memory (LSTM) model [6] to track student knowledge. It uses one-hot encoded skill tags and associated responses as inputs and it trains the neural network to predict the next student response. The hidden state of the LSTM can be considered as the latent knowledge state of a student and can carry the information of the past interactions to the output layer. The output layer of the model computes the probability of the student answering correctly a question relating to a specific Knowledge Component.

Another approach for predicting student performance is the Dynamic Key-Value Memory Network (DKVMN) [24] which relies on an extension of *memory networks* proposed in [12]. The model tries to capture the relationship between different concepts. The DKVMN model outperforms DKT using memory slots as key and value components to encode the knowledge state of students. Learning or forgetting of a particular skill are stored in those components and controlled by read and write operations through the Least Recently Used Access (LRUA) attention mechanism [16]. The key component is responsible for storing the concepts and is fixed during testing while the value component is updated when a concept state changes. The latter means that when a student acquires a concept in a test the value component is updated based on the correlation between exercises and the corresponding concept.

The Deep-IRT model [23] is the newest approach that extends the DKVMN model. The author combined the capabilities of DKVMN with the Item Response Theory (IRT) [5] in order to measure both student ability and question difficulty. At the same time, another model, named Sequential Key-Value Memory Networks (SKVMN) [1], tried to overcome the problem of DKVMN to capture long term dependencies in the sequences of exercises and generally in sequential data. This model combines the DKVMN mechanism with the Hop-LSTM, a variation of LSTM architecture and has the ability to discover sequential dependencies among exercises, but it skips some LSTM cells to approach previous concepts that are considered relevant. Finally, another newly proposed model is Self Attentive Knowledge Tracing (SAKT) [13]. SAKT utilizes a self-attention mechanism and mainly consists of three layers: an embedding layer for interactions and questions followed by a Multi-Head Attention layer [19] and a feed-forward layer for student response prediction.

The above models either use simple features (e.g. PFA) or they use machine learning approaches such as key-value memory networks or attention mechanisms that may add significant complexity. However we will show that similar and often, in fact, better performance can be achieved by simpler dynamic models combining embeddings and recurrent and/or time-delay feed-forward networks as proposed next.

3. PROPOSED APPROACH

3.1 Dynamic Models

As referenced in the relative literature, knowledge change over time is often modeled by dynamic neural networks. The dynamic models produce output based on a time window, called "context window", that contains the recent history of inputs and/or outputs.

There are two types of dynamic neural networks (Figure 1):

(a) Time-Delay Neural Networks (TDNN), with only feed-forward connections and finite-memory of length L equal to the length of the context window, and (b) Recurrent Neural Networks (RNN) with feed-back connections that can have potentially infinite-memory although, practically, their memory length is dictated by a forgetting factor parameter.

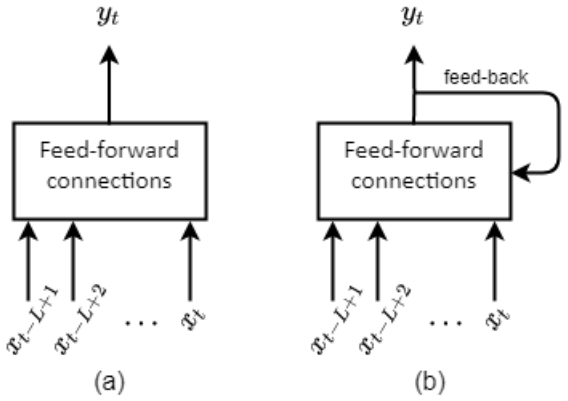

Figure 1: Dynamic model architectures: (a) Time-Delay Neural Network (b) Recurrent Neural Network.

3.2 The Proposed Models

We approach the task of predicting the student response (0=wrong, 1=correct) on a question involving a specific skill as a dynamic binary classification problem. In general, we view the response r_t as a function of the previous student interactions:

$$r_t = h(q_t, q_{t-1}, q_{t-2}, \dots, r_{t-1}, r_{r-2}, \dots) + \epsilon_t \qquad (1)$$

where q_t, is the skill tested on time t and ϵ_t is the prediction error. The response is therefore a function of the current and the previous tested skills $\{q_t, q_{t-1}, q_{t-2}, \dots\}$, as well as the previous responses $\{r_{t-1}, r_{t-2}, \dots\}$ given by the student.

We implement h as a dynamic neural model. Our proposed general architecture is shown in Figure 2. The inputs are the skill and response sequences $\{q\}$, $\{r\}$ collected during a time-window of length L prior to time t. Note that the skill sequence includes the current skill q_t but the response sequence does not contain the current response which is actually what we want to predict. The architecture consists of two main parts:

- The Encoding sub-network. It is used to represent the response and skill input data using different embeddings. Clearly, embeddings are useful for encoding skills since skill ids are categorical variables. We found that using embeddings to encode responses is also very beneficial. The details of the embeddings initialization and usage are described in the next section.
- The Tracing sub-network. This firstly estimates the knowledge state of the student and then uses it to predict his/her response. Our model function consists of two parts: (i) the Knowledge-Tracing part, represented by the dynamic model f, which predicts the student knowledge state $\mathbf{v}_t$ and (ii) the classification part g, which predicts the student response based on the estimated knowledge state:

$$\mathbf{v}_t = f(q_t, q_{t-1}, q_{t-2}, \dots, r_{t-1}, r_{r-2}, \dots) \qquad (2)$$
$$\hat{r}_t = g(\mathbf{v}_t) \qquad (3)$$

Depending on the memory length, we obtain two categories of models:

(a) models based on RNN networks which can potentially have infinite memory. In this case the KT model is recurrent:

$$\mathbf{v}_t = f(\mathbf{v}_{t-1}, q_t, q_{t-1}, \dots, q_{t-L}, r_{t-1}, \dots, r_{r-L})$$

(b) models based on TDNN networks which have finite memory of length L. In this case the KT model has finite impulse response L:

$$\mathbf{v}_t = f(q_t, q_{t-1}, \dots, q_{t-L}, r_{t-1}, \dots, r_{r-L})$$

Although RNNs have been used in the relevant literature, it is noteworthy that TDNN approaches have not been investigated in the context of knowledge tracing. The classification part is modeled by a fully-connected feed-forward network with a single output unit.

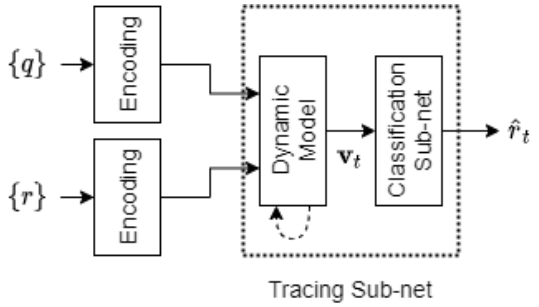

Figure 2: General proposed architecture. The dynamic model can be either a Recurrent Neural Network (with a feedback connection from the output of the dynamic part into the model input) or a Time Delay Neural Network (without feedback connection).

We investigated two different architectures: one based on recurrent neural networks and another based on time delay neural networks. The details of each proposed model architecture are described below.

3.3 Encoding Sub-network

The first part in all our proposed models consists of two parallel embedding layers with dimensions d_q and d_r, respectively, which encode the tested skills and the responses given by the student. During model training the weights of the Embedding layers are updated. The response embedding vectors are initialized randomly. The skill embedding vectors, on the other hand, are initialized either randomly or using pretrained data. In the latter case we use pretrained vectors corresponding to the skill names obtained from Word2Vec [11] or FastText [7] methods.

A 1D spatial dropout layer [18] is added after each Embedding layer. The intuition behind the addition of spatial

dropout was the overfitting phenomenon that was observed in the first epochs of each validation set. We postulated that the correlation among skill name embeddings, that might not actually exist, confused the model.

3.4 Tracing Sub-network

We experimented with two types of main dynamic sub-networks, namely Recurrent Neural Networks and Time Delay Neural Networks. These two approaches are described next.

3.4.1 RNN Approach: Bi-GRU Model

The model architecture based on the RNN method for the knowledge tracing task is shown in Figure 3.

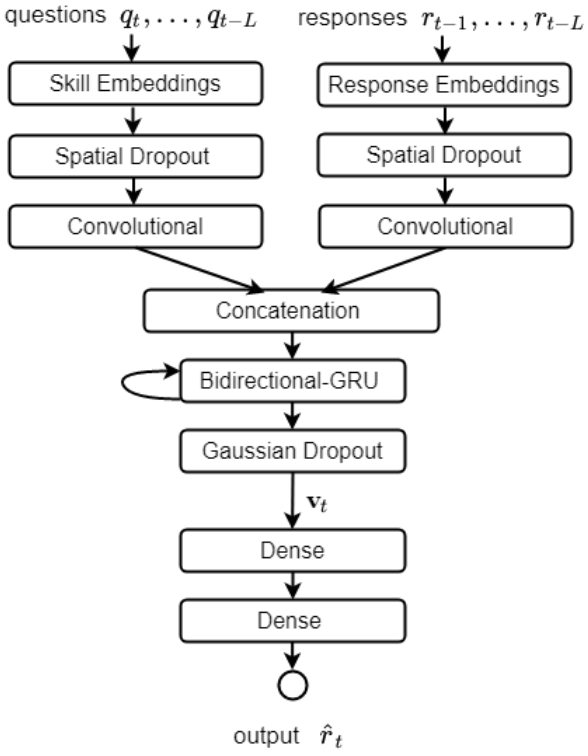

Figure 3: Bi-GRU model

The Spatial Dropout rate following the input embedding layers is 0.2 for most of used datasets. Next, we feed the skills and the responses input branches into a Convolutional layer consisting of 100 filters, with kernel size 3, stride 1, and ReLU activation function. The Convolutional layer acts as a projection mechanism that reduces the input dimensions from the previous Embedding layer. This is found to help alleviate the overfitting problem. To the best of our knowledge, Convolutional layers have not been used in previously proposed neural models for this task. The two input branches are then concatenated to feed a Bidirectional Gated Recurrent Unit (GRU) layer with 64 units [3]. Batch normalization and ReLU activation layers are applied between convolutional and concatenation layers. This structure has resulted after extensive experiments with other popular recurrent models such as LSTM, plain GRU and also bi-directional versions of those models and we found this to be the proposed architecture is the most efficient one.

On top of the RNN layer we append a fully connected sub-network consisting of three dense layers with 50 and 25 units and one output unit respectively. The first two dense layers have a ReLU activation function while the last one has sigmoid activation which is used to make the final prediction ($0 < \hat{r}_t < 1$).

3.4.2 TDNN Approach

In our TDNN model (Figure 4) we add a Convolutional layer after each embedding layer with 50 filters and kernel size equal to 5.

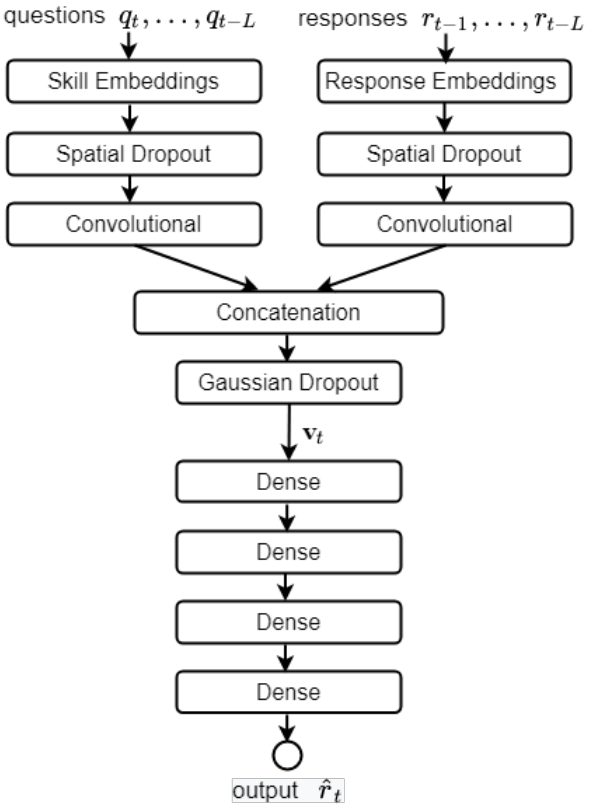

Figure 4: TDNN model

Batch normalization is used before the ReLU activation is applied. As with the RNN model, the two input branches are concatenated to feed the classification sub-network. It consists of four dense layers with 20, 15, 10, and 5 units respectively, using the ReLU activation function. This funnel schema of hidden layers (starting with wider layers and continuing with narrower ones) has helped achieve better results for all datasets we have experimented with. In the beginning of the classification sub-network we insert a Gaussian Dropout layer [17] which multiplies neuron activations with a Gaussian random variable of mean value 1. This has been shown to work as good as the classical Bernoulli noise dropout and in our case even better.

4. DATASETS

We tested our models using four popular datasets from the ASSISTments online tutoring platform. Three of them, "*AS-*

Table 1: Datasets Overview.

Dataset	Skills	Students	Responses	Baseline Accuracy
ASSISTment09	110	4,151	325,637	65.84%
ASSISTment09 corrected	101	4,151	274,590	66.31%
ASSISTment12	196	28,834	2,036,080	69.65%
ASSISTment17	101	1,709	864,713	62.67%
FSAI-F1toF3	99	310	51,283	52.98%

SISTment09", "*ASSISTment09 corrected*"[1], and "*ASSISTment12*"[2] were provided by the above platform. The fourth dataset, named "*ASSISTment17*" was obtained from 2017 Data Mining competition page[3]. Finally a fifth dataset, "*FSAI-F1toF3*" provided by "Find Solution Ai Limited" was also used in our experiments. It is collected using data from the from the 4LittleTrees[4] adaptive learning application.

4.1 Datasets Descriptions

The ASSISTments datasets contain data from student tests on mathematical problems [2] and the content is organized in columns style. The student's interaction is recorded on each line. There are one or more interactions recorded for each student. We take into account the information concerning the responses of students to questions related with a skill. Thus, we use the following columns: "*user_id*", "*skill_id*", "*skill_name*", and "*correct*". The "*skill_name*" contains a verbal description of the skill tested. The "*correct*" column contains the values of the students' responses which are either 1 (for correct) or 0 (for wrong).

The original "*ASSISTment09*" dataset contains 525,534 student responses. It has been used extensively in the KT task from several researchers but according to [2] data quality issues have been detected concerning duplicate rows. In our work we used the "*preprocessed ASSISTment09*" dataset found on DKVMN[5] and Deep-IRT[6] models GitHubs. In this dataset the duplicate rows and the empty field values were cleaned, so that finally 1,451 unique students participate with 325,623 total responses and 110 unique skills.

Even after this cleaning there are still some problems such as duplicate skill ids for the same skill name. These problems have been corrected in the "*Assistment09 corrected*" dataset. This dataset contains 346,860 students interactions and has been recently used in [21].

The "*ASSISTment12*" dataset contains students' data until the school year 2012-2013. The initial dataset contains 6,123,270 responses and 198 skills. Some of the skills have the same skill name but different skill id. The total number of skill ids is 265. The "*Assistment17*" dataset contains 942,816 students responses and 101 skills.

[2]https://sites.google.com/site/assistmentsdata/home/2012-13-school-data-with-affect
[3]https://sites.google.com/view/assistmentsdatamining/data-mining-competition-2017
[4]https://www.4littletrees.com
[5]https://github.com/jennyzhang0215/DKVMN
[6]https://github.com/ckyeungac/DeepIRT

Finally, the "*FSAI-F1toF3*" dataset is the smallest dataset we used. It involves responses to mathematical problems from 7th grade to 9th grade Hong Kong students and consists of 51,283 students responses from 310 students on 99 skills and 2,266 questions. As it is commonly the case in most studies using this dataset, we have used the question tag as the model input q_t.

4.2 Data Preprocessing

No preprocessing was performed on the "*ASSISTment09*" and "*FSAI-F1toF3*" datasets. For the remaining datasets we followed three preparation steps.

First, the skill ids had been repaired by replacement. In particular, the "*ASSISTments09 corrected*" dataset contained skills of the form of "*skill1_skill2*" and "*skill1_skill2_skill3*" which correspond to the same skill names, so we have merged them into the first skill id, found before the underscore. In other words, the skill "*10_13*" was replaced with skill "*10*" and so on. Moreover, few misspellings were observed that were corrected and the punctuations found in three skill names were converted to the corresponding words. For example, in the skill name "*Parts of a Polnomial Terms Coefficient Monomial Exponent Variable*" we corrected the "*Polnomial*" with "*Polynomial*". Also, in the skill name "*Order of Operations +,-,/,*() positive reals*" we replaced the symbols "*+,-,/,* ()*" with the words that express these symbols, ie. "*addition subtraction division multiplication parentheses*". The latter preprocessing action was preferred over the removal of punctuations since the datasets referred to mathematical methods and operations and without them, we would lose the meaning of each skill. Similar procedure has been followed for the "*ASSISTments12*" dataset. Furthermore, spaces after some skill names were removed i.e. the skill name "*Pattern Finding* " became "*Pattern Finding*". In the "*ASSISTment17*" dataset we came across skill names as "*application: multi-column subtraction*" and corrected them by replacing punctuation marks such as "*application multi column subtraction*". That text preparation operations made to ease the generation of word embeddings of the skill names descriptions. In addition, in the "*ASSISTment17*" dataset, the problem ids are used instead of the skill ids. We had to match and replace the problem ids with the corresponding skill ids with the aim of uniformity of the datasets between them.

Secondly, all rows containing missing values were discarded. Thus, after the preprocessing, the statistics of the data sets were formulated as described in the Table 1.

Finally, we split the datasets so that 70% was used for training and 30% for testing. Then, the training subset was further split into five train-validation subsets using 80% for

training and 20% for validation.

5. EXPERIMENTS

In this section we experimentally validate the effectiveness of the proposed methods by comparing them with each other and also with other state-of-the-art performance prediction models. The Area Under the ROC Curve (AUC) [10] metric is used for comparing the predicting probability correctness of student's response.

The state-of-the-art knowledge tracing models we are compared with the DKT, DKVMN and Deep-IRT. We performed the experiments for our proposed models Bi-GRU, TDNN as well as for each of the previous model for all datasets, using the code provided by the authors on their GitHubs. It is worth noting that the python GitHub code[7] used for the DKT model experiments requires the entire dataset file and the train/test splitting is performed during the code execution.

All the experiments were performed on a workstation with Ubuntu operating system, Intel i5 CPU and 16GB Titan Xp GPU card.

5.1 Skill embeddings initialization

As mentioned earlier, skill embeddings are initialized either randomly or using pretrained vectors. Regarding the initialization of the skill embeddings with pretrained vectors we used two methods described next. In first method we used the text files from Wikipedia2Vec[8] [22] that is based on Word2Vec method and contains pretrainable embeddings for the word representation vectors in English language in 100 and 300 dimensions. In second method we used the "*SISTER*" (SImple SenTence EmbeddeR)[9] library to prepare the skill name embeddings based on FastText in 300 dimensions pretrained word embeddings. Each skill name consists of one or more words. Thus, for the Word2Vec method, the skill name embeddings vector is created by adding the word embeddings vectors, while in case of FastText, the skill name embeddings are created by taking the average of the word embeddings.

Especially for the FsaiF1toF3 dataset, the question embeddings are initialized either randomly or using the pretrained word representations of the corresponding skill descriptions by employing the Wikipedia2Vec and SISTER methods as described above. Since many questions belong to the same skill, in this case the corresponding rows in the embedding matrix are initialized by the same vector.

5.2 Experimental Settings

We performed the cross-validation method for the 5 training and validation set pairs. This was to choose the best architecture and parameter settings for each of the proposed models. Using the train and test sets we evaluated the chosen architectures for all the datasets.

[7]https://github.com/lccasagrande/Deep-Knowledge-Tracing

[8]https://wikipedia2vec.github.io/wikipedia2vec/

[9]https://pypi.org/project/sister/

One of the basic hyperparameters of our models that affect to the inputs is the L. It represents the student's interaction history window length. The inputs with L sequence of questions and $L-1$ sequence of responses. The best results we succeeded are when using $L = 50$ for the both Bi-GRU and TDNN models. The batch sizes used in the models during the training are: 32 in Bi-GRU and 50 in TDNN.

Since specific dimensions of the pretrained word embeddings are provided, we used the same dimensions in case of random embedding in order to take the comparable results. Skill embeddings and responses embeddings set in the same dimensions.

The scheduler learning rate is implementing in Bi-GRU starting from 0.001 and reducing over the training operation of the models that performs for 30 epochs. During training we applied the following learning rate schedule depending on the epoch number n:

$$lr = \begin{cases} r_{init} & \text{if } n < 10 \\ r_{init} \times e^{(0.1 \cdot (10-n))} & \text{otherwise} \end{cases}$$

In case of the TDNN-based model, the learning rate equals 0.001 and is the same during the whole training process for 30 epochs. We used cross-entropy optimization criterion and the Adam or AdaMax [8] learning algorithms.

Dropout with rate = 0.2 or 0.9 is also applied to the Bi-GRU model while the dropout rate of the TDNN equals to one of the $(0.2, 0.4, 0.6, 0.9)$ values through to the Gaussian dropout layer. We observed a reduction of overfitting during model training by changing the Gaussian dropout rate relative to the dataset's size. Thus, the smaller dataset size is, the bigger dropout rate has been used.

The various combinations of parameters settings were applied during the experimental process for all proposed models presented in Table 2.

5.3 Experimental Results

The experiments results of our models are shown in Table 3. Comparing our models with each other we can see that the RNN-based Bi-GRU model outperforms the TDNN-based model in all datasets. It achieved best results when 100d embeddings were used either in pretrained or the random initialization type.

We observed that in both Bi-GRU or TDNN, the embedding type is not the significant parameter that affects the models performance. The differences between the results of the experiments showed that the size of embeddings dimensions not particularly contributed to the final result and the difference in performance of the models was small.

Except for our models, we performed experiments for all datasets on the previous models we compared. For three of the datasets, specifically for "*ASSISTment09 corrected*", "*ASSISTment12*" and "*ASSISTment17*" there were not available results in the corresponding papers. In this paper, we present the results of the experiments we run using that models codes.

Table 2: Models experiments settings

Parameters	Bi-GRU	TDNN
Learning rate	0.001	0.001
Learning rate schedule	yes	no
Training epochs	30	30
Batch size	32	50
Optimizer	Adam	AdaMax

(e)

The best experimental results of the ours models in comparison with the previous models for each dataset are presented in Table 4. The model that has the best performance for the four of datasets is the Bi-GRU. Except for that, the TDNN-based model has better performance in comparison to the previous models for four datasets. The only dataset, for which the previous models overcomed our models is the "*ASSISTment12*".

5.4 Discussion

Our model architecture is loosely based on the DKT model and offers improvements in the aspects discussed below. First, we employ embeddings for representing both skills and responses. It is known that embeddings offer more useful representations compared to one-hot encoding because they can capture the similarity between the items they represent [20]. Second, we thoroughly examined dynamical neural models for estimating the student knowledge state by trying both infinite-memory RNNs and finite-memory TDNNs. To our knowledge, TDNNs have not been well studied in the literature with respect to this problem. Third, we used convolutional layers in the inputs encoding sub-net. We found that this layer functioned as a reducing mechanism of the embedding dimensions and in conjunction with the dropout layer mitigated the overfitting problem. The use of Convolutional layers is a novelty in models tackling the knowledge tracing problem. Fourth, unlike DKT, we used more hidden layers in the classification sub-net. Our experiments demonstrate that this gives more discriminating capability to the classifier and improves the results. Finally, our experiments with key-value modules and attention mechanism did not help further improve our results and so these experiments are not reported here. In the majority of the datasets we examined our model outperforms the state-off the models employing key-value mechanisms such as DKVMN and Deep-IRT.

evaluating the performance of our machine learning models, we applied statistical significance testing to check the similarity between out Bi-GRU and TDNN models. Specifically, we performed a T-Test between the outcomes of the two models in all training data using the best configuration settings as shown in Table 4. The results reported in Table 5 show that the P-value calculated in all cases is practically zero which proves the hypothesis that the two models are significantly different.

6. CONCLUSION AND FUTURE WORK

In this paper we propose a novel two-part neural network architecture for predicting student performance in the next exam or exercise based on their performance in previous exercises. The first part of the model is a dynamic network which tracks the student knowledge state and the second part is a multi-layer neural network classifier. For the dynamic part we tested two different models: a potentially infinite memory recurrent Bidirectional GRU model and a finite memory Time-Delay neural network (TDNN). The experimental process showed that the Bi-GRU model achieves better performance compared to the TDNN model. Despite the fact that TDNN models have not been used for this problem in the past, our results have shown that they can be just as efficient or even better compared to previous state-of-art RNN models and only slightly worse than our proposed RNN model. The model inputs are the student's skills and responses history which are encoded using embedding vectors. Skill embeddings are initialized either randomly or by pretrained vectors representing the textual descriptions of the skills. A novel feature of our architecture is the addition of spatial dropout and convolutional layers immediately after the embeddings layers. These additions have been shown to reduce the overfitting problem. We found that the choice of initialization of the skill embeddings has little effect on the outcome of our experiments. Moreover, noting that there is a different use of the same datasets in different studies, we described in detail the process of the datasets pre-processing, and we provide the train, validation and test splits of the data that were used in our experiments on our GitHub repository[10]. The extensive experimentation with more benchmark datasets as well as the study of variants of the proposed models will be the subject of our future work with the aim of even further improving the prediction performance of the models.

7. ACKNOWLEDGMENTS

We would like to thank NVIDIA Corporation for the kind donation of an Titan Xp GPU card that was used to run our experiments.

ABSTRACT
We investigated the feasibility of using automatic speech recognition (ASR) and natural language processing (NLP) to classify collaborative problem solving (CPS) skills from recorded speech in noisy environments. We analyzed data from 44 dyads of middle and high school students who used videoconferencing to collaboratively solve physics and math problems (35 and 9 dyads in school and lab environments, respectively). Trained coders identified seven cognitive and social CPS skills (e.g., sharing information) in 8,660 utterances. We used a state-of-the-art deep transfer learning approach for NLP, Bidirectional Encoder Representations from Transformers (BERT), with a special input representation enabling the model to analyze adjacent utterances for contextual cues. We achieved a micro-average AUROC score (across seven CPS skills) of .80 using ASR transcripts, compared to .91 for human transcripts, indicating a decrease in performance attributable to ASR error. We found that the noisy school setting introduced additional ASR error, which reduced model performance (micro-average AUROC of .78) compared to the lab (AUROC = .83). We discuss implications for real-time CPS assessment and support in schools.

Keywords
Collaborative problem solving; natural language processing; collaborative interfaces

1. INTRODUCTION
The modern world will increasingly require teams of heterogeneous individuals to coordinate their efforts, share skills and knowledge, and communicate effectively in order to solve complex and pressing problems like the global pandemic and climate change. Accordingly, collaborative problem solving (CPS) – defined as two or more people engaging in a coordinated attempt to construct and maintain a joint solution to a problem [57] – has been identified as a critical skill for the 21st century workforce [23, 27]. Despite its increasing importance, the most recent 2015 Programme for International Student Assessment (PISA) assessment revealed troubling deficiencies in CPS competency worldwide [49]. As a result, improving CPS proficiency has become a priority in educational research and policy [7, 8, 16, 37, 49].

Technology has fundamentally transformed both the modern workplace and classroom. Co-located teams in shared spaces are becoming less common, while distributed teams that work and collaborate remotely through virtual interfaces are on the rise [22, 36]. In 2020, the COVID-19 pandemic thrust this issue to the forefront of our attention, as workers and students across the globe were forced to adapt to a remote environment for extended periods of time. Accordingly, educational practitioners have emphasized the importance of providing students with the skills necessary to effectively collaborate in virtual settings [60].

The rise of videoconferencing in both workplace and learning environments brings with it the exciting opportunity to develop next-generation collaborative interfaces that can aid in teaching, assessing, and supporting CPS. Here we focus on the task of assessing CPS skills from spoken language with an eye for downstream applications including reflective feedback and dynamic interventions to improve CPS skills.

Like any latent construct (e.g., intelligence, knowledge), assessment of CPS skills entails identifying objective evidence for those constructs. Because collaboration inherently involves communication, one promising approach is to analyze communication between team members [58]. Indeed, the content of communication during CPS provides information about a team's cognitive and affective states, knowledge, information sharing, and coordination [27], and can serve as evidence of relevant CPS skills [3, 4].

However, analyzing the large amounts of data generated during open-ended collaboration is time consuming and costly, requiring trained human coders to review large corpus and hand code individual items for indicators of CPS. Previous work [24, 29, 58, 65] has attempted to automate this coding process using natural language processing (NLP) techniques. However, with the exception of [65], this has been limited to restricted forms of communication such as text chat, rather than open-ended verbal communication, which is characteristic of most real world CPS. As we elaborate below, the one study [65] that successfully analyzed spoken communications for evidence of CPS skills used data collected in a highly controlled lab environment, leaving open the question as to whether this approach will succeed in the wild, such as in noisy classroom environments.

In this work, we address the challenge of using speech recognition and NLP to automatically analyze open-ended student speech during videoconferencing-enabled collaborative problem solving in both real-world schools and in lab environments. Pursuing technologies capable of automatically capturing and analyzing spoken language during open-ended verbal CPS in authentic environments, whether face-to-face or via videoconferencing, is an important avenue of research. These technologies hold the potential for significantly improving real-

time assessment and support of CPS [58], whether by providing teachers with feedback on CPS in student groups or enabling just-in-time interventions to steer groups of problem solvers in the right direction.

1.1 Background and Related Work

We first present a brief discussion on theoretical frameworks of CPS to situate the CPS skills modeled in this study within the CPS literature. Then, we discuss prior work on computational models of CPS, specifically focusing on language-based models.

1.1.1 Frameworks of CPS

CPS has been defined as problem solving activities that involve interactions among a group of individuals [47]. One early attempt to conceptualize CPS was by Roschelle and Teasley [57] who proposed a joint problem space model that emphasized shared understanding of the task as a central aspect of CPS. More recently, the Assessment and Teaching of Twenty-First Century Skills (ATC21S) framework [28, 30] described CPS through a measurable and teachable set of social and cognitive skills based on interaction, self-evaluation and goal setting. Relatedly, the PISA 2015 [49] framework conceptualized CPS as a complex process involving three collaborative dimensions that overlap with four problem-solving processes resulting in 12 CPS skills. Building on these frameworks, Sun et al. [68] proposed a generalized competency framework for CPS skills based on interactions among triads, which defines a hierarchical CPS model involving three high-level facets of CPS, each composed of sub-facets and associated behavioral indicators. Another approach, and the framework adopted in this work, is the in-task assessment framework [34]. Informed by principles of evidence-centered design [41], this framework characterizes CPS through a hierarchical ontology [3], which lays out theoretically-grounded, generalizable CPS skills along with behavioral indicators of these skills.

1.1.2 Computational Models of CPS

The stream of interactions generated during problem solving is considered the richest source of information about a team's knowledge, skills, and abilities [27, 38]. Accordingly, prior research has used non-verbal behavioral signals like facial expressions to detect rapport loss in small groups during open-ended discussions [43]. Multimodal combinations of facial expressions, acoustics and prosody, eye gaze, and task context have been explored to predict CPS outcomes like task performance [42, 67]. Additionally, learning gains [32, 50], subjective performance [72] and CPS competence [13, 14] have been modelled using multimodal signals.

Focusing our review on studies that explored the use of language and speech based data, researchers have successfully used language to model CPS processes like idea sharing [24, 29], negotiation [65], and argumentation [58], as well as CPS outcomes such as task performance [10, 44, 51] and learning gains [55]. A common NLP approach involves quantifying the frequency of words and word phrases (n-grams) [24, 29, 44, 54, 58]. Further, some research has experimented with the use of additional lexical features like punctuation [24, 29, 58], part-of-speech tags [21, 44, 58], or emoticons [29]. In addition to using lexical features from language itself, researchers have derived features from conversational data which index team and conversational dynamics (e.g., turn taking). This approach has been used to provide feedback on collaboration [59], identify sociocognitive roles [20], and model intra- and interpersonal dynamics [19] during CPS.

Closely related to our work, Hao et al. [29] used pre-selected n-grams and emoticons to model four CPS facets of sharing ideas, negotiating, regulating problem-solving activities, and maintaining communication. Their study involved data collected from 1000 participants with at least one year of college experience randomly grouped into dyads. They used a linear chain conditional random field and extracted lexical features from sequential text chats between dyads. They found that sequential modeling achieved an average accuracy of 73.2%, which outperformed a majority-class baseline accuracy of 29%, and slightly outperformed standard classifiers (accuracies of 66.9% to 71.9%).

Whereas the Hao study analyzed text-chats among dyads, Stewart et al. [65] modeled the three CPS facets of construction of shared knowledge, negotiation and coordination, and maintaining team function from spoken trialogues (conversations among triads). The study involved 32 triads of undergraduate students from a medium-sized private university, engaged in a 20-minute computer programming task using video conferencing software in a lab setting. They used ASR to generate transcripts of the team's speech during problem solving, from which they derived n-gram features for modeling. They obtained area under the receiver operating characteristic curve (AUROC) scores of .85, .77 and .77 for the three CPS facets using random forest classifiers, exceeding chance baselines of 0.5. In a follow-up study [66], they investigated whether including additional modalities (facial expression, acoustic-prosodic features, task context) in addition to language improved classification accuracy. They found that a combination of language and task context yielded slight improvement over unimodal language models.

1.2 Current Study and Novelty

There are several novel aspects of this work. First, although recent work [65, 66] has successfully used ASR and NLP to automatically analyze speech during CPS in the lab, it is currently unknown whether this approach can be effective in the wild, for example in noisy real-world classrooms where CPS interactions would occur. Lab environments have the advantage of being free from ambient noises, distractions from other students, and various other complicating factors present in school environments.

Further, previous work has been limited to adults, namely undergraduate students. However, given the importance of CPS, it is imperative that technologies be developed that can help instruct and support CPS in middle and high school-aged students. Therefore, a second important question is whether this approach can be applied to children, who may have differing CPS abilities and communication styles. An accompanying question is whether ASR can provide sufficiently accurate transcripts of children's speech, as research has documented the degradation of ASR performance on children's speech due to ASR systems primarily trained on adult speech, and age-dependent spectral and temporal variability in speech signals [26, 45, 53].

We address these questions by recording audio of remote CPS among middle and high school students in both the lab and

computer-enabled classrooms with multiple teams interacting. We show for the first time that in noisy school environments, ASR can provide transcripts of sufficient accuracy to model CPS skills. Additionally, we quantify the decrease in predictive accuracy that can be attributed to ASR error (vs. NLP error) by comparing with models trained on human transcripts, and comparing lab- vs. classroom- environments.

Finally, an open question in this domain is which NLP algorithms should be used to automatically analyze CPS language. We explore the use of deep transfer learning for this NLP problem. Recent advances in state-of-the-art NLP have been attained by adapting attention-based language models [71], pre-trained on large amounts of unlabeled data, to specific NLP tasks (e.g., text classification) [31]. We demonstrate the efficacy of this approach, using the popular Bidirectional Encoder Representations from Transformers (BERT) model [18] for our NLP task, and compare results with a more traditional n-gram approach using random forest classifiers. We also investigate whether a sequential classifier, which considers adjacent (i.e. previous, subsequent) utterances for contextual cues, yields improved performance over single utterance classifiers. We present a method, similar to the approaches used in [12, 69], to capture adjacent utterances for context by constructing a special input representation for the BERT model, which improves classification accuracy.

2. METHOD

2.1 Data Collection

2.1.1 Contexts

Our primary data collection occurred in one United States east coast public middle school and one public high school from the same district. The study was run over two data collection periods. The first period included 61 students in the high school and 44 students in the middle school. Here, students participated in two 43 minute class periods. The second collection included 18 students from the same middle school. Because we did not have control over the acoustic environment in the school context, we also collected supplementary data from 18 students in the lab. In the second collection, students completed one 90 minute session. In both collections, students in the school environment completed the study from a computer lab in the school in which other students were also participating in the study. Data collection occurred prior to the COVID-19 pandemic, and as such classrooms were at normal capacity. Students in both environments were equipped with a personal headset and microphone (MPOW 071 USB Headset).

2.1.2 Participants

In all, 141 middle and high school students (age range: 12-15) completed some or all of the study. However, only a subset of 74 sessions (a session entails one dyad completing one of the tasks) were included in this analysis. Participants were excluded for the following reasons: we experienced technical challenges on the first day of data collection, either team member did not complete a consent form, one team member did not show up, or there were quality issues with the recorded audio stream. Our analyzed dataset consisted of 88 students (65% female; mean age = 13.6, SD = 0.90). The lab subset contained 18 students (50% female; mean age = 13.6, SD = 1.01) and the school subset contained 70 students (69% female; mean age = 13.6, SD = 0.87). The sample of 88 students was quite diverse with 26.1% self-reporting as Black/African American, 19.3% Hispanic/Latino, 15.9% Multiracial, 13.6% Asian/Asian American, 12.5% White, 2.3% American Indian/Alaska Native, 6.8% reported "Other", and 3.4% did not report ethnicity.

2.1.3 CPS Tasks

The study involved two separate CPS tasks. In one task on linear functions and argumentation (T-Shirt Math Task [1]), students worked together through a series of task items in which they sought to determine which of three t-shirt companies was the best choice for a student council to purchase t-shirts for classmates. They compared three companies with differing variable costs (price per shirt) and fixed costs (upfront fee) to determine which company should be chosen given the number of t-shirts to be purchased. Individual questions included populating the cost equation y = mx + b according to the costs of each company (see Figure 1B), identifying the correct graph for a given company's cost equation, and providing a recommendation as to which company was the best deal. During this task, only one student controlled the screen at a time (i.e. to enter responses to the questions), and the two students could alternate control as they chose.

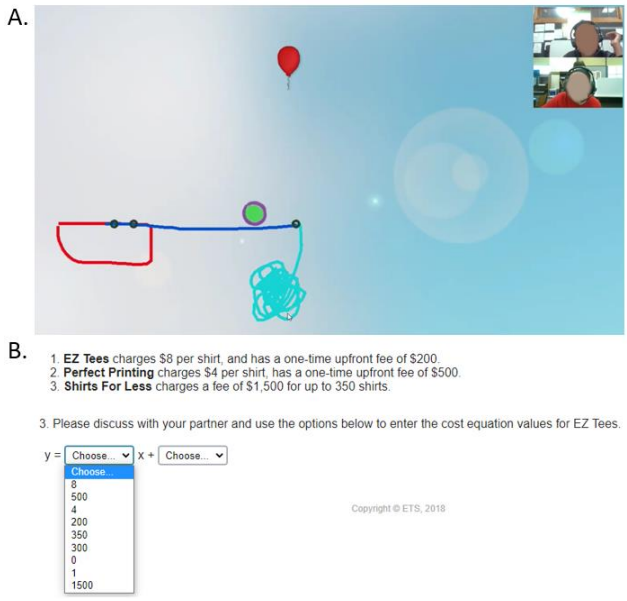

Figure 1. Screenshot examples of the videoconferencing setup and two CPS tasks. (A) Shows a level in Physics Playground, (B) shows a question from the T-Shirt Math Task (reproduced with permission from ETS).

The second task (Physics Playground [62]) was an educational physics game designed to help students learn concepts in Newtonian physics. In this task, students completed a series of six game levels in which they were tasked with drawing objects (e.g., lever, ramp, springboard) to guide a ball to hit a balloon target (see Figure 1A in which students are drawing a weight attached to the springboard to launch the ball towards the balloon). During this task, only one student controlled the game at a time. One student was selected to control first, and after

three levels had been completed (or half of the allotted time had elapsed), control was switched to the other student for the following three levels. Whereas the math task resembles more traditional school work and is more constrained by prior knowledge, the physics game provides more opportunities for creative exploration [35].

2.1.4 Procedure

Students were randomly assigned to pairs (27 mixed-gender, 17 same-gender pairs) and each student first individually completed a series of pre-surveys; details are not relevant here. Once both students in the pair completed the pre-surveys, a researcher enabled audio and video recording on each student's computer using Zoom video conferencing software (https://zoom.us) to record students' computer screens, faces, and voices. The student teams then worked together to complete the two CPS tasks, either on a different day or the same day (see above). The order of the tasks was counterbalanced so that half of the teams completed Physics Playground first and the other half completed the T-Shirt Math Task first. After completing each task students individually completed additional questionnaires not analyzed here.

2.2 CPS Ontology and CPS Skills

2.2.1 CPS Ontology (Framework)

We used a competency model represented as an ontology [3, 4] (similar to a concept map), which lays out the components of CPS and their relationships, along with indicators of CPS skills. The development of the ontology was based on discussions with subject matter experts as well as a literature review in relevant areas such as computer-supported collaborative learning, individual problem solving, communication, and linguistics [30, 39, 46, 48, 49, 64].

Our CPS ontology [3] includes nine high-level CPS skills across social and cognitive dimensions and sub-skills that correspond to each high-level skill. The social dimension includes four CPS skills: (1) *Maintaining communication* corresponds to content irrelevant social communications among teammates (e.g., greeting teammates or engaging in off-topic conversations); (2) *Sharing information* corresponds to task-relevant communication that is useful for solving the problem (e.g., sharing one's own knowledge, sharing the state of one's understanding); (3) *Establishing shared understanding* includes communication used to learn the perspectives of others and ensure that what has been said is understood by teammates (e.g., requesting information from teammates, providing responses that indicate comprehension); and (4) *Negotiating* corresponds to communication used to express agreement, express disagreement, or resolve conflicts that arise.

The cognitive dimension includes five CPS skills: (1) *Exploring and understanding* corresponds to communication and actions used to explore the environments in which teammates are working or understand the problem at hand (e.g., rereading problem prompts); (2) *Representing and formulating* includes communication used to build a mental representation of the problem and formulate hypotheses; (3) *Planning* corresponds to communication used to develop a plan for solving the problem (e.g., determining goals or establishing steps for carrying out a plan); (4) *Executing* corresponds to actions and communication used to carry out a plan (e.g., taking steps to carry out a plan, reporting to teammates what steps you are taking, or making suggestions to teammates about what steps they should take to carry out the plan); and (5) *Monitoring* includes communication used to monitor progress towards the goal or monitor teammates (e.g., checking the progress or status of teammates).

Table 1. The 7 CPS skills modeled, ordered from highest to lowest prevalence

CPS Skill	Base Rate	Dimension	Example Human Transcript	Corresponding ASR Transcript
Sharing Information	.26	Social	(Math) "Okay so first I think we should create like three equations to for each company"	"Okay Sir thank first we should create like three D creations for each arm company"
Establishing Shared Understanding	.25	Social	(Math) "Which one do you think is the best one"	"Twenty it's the best"
Negotiating	.16	Social	(Physics) "Umm no let's just do another idea I don't think it's gonna work anymore"	"Let's just do it another day I don't think it's going to work anymore"
Executing	.14	Cognitive	(Physics) "Okay and now put a weight down on that"	"Okay and now put a weight down on the"
Maintaining Communication	.07	Social	(Physics) "(laughs) Oh no this game is funny bro yeah I don't know what to do"	"This came funny I would like to do"
Monitoring	.06	Cognitive	(Physics) "That didn't work oh no"	"That didn't recall about"
Planning	.05	Cognitive	(Math) "Alright now we have to find a graph for this one now"	"Now we have to find a crusher this one now"

2.2.2 CPS Coding

Video recordings of student task sessions were segmented at the turn (or utterance) level and then coded by three trained raters using Dedoose qualitative analysis software [17]. For the coding, raters viewed each turn for each individual in a team and then labeled the turn as one of the CPS skills from the CPS ontology. To establish reliability, the three trained raters triple coded 20% of the videos. Intraclass correlations (ICCs) were used to estimate interrater reliability across rater judgments, as it can provide information about the consistency of the judgments among raters. The median ICC across the CPS skill ratings was .93, corresponding to excellent agreement [11].

Once reliability was established, the remaining videos were split among the three raters and coded independently. A total of 10,239 turns were coded across 80 CPS sessions with an average of 128 turns per session (SD = 70.5). Two CPS skills (exploring and understanding, and representing and formulating) occurred very infrequently (base rate < 1%) and were excluded from our analysis. The remaining seven CPS skills, with their base rate, cognitive/social dimension, and a sample utterance from the dataset, are shown in Table 1.

2.3 ASR and Human Transcript Generation

After segmenting and coding each utterance, we used the IBM Watson speech-to-text service [33] to generate ASR transcripts for each video. The service outputs transcripts with word-level start and stop times, as well as word-level confidence (between 0 and 1) for each word recognized. We constructed the transcript for each coded utterance by concatenating transcribed words within the utterance's human segmented time window. The confidence for each utterance was computed by taking the mean word confidence over all words in the utterance transcript. Utterances in which no words were recognized were assigned a confidence of 0. Because a single audio stream of each session was recorded (rather than individual audio streams from each student), the ASR transcripts can contain words from both speakers if there was overlap (elaborated below).

We also manually transcribed each utterance from the CPS videos. Human transcribers viewed the video segment (with audio) of each coded utterance and transcribed the words spoken by the indicated speaker (each utterance was coded for an individual student). Speech from the other student, if present in the segment, was not transcribed. Prior to transcription, guidelines were established among the human transcribers to ensure consistency in transcribing informal words or phrases (e.g., gonna, c'mon).

Because the segmented utterances sometimes contained speech from both speakers, we had alignment inconsistencies, as the ASR transcribed all words in a segment while the human transcripts only contained words spoken by the indicated student. To better assess ASR accuracy, we randomly sampled 10 utterances from each CPS session (8.5% of the data) and re-transcribed the utterances to include all words spoken in the segment, regardless of speaker. We refer to this as the Human Transcript Subset. We then computed a word error rate (WER) [9] for each utterance in this subset defined as (substitutions + insertions + deletions) / (words in human transcript), using the python package Jiwer [70].

2.4 Analyzed Dataset

Our dataset contains 74 CPS task sessions from 44 teams. This includes 30 teams with both the math and physics tasks in the dataset, nine teams with only the math task and five teams with only the physics task. 18 of the 74 sessions occurred in the lab, and the remaining 56 sessions occurred in school environments. The dataset consists of 8,660 utterances coded with CPS skills, and corresponding transcripts. Of these utterances, 2,751 (32%) were from lab sessions and the other 5,909 (68%) were from school sessions.

2.5 Machine Learning

We adopted a supervised classification approach to predict the ground truth CPS skill for each utterance. We first implemented a bag-of-n-grams approach using a Random Forest Classifier, as recent literature [65] has shown this method to be effective for the classification of CPS utterances. Next, we explored deep transfer learning as a means to improve upon this method. In particular, we leveraged pre-trained language models and employed the popular Bidirectional Encoder Representations from Transformers (BERT) model [18]. Additionally, we tested a method (BERT-seq) which takes a sequence of utterances as input (the utterance to classify plus the previous and subsequent utterances) to capture contextual information, in order to determine if including adjacent utterances improves classification accuracy. We trained separate models (RF, BERT, and BERT-seq) using the ASR transcripts and human transcripts as input.

2.5.1 Random Forest N-Grams

We first followed the approach outlined in [65] and trained Random Forest Classifiers to predict the CPS skill for each utterance using n-gram features. We used unigrams (words) and bigrams (two-word phrases) as the features for our Random Forest classifiers. Trigrams and beyond were not used since very few unique trigrams (only 6) occurred in >1% of utterances. We explored excluding n-grams that occurred at less than a minimum frequency in the training dataset, testing values of 0% (no filtering), 1% and 2% as hyperparameters. We used the scikit-learn [52] library's implementation of the Random Forest Classifier with 200 estimators.

2.5.2 BERT

We used a transfer learning approach and fine-tuned pre-trained BERT models to predict the CPS skill for each utterance. This entailed starting with a BERT model pre-trained on a large amount of unlabeled data, then fine-tuning it on our dataset of transcribed utterances and corresponding labels (CPS skills). We first processed the transcribed utterances using WordPiece tokenization [61]. This process entailed splitting an utterance into a sequence of words, or parts of words. Each unique word or word piece was then converted to an integer (called a token) according to BERT's pre-specified vocabulary. Finally, special tokens ([CLS] and [SEP]) were appended to the beginning and end of this sequence of integers and the sequence was provided as input to BERT (see Figure 2A). BERT mapped each input token to a 768-dimensional embedding, which serves as a semantic representation of the input token (the embedding of the special [CLS] and [SEP] tokens capture a semantic representation of the entire sequence of input tokens).

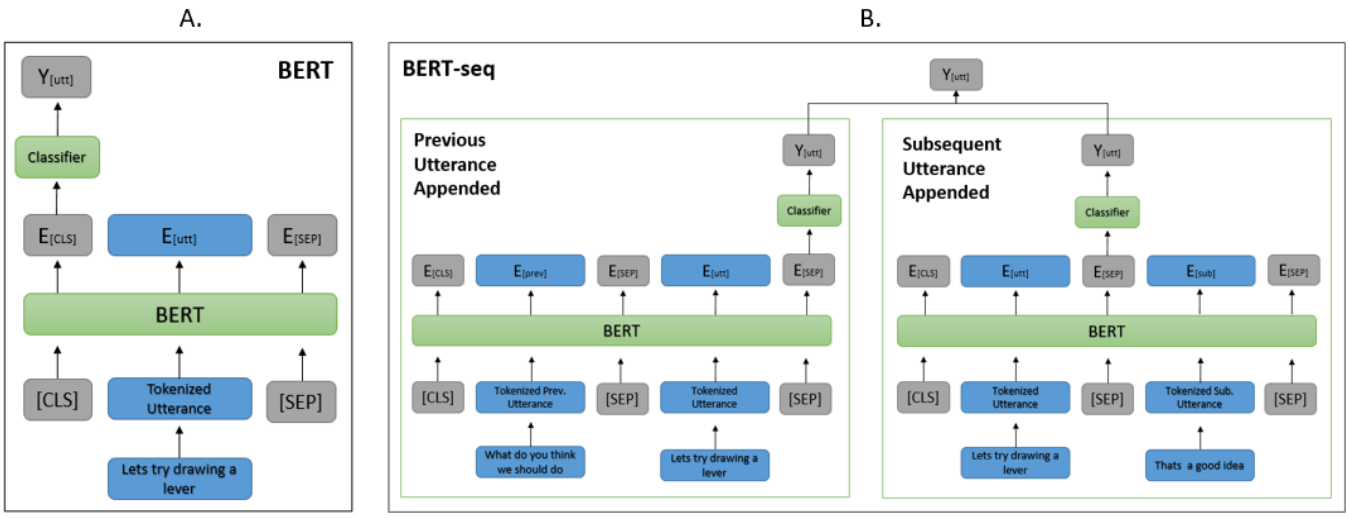

Figure 2. (A) The traditional BERT model used for text classification. (B) Our BERT-seq model which captures contextual information from the previous and subsequent utterances during classification.

For classification, the embedding of the [CLS] token was used as input to a fully connected layer (classifier), which output predicted probabilities for the seven CPS skills. We used multiclass learning, meaning that all seven CPS skills were predicted by one model.

2.5.3 BERT-seq

We propose a method to incorporate contextual utterances during classification by creating a special input representation, without augmenting the BERT architecture. This method takes a sequence of three utterances as input (the utterance to classify plus the previous and subsequent utterances), which are used to train two separate BERT models, each including either the previous or subsequent utterance in the BERT input (see Figure 2B). To add a pair of adjacent utterances to the input, we first processed each utterance individually using WordPiece tokenization as described above. The special [CLS] token was then added to the beginning of this sequence, and a [SEP] token was added to the end of both the first and second utterances. To classify the utterance, the embedding of the corresponding [SEP] token was used as input to a fully connected layer, which output predictions for the 7 CPS skills. Finally, the predicted probabilities of the previous and subsequent utterance models were averaged. This method of representing a sequence of utterances enables the self-attention layers of BERT to leverage contextual information from the previous and subsequent utterances, while still utilizing the pre-trained BERT weights.

For both BERT and BERT-seq we started with the transformers [73] library's implementation of the BertModel with the "bert-base-uncased" pre-trained weights, and used the BertTokenizer to process our utterances. We then fine-tuned the models for three epochs using a batch size of 16. We found that fine-tuning beyond three epochs did not substantially improve model performance.

2.5.4 Cross Validation

We used team-level 10-fold cross-validation to assess the accuracy of our classifiers. With our dataset of 44 teams, this entailed training a model with utterances from 90% of teams (39 or 40 teams), then evaluating the model's predictive accuracy on a test set containing utterances from the 10% of teams withheld during training (4 or 5 teams). This process was repeated ten times, such that every team appeared in the test set once. To compute accuracy metrics, predictions from all ten folds were aggregated and a single metric was computed on the full dataset. Team-level cross validation yields a better assessment of the method's generalizability to new teams because it ensures each model is never trained and evaluated on utterances from the same speaker. We used identical cross-validation folds for the RF, BERT and BERT-seq models as well as the human and ASR transcripts to ensure that differences in performance were not an artifact of the folds used. This experiment was repeated for 5 iterations, and different randomized cross-validation folds were used for each iteration.

3. RESULTS

3.1 ASR Accuracy

We compared WER in the lab and school subsets in order to quantify the speech recognition error that could be attributed to noisy school environments, as opposed to other factors such as difficulty recognizing children's speech, whispering or mumbling, audio quality, or inevitable ASR mistakes. We used the Human Transcript Subset as described in Section 2.3 for this comparison. The distributions of WER in the lab and school environments are shown in Figure 3. We found that WER was much lower in the lab environment than in schools (mean WER of .54 and .76, median WER of .50 and .91, respectively), indicating that significant ASR error is due to noisy school environments. We performed a non-parametric Kruskal-Wallis test [40] to statistically compare WER in the lab and school samples, and found that they differed significantly ($\chi^2(1) = 62.13$, $p < .001$).

As evident in Figure 3, a large proportion (47%) of the school utterances had a WER of 1 (compared to 19% for lab data), meaning no words were correctly recognized. However, WER was also high in the controlled lab environment, suggesting that speech recognition error may in part be attributable to factors beyond the complications of noisy school environments.

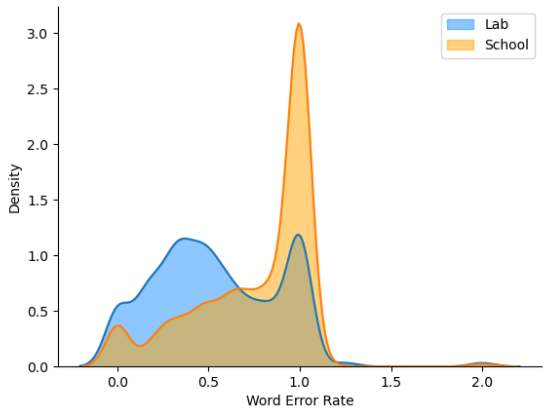

Figure 3. Gaussian kernel density estimates of the distribution of word error rates in the lab and school environments.

We also investigated the correlation between WER and ASR confidence to determine whether the confidence values produced by the ASR provided a good estimate of transcript accuracy. We found that WER and ASR confidence were significantly correlated (Spearman *rho* = -.74, $p < .001$).

3.2 Model Comparison

Next we compared the performance of our three NLP models (RF, BERT, BERT-seq). The models output a probability from 0 to 1 that an utterance is coded with each CPS skill. Accordingly, we report the area under the receiver operating characteristic curve (AUROC) for each skill, a common accuracy metric for model performance [6] which takes into account the true positive and false positive tradeoff across classification thresholds. Mean AUROC scores (over the five iterations) for the RF, BERT and BERT-seq models, using both human and ASR transcripts are reported in Table 2. We also report a chance baseline, created by randomly shuffling the labels within each CPS session and computing accuracy accordingly. Because shuffling is within sessions, the AUROCs for the shuffled models will slightly deviate from the 0.5 chance baseline. To determine if the three model's AUROC scores were significantly different for each CPS skill, we used a bootstrap method to statistically compare the AUROC values. Since five iterations of this experiment were conducted, we selected the model corresponding to the median AUROC value across the five iterations (for both human and ASR transcripts) on each CPS skill for statistical analysis. We performed this analysis in R using the pROC package [56] with 2,000 bootstrap permutations. Finally, we adjusted the resulting p-values using a false discovery rate (FDR) correction [5] to account for multiple testing across the seven CPS skills.

Without exception BERT-seq quantitatively yielded the highest AUROC scores for all seven CPS skills using both human and ASR transcripts, indicating that our method of incorporating adjacent utterances improves performance over single utterance classifiers. On average, BERT outperformed the RF model on both human and ASR transcripts, although there were some skills for which the RF AUROC scores were higher. From the statistical analysis described above, we found that with ASR transcripts BERT-seq had a significant advantage over the other two models for most skills (four of seven for BERT, five of seven for RF). We also found that there was no significant difference between BERT and RF for six of seven skills.

Table 2. Mean AUROC values (across 5 iterations) of the RF N-gram, BERT, and BERT-seq models on ASR and Human transcripts for all CPS skills.

CPS Skill	ASR Transcripts			Human Transcripts			
	RF	**BERT**	**BERT-seq**	**RF**	**BERT**	**BERT-seq**	**Shuffled**
Sharing Information	0.711	0.745 ^{R}	0.756 ^{R}	0.837	0.866 ^{R}	0.877 ^{R}	0.540
Establishing Shared Understanding	0.713	0.724	0.740 ^{RB}	0.872	0.894 ^{R}	0.907 ^{RB}	0.509
Negotiating	0.721	0.719	0.741 ^{B}	0.896	0.901	0.916 ^{RB}	0.510
Executing	0.745	0.767	0.784 ^{R}	0.897	0.914 ^{R}	0.926 ^{R}	0.574
Maintaining Communication	0.673	0.667	0.750 ^{RB}	0.849	0.853	0.901 ^{RB}	0.557
Monitoring	0.632	0.594	0.677 ^{RB}	0.812	0.792	0.843 ^{RB}	0.513
Planning	0.700	0.692	0.718	0.861 ^{B}	0.818	0.872 ^{B}	0.502
Micro Avg.	0.773	0.782	0.799	0.887	0.895	0.914	0.607

^{R} and ^{B} indicate the AUROC score was significantly higher than the RF and/or BERT models, respectively. Neither RF nor BERT ever outperformed BERT-seq.

We observed a similar pattern on the human transcripts, where BERT-seq significantly outperformed BERT on five of seven skills and RF on six of seven skills. Interestingly, on human transcripts the advantage of BERT over RF increased, with BERT having significantly higher scores on three skills, while RF was significantly better on only one. This finding suggests that with high quality transcripts which accurately capture the content of an utterance, BERT was the better model, whereas with noisy ASR transcripts there was no clear difference.

These results indicate that BERT-seq quantitatively outperformed both the traditional BERT and the RF n-gram approach for all seven CPS skills, using both the human and ASR transcripts. However, the statistical analysis revealed that for some CPS skills, this advantage was not statistically significant. As BERT-seq was the best model across CPS skills, we refer to these results in our comparison of human and ASR transcripts, and throughout the rest of this paper.

3.3 ASR vs. Human Transcripts

We found that using the ASR transcripts as input, our best model (BERT-seq) was able to accurately classify the seven CPS skills, yielding a micro-average AUROC score of .799. However, when the human transcripts were used, this average increased to .914 (see Table 2). We compared the human and ASR transcript results using the bootstrap method described above, and found that the human transcript AUROC scores were significantly (FDR corrected $p < .05$) higher than the ASR transcript scores for all seven CPS skills, an unsurprising result given the high word error rates in the ASR transcripts. However, we note that despite significant loss in performance due to speech recognition error, our model easily outperformed a shuffled baseline (micro-average AUROC of .607), supporting the hypothesis that CPS skills can be automatically predicted from ASR transcripts.

3.4 Classification Accuracy in Lab and School Environments

Next we compared classification accuracy in the lab and school environments in order to investigate the extent to which higher rates of ASR error in the school subset affected model performance. We report AUROC scores for the lab and school environments in Table 3. We found that on average, classification accuracy was substantially lower in the school subset compared to the lab subset (micro-average AUROC of .783 and .830, respectively). Further, for every individual skill, AUROC scores were quantitatively higher in the lab subset than in the school subset, with differences in AUROC values for individual skills ranging from .031 (Executing) to .102 (Negotiating). We again used the bootstrap method to statistically compare AUROC scores in the lab and school for each skill and found that scores were significantly higher in the lab subset for five out of seven CPS skills (see Table 3).

3.5 Classification Accuracy as a Function of ASR Confidence

Lastly, we examined the relationship between ASR confidence and classification accuracy. As discussed in section 3.1, the ASR confidence is a good proxy for word error rate, as the two values are significantly correlated. Therefore, we separated our 8,660 utterances into ten ASR confidence bins (0.0 – 0.1, etc.) and computed the micro-average AUROC score for each bin. The distribution of utterances and corresponding AUROC scores for each bin are shown in Figure 4A and 4B, respectively. Figure 4B also shows the human transcript AUROC score as a benchmark of the accuracy that would be expected under conditions of near-perfect speech recognition. The shuffled baseline is also shown to visualize improvement over chance.

Table 3. Mean AUROC scores (across 5 iterations) for each CPS skill in Lab and School environments. Results are from the BERT-seq model using ASR transcripts. Values marked with * were significantly higher in the Lab vs. School.

CPS Skill	Lab		School	
	AUC	**Base Rate**	**AUC**	**Base Rate**
Sharing Information	0.782*	.25	0.743	.27
Establishing Shared Understanding	0.786*	.26	0.716	.25
Negotiating	0.807*	.18	0.705	.15
Executing	0.804	.15	0.773	.13
Maintaining Communication	0.803*	.03	0.717	.08
Monitoring	0.701	.05	0.663	.07
Planning	0.760*	.06	0.688	.04
Micro Avg.	0.830		0.783	

We found that a large proportion of utterances (20%) fall in the [0.0 - 0.1) bin, indicating that the ASR had little to no confidence in their content. In fact, nearly all (97%) of the utterances in this bin have an empty ASR transcript, meaning no words were recognized during the utterance's segmented time window. In many cases, this occurred due to the students whispering or mumbling, which the ASR was unable to recognize. Excepting the significant zero inflation, the utterances appeared to be normally distributed around the [0.6 - 0.7) bin.

We observed a strong correlation between ASR confidence bin and classification accuracy (Spearman $rho = .94$, $p < .001$). Unsurprisingly, we found that for low confidence transcripts (< 0.3) a substantial gap exists between the ASR transcript AUROC score and the benchmark human transcript score (see Figure 4B). On these low confidence transcripts, model performance is near the shuffled chance baseline. Interestingly, despite many (77%) of these low confidence transcripts containing no words, the model was still able to outperform the chance baseline by learning the distribution of skills among empty transcripts in the training data. We found that accuracy increases steadily among the medium confidence transcripts (0.3 - 0.7). For high confidence transcripts (≥0.7), AUROC scores are near (though still lower than) the benchmark human transcript values. The

relationship between ASR confidence and classification accuracy indicates that it might be viable to filter out utterances with low confidence to improve reliability for downstream applications.

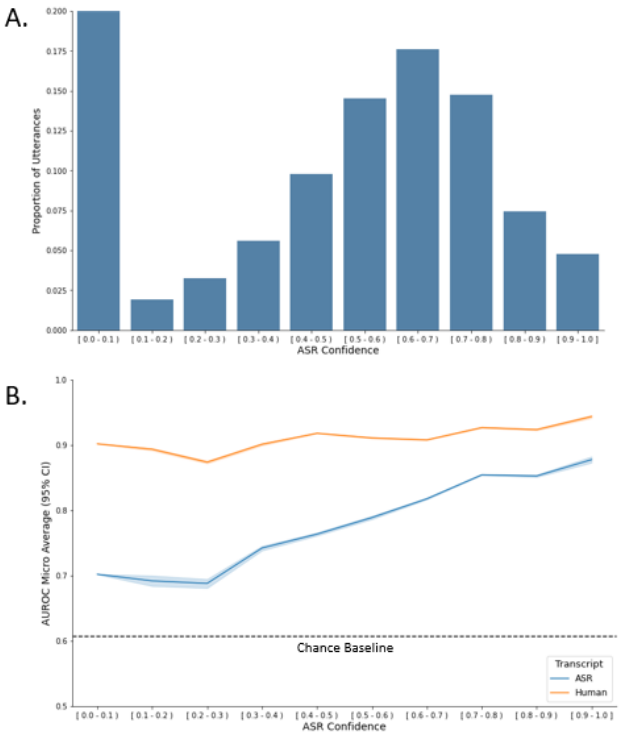

Figure 4. (A) Distribution of ASR confidence on all 8,660 utterances. (B) Model accuracy as a function of ASR confidence. Micro-average AUROC scores across the 7 CPS skills (with 95% CI across 5 iterations) are plotted for Human and ASR transcripts.

4. DISCUSSION

We investigated the feasibility of using automatic speech recognition and natural language processing to automatically classify student speech with CPS skills using data collected in both lab and real-world school environments. We compared performance using imperfect ASR transcripts with human transcripts, investigated differences between the lab and school environments, and explored three NLP approaches including bag-of-n-grams and deep transfer learning. In the rest of this section we discuss our main findings, applications of our models, as well as limitations and future directions of research.

4.1 Main Findings

We found that it is feasible to use ASR to transcribe middle and high school student's speech during CPS in both lab and school environments. However, we found that significant speech recognition error is introduced when speech is recorded in schools (mean WER of .76), likely as a result of noisy environments and distractions from other students. That said, speech recognition error was also high in the lab environment (mean WER of .54), suggesting that there may still be fundamental limitations associated with using ASR on children's speech in the context of remote CPS.

Despite imperfect speech recognition, we demonstrated that it is possible to automatically predict CPS skills from student speech in a real-world school environment. We built team-independent models that were able to predict CPS skills with reasonable accuracy (micro-average AUROC of .80) using ASR transcripts. Importantly, this result outperformed a shuffled baseline (micro-average AUROC of .61) by a significant margin. This finding is encouraging because it was previously unknown whether ASR could yield transcripts of sufficient quality to model CPS skills in noisy environments. Further, we demonstrated that by using high-fidelity human transcripts, this accuracy could be significantly improved (micro-average AUROC of .91). We demonstrated that in the absence of ASR error our NLP models were highly accurate, suggesting a useful upper bound of what can be achieved from spoken content alone.

We also improved upon NLP approaches previously used in CPS literature, demonstrating the advantage of deep transfer learning over standard classifiers for modeling CPS language. We found that on average, using both ASR and human transcripts, the deep transfer learning model (BERT) achieved slightly better accuracy than the Random Forest n-gram model (though the two were statistically tied for 3/7 CPS skills with human transcripts and 6/7 skills with ASR transcripts). This finding was unsurprising given that pre-trained language models have achieved state-of-the-art performance on many NLP benchmark tasks, including text classification.

Importantly, we found that we were able to further improve classification accuracy by constructing an input representation that enables BERT to capture information from adjacent utterances. This method showed significant improvement over the single utterance BERT and RF models, providing preliminary evidence of its viability. This finding suggests that in CPS, the context of an utterance (what was said before and after) may be important for accurate identification of particular CPS skills.

Finally, we examined the relationship between ASR confidence – a proxy for transcription quality – and classification accuracy. We found that the two were highly correlated, suggesting that downstream applications may be able to improve reliability of predictions by filtering out low confidence transcripts.

4.2 Applications

A key application of this work is the automatic assessment of CPS skills from open-ended speech in classrooms and beyond. As previously discussed, analyzing verbal communication for evidence of CPS skills is a costly and time-intensive process when trained human coders are used. Our findings suggest that automated methods using ASR and NLP may provide a viable alternative to the human-coding process. These automated methods hold great potential in improving the assessment and training of CPS skills, a priority of modern education [49]. However, given the imperfect accuracy of our models, and unanswered questions regarding how this approach may generalize to students with differing communication styles or cultural and linguistic backgrounds, this approach should be limited to formative assessment [63] focused on learning and improvement, rather than evaluation.

Our approach could advance this goal in several ways. For example, automatically generated reports could be sent to a teacher monitoring many groups of students engaged in CPS, informing the teacher of the extent to which each group is demonstrating CPS skills. Such a system could help the teacher

identify which groups need support and allocate their limited presence toward assisting those groups. Similarly, these reports could be used to identify individual student's strengths and weaknesses, and set appropriate goals for improvement. For instance, a student who frequently shares information yet seldom engages in negotiation or establishing shared understanding could be encouraged to listen to the ideas of their teammates and work to build on those ideas together.

In addition to passive assessment and off-line feedback, this approach could be leveraged by next-generation intelligent systems that actively monitor ongoing CPS and dynamically intervene in real time to yield improved CPS outcomes [15], or provide personalized on-line feedback to students. For example, a group frequently engaging in off-topic conversation could be prompted by the system to focus back on the problem-solving task, or a particular student within a group who hasn't shared information could be encouraged to share their ideas with the team. The specific intervention strategies, including when to intervene, how to present the intervention, and who the intervention should be targeted at (whole group vs. individual student) await design, testing, and refinement.

Importantly, a technology devised to assist in the training and assessment of CPS does little good if it is confined to the lab. Thus, the present results take a step towards the development of a system that can support CPS in real-world classrooms by monitoring open-ended verbal communication for CPS skills.

4.3 Limitations

There were some limitations of this work. First, although we used an automated approach for utterance transcription and CPS skill prediction, the sessions were segmented into utterances beforehand by human coders. This is a limitation because a fully automated pipeline would require the ASR to automatically detect and segment recorded speech into individual utterances, an already difficult task that may be further complicated by noisy school environments or the peculiarities of children's speech. Another related limitation is that due to the utterance segmentation and ASR transcription process we used, our ASR transcripts contain all speech that was recognized during an utterance's segmented time window. This means that some ASR transcripts contain words from both speakers, which introduces alignment inconsistencies between the ASR transcript and the coded CPS skill because utterances were coded at the individual student level. In particular, this introduces noise into the ASR transcripts when student's utterances overlap.

Another limitation of this work is that we considered only linguistic features to predict the coded CPS skills. We expect that model performance can be improved by modeling not only what students say (language), but considering how they say it (acoustic-prosodic information) and in the context of what they're doing (task-specific information). We hypothesize that the inclusion of these additional modalities may particularly improve performance for low confidence ASR transcripts, where the language transcribed by the speech recognizer is either missing altogether, or is a poor representation of what was actually said. Finally, although we demonstrated that our method for capturing contextual information from adjacent utterances improved accuracy, we did not compare this with other methods for incorporating contextual utterances such as conditional random fields or recurrent neural networks.

4.4 Future Work

The findings and limitations discussed in this section present several possibilities for improvement in future research. First, in order to develop a fully automated approach for modeling CPS skills, we plan to incorporate automatic utterance segmentation and speaker diarization into our ASR pipeline. Further, we plan to explore methods for incorporating information from other modalities in addition to language. For instance, including features such as acoustic-prosodic information, task context, facial expression, or body movement may enable more accurate prediction of CPS skills in cases where ASR fails to capture the content of an utterance.

Another direction of future research involves further exploration of how contextual utterances can be used to improve classification accuracy. We demonstrated a method for incorporating adjacent utterances in our model input, which improved performance over single utterance classifiers. In future work, we will explore methods for capturing contextual information beyond the previous and subsequent utterances (e.g., the five previous utterances). We also plan to investigate how the approach demonstrated in this paper, which leverages the model's attention mechanism to capture context, compares with other approaches (e.g., recurrent neural networks).

In addition to exploring methods for improving the accuracy of our models, we plan to investigate the utility of our CPS models. An open question is how accurate model predictions need to be to provide useful and actionable estimates for assessment, feedback, or intervention. Specifically, recent work [2, 25] has clustered students using the frequency of CPS skills to derive theoretically grounded profiles of collaborative problem solvers (e.g., active collaborators, social loafers). We plan to investigate whether model-derived estimates of CPS skill frequencies will yield high agreement to the clustering produced using human codes.

5. CONCLUSION

We combined automatic speech recognition and natural language processing to automatically predict CPS skills from student speech during problem solving in both lab and real-world school environments. Our findings suggest that despite significant speech recognition error in school environments, it is possible to predict expert-coded CPS skills using automatically generated transcripts. These findings open many possibilities for next-generation technologies that can further the goal of improved CPS training, assessment, and support in schools.

ABSTRACT

Feedback on how students progress through completing subgoals can improve students' learning and motivation in programming. Detecting subgoal completion is a challenging task, and most learning environments do so either with *expert-authored* models or with *data-driven* models. Both models have advantages that are complementary – expert models encode domain knowledge and achieve reliable detection but require *extensive authoring efforts* and often cannot capture all students' possible solution strategies, while data-driven models can be easily scaled but may be less accurate and interpretable. In this paper, we take a step towards achieving the best of both worlds – utilizing a data-driven model that can intelligently detect subgoals in students' correct solutions, while benefiting from human expertise in editing these data-driven subgoal rules to provide more accurate feedback to students. We compared our hybrid "humanized" subgoal detectors, built from data-driven subgoals modified with expert input, against an existing data-driven approach and baseline supervised learning models. Our results showed that the hybrid model outperformed all other models in terms of overall accuracy and F1-score. Our work advances the challenging task of automated subgoal detection during programming, while laying the groundwork for future hybrid expert-authored/data-driven systems.

Subgoals, Formative feedback, Data-driven hybrid models

1. INTRODUCTION

Formative feedback has been shown to be an effective form of automated feedback that can improve students' learning and motivation [54, 38, 8, 20]. In programming, *immediate* formative feedback *during* problem-solving is important because some problems require students to find one of many correct solutions [16], and novices may be uncertain about when they are on the right track [62]. This uncertainty may lead some students to give up [43], and can also negatively impact student confidence and motivation in computer science (CS) [32]. Prior research has shown that immediate feedback can address this, reducing novices' uncertainty and improving their confidence, engagement, motivation, and learning [42, 8, 33, 21, 38, 39].

One effective form of immediate feedback is subgoal feedback [40], which indicates students' progress on specific sub-steps of the problem. Feedback on subgoals offers special advantages because it demonstrates how a student can *break down a problem into a set of smaller sub-tasks*; which is a key to simplifying the learning process [37, 38], and can promote students' retention in procedural domains [35]. To generate such feedback, learning environments need to be able to do *subgoal detection*, which is the process of detecting when a student completes a key objective or sub-part of a programming task (e.g. receiving and validating user input). However, subgoal detection *during* problem-solving is known to be extremely challenging because it requires assessing students' *intended problem solving approach* rather than their *program output*. In other words, it is difficult to automatically evaluate whether a student completed a subgoal *in the middle* of problem-solving due to the many possible strategies that students can approach to solve a problem, even when using test cases or autograders.

Historically, to provide feedback on subgoals, learning environments have used expert-authored models, where human experts encode a set of rules to predict solution strategies that students might perform to complete a specific subgoal. While expert models can generate accurate feedback with interpretable explanations, they also require extensive human participation particularly for open-ended programming tasks, where it becomes unmanageable to capture every possible correct solution [59]. More recently, data-driven (*DD*) models, where the model learns rules from historical data, have become more prominent models. This is because *DD* models reduce the expert-authoring burden, and have the potential to be easily scaled to more problems and contexts. Moreover, *DD* models learn from multiple students' solutions, which makes it capture code situations that human experts cannot easily perceive, particularly in open-ended programming tasks [49, 45]. However, *DD* models are dependent on the quality of the data, and may have lower accuracy than expert models [59, 48]; and, therefore, may sometimes provide misleading feedback in practice [48]. Both of these models have strengths and weaknesses, and in this paper we propose an approach that takes advantage of both.

We present a hybrid approach that leverages both a data-driven model and expert insights to detect subgoal completion during problem-solving block-based programs. Our hybrid model is based on three main steps. First, we used an unsupervised data-driven model to generate subgoal detectors for a programming task, and represent them as a set of human-*interpretable* and human-*editable* rules. Second, this representation allowed us to evaluate the accuracy of the subgoal detectors; particularly when they have inaccurate detections. Third, we used human expert insights to refine and fix rules that led to inaccurate subgoal detections. These three steps resulted in a *hybrid* data-driven approach that generates subgoal detectors with high accuracy, that target expert-authoring effort *only* where improvements are needed, and that can also be easily scaled to various problems and contexts.

We evaluated our hybrid data-driven model to a block-based programming problem from an introductory CS classroom against the same, fully data-driven (*DD*) model, *but* without experts' intervention. We evaluated the accuracy of both models by comparing their subgoal detections on a given programming task, to that of human experts, and we hypothesize that our hybrid model will surpass the accuracy achieved by the *DD* model. We found that the expert evaluations of subgoal detections achieved significantly higher agreement with our hybrid model than that achieved with the *DD* model. We also found that our hybrid model outperforms the state-of-the-art supervised models: code2vec [53], Support Vector Machine (SVM) [14], and XGBoost [9]. In addition, we present case studies of how the hybrid model led to differing subgoal detections in student programs compared to the *DD* model. We also discuss how we can close the loop by applying our hybrid model in block-based programming classrooms to provide students with immediate feedback on subgoals.

In summary, in this paper we investigate this research question: **RQ:** *How well does a hybrid data-driven model combined with expert insights perform compared to: 1) a data-driven model without expert augmentation and 2) baseline supervised learning approaches that leverage expert subgoal labels?* Our work provides the following contributions: (1) we present a hybrid subgoal detection approach which combines an unsupervised data-driven model with domain expertise to achieve the benefits of both data-driven models, and expert models, and (2) we demonstrate how our hybrid approach advances the state of the art in subgoal detection in open-ended programming tasks over supervised and unsupervised baselines, with an accuracy range of 0.80 - 0.92.

2. LITERATURE REVIEW

In this work, we investigate the challenge of automatically detecting subgoals effectively. We propose a method that involves a hybrid approach where human experts modify data-driven models to build effective subgoal detectors. In the following, we first review prior work on the immediate feedback with a focus on subgoal feedback. Then, we review prior work that involves merging machine and human expert intelligence to improve performance of machine learned models. Finally, we review both state-of-the-art supervised learning models and an unsupervised data-driven model that we used for subgoal detection in a programming task.

2.1 Feedback and Subgoal Detection

Formative feedback is defined as a type of task-level feedback that provides *specific*, *timely* information to a student in response to a particular problem, based on the student's current ability [54]. In a review of effective formative feedback in education, Shute shows that immediate formative feedback is effective because it can improve students' learning [11, 38] and retention [54, 44], particularly in procedural skills such as programming [54]. Most intelligent tutoring systems provide immediate feedback through identifying errors (e.g. error detectors [5, 55], anomaly detectors [31], or misconception feedback [25, 24]); however far less work has been devoted to providing feedback on students' *subgoals*. Automated assessment systems (i.e. autograders) can provide feedback on correct subgoals by showing the *passing* test cases using expert-authored models [7, 28, 26, 38]. For example, most autograders use instructor test cases to check for correct program output; however they require students to submit an almost-complete program to obtain feedback [7, 29]. As a result, this feedback is often not available in the early stage of programming when timely feedback on subgoals is mostly needed. To provide timely subgoal feedback, prior research has taken two exclusive approaches: *expert-authored* approach and *data-driven* approach.

Expert-authored Approaches: Prior work has explored student completion to subgoals by diagnosing students' solutions against expert models (e.g. constraint-based models [42]), even when a student has incomplete submissions, to provide feedback on whether they are on track [27], or whether they completed key objectives of short programming tasks [38]. However, these systems often require extensive expert effort to create rules. To address this authoring burden, example-tracing tutoring systems infer tutoring rules based on examples of potential student behaviors. This still requires an author with some domain expertise, but it allows rules to be constructed by non-programmers who have domain expertise [2]. An expert can create different example solutions to capture different solution strategies; and augment them with hints or feedback. Example-tracing tutors have been developed in multiple non-programming domains like genetics [12], mathematics [1], and applied machine learning, and they have been shown to improve the problem-solving process and student learning [2]. Despite the accuracy of expert models in providing feedback on test cases or correct features, which can be equivalent to subgoals, it is unclear how feasible they are in domains with vast solution spaces and open-ended problems, such as in programming tasks [59, 39, 25].

Data-driven Approaches: Data-driven approaches refers to systematically collecting and analyzing various types of educational data, to guide a range of decisions to help improve the success of students [15, 50]. Data-driven models largely avoid the need for expert authoring altogether by using prior students' correct solutions, instead of expert rules or instructor solutions, to learn patterns of correct solutions. This enables automated assessment feedback on student code [21]. Many data-driven models work by executing a comparison function that calculates the distance between students' code and all the possible correct solutions, and then compares the path of the most close solution with that of the student [47, 49, 59, 39]. While most data-driven methods have

been used to generate fine-grained feedback – such as hints in the hint factory [58], little work has used these methods to generate subgoal feedback. For example, Diana et al. developed a model that searches for meaningful code chunks in student code to generate data-driven rubric criteria to automatically assess students' code [19]. Diana et al show that a data-driven model can have agreement with that of the experts [19]. In the iList tutor, Fossati et al. used a data-driven model to provide feedback on correct steps, where they assess student code edits as *good*, if it improves the student's probability to reach the correct solution, or *uncertain* if a student spent more time than that taken by prior students at this point [21]. Fossati et al. found that this feedback was well-perceived by students, and improved their learning [21]. However, data-driven models are dependent on the similarity of the current student's approach to prior student submissions, making it difficult to control the quality of their feedback [39, 51, 59, 46]. In a case study paper, Shabrina et al. discuss the practical implications of data-driven feedback on subgoals, showing that the quality of feedback is important, even positive feedback, since inaccurate feedback can cause students to spend more time on a task even after they were done [51]. Because of such challenges and perhaps other reasons such as the inability for individual instructors to augment autograder feedback, few tools have been built to provide immediate feedback to students on whether they have achieved subgoals during their programming tasks [34].

2.2 Integrating Expert Knowledge into Models

In recent years, combining machine and human intelligence has been extensively explored in a wide range of domains including artificial intelligence and software engineering. For example, Chou et al developed a virtual teaching assistant (VTA) that uses teachers' answers as human intelligence, and machine intelligence to use teachers' answers to locate student errors, and generate hints [10]. Chou et al found that these mechanisms reduce teacher tutoring load and reduce the complexity of developing machine intelligence [10]. In the software engineering domain, there is an emerging approach called *collective intelligence* that merges the wisdom of multiple developers with program synthesis algorithms, which has been shown to significantly improve the efficiency and accuracy of program synthesis [61].

Human-in-the-loop methods are another effective trend that use human intelligence to improve the efficiency of Machine Learning models, *while* the model is learning [23, 56, 30, 63]. For example, Goecks introduces a theoretical foundation that incorporates human input modalities, like demonstration or evaluation, to leverage the strengths and mitigate the weaknesses of reinforcement learning (RL) algorithms [23]. Their results show that using human-in-the-loop methods accelerates the learning rate of RL models, with a more efficient sample, in real time [23]. Our work also uses human intelligence to improve the accuracy of a machine learning model; however, it does so *after* the model is trained.

In the educational domain, expert knowledge is widely applied to augment data-driven and machine-learned models for problem solving and feedback. For example, in a logic tutor that provides data-driven hints using students' solutions, Stamper et al. used an initial small amount of sample data generated by human experts to enhance the automatic delivery of hints [57]. Moreover, example-tracing tutors allow experts to specify moderately-branching solutions for open-ended problems, allowing some intelligent tutors *originally* implemented using complex expert systems to be almost completely replicated to support practical learning needs [2].

2.3 Supervised Learning Models of Code Analysis

Supervised learning algorithms leverage labels created by human experts, to guide the model search process. With available labels, automated learning algorithms can be applied to the subgoal detection tasks for programming data. As shown in [6], one baseline is to extract term frequency-inverse document frequency (TF-IDF) features and uses traditional machine learning algorithms such as support vector machines (SVM) [14] and XGBoost [9]. However, as word- or token-based features such as TF-IDF lose important structural information from programming data [3], recent work uses structural representations from code and a more complex model structure to learn more complex features. For example, Shi et al. applied a code2vec [4] model to detect the completion of rubrics on student programming data [53]. In this work, we compared our hybrid data-driven model to these existing supervised learning baseline models to check our improvement on the subgoal detection task.

2.4 Data-Driven Subgoal Detection Model

Among the various data-driven models for detecting subgoals, or rubric items [39, 18, 19], we built our proposed hybrid model on top of an unsupervised data-driven subgoal detection (*DD*) algorithm, presented in [64]. We applied this algorithm on a programming task called *Squiral* (described in Section 3) by running the following steps. First, the algorithm extracts prior student solutions in *Squiral* as abstract syntax trees (ASTs) [49, 47]. Then, it applies hierarchical code clustering for feature extraction and selection by: (1) extracting common **code shapes**, which are common subtrees, in ASTs of correct students' solutions (Figure 2 shows examples of code shapes); (2) filtering redundant code shapes; (3) identifying decision shapes, which consist of a disjunction of code shapes (i.e. $C_1 \wedge \ldots \wedge C_n$) that are usually mutually-exclusive (e.g. a program uses a loop, or a repeated set of commands, but not both), and (4) hierarchically clustering frequently co-occurring code shapes into *subgoals*. In [64], the authors found a meaningful Cohen's Kappa (0.45) in agreement of the algorithm and expert subgoal detection on student data, suggesting that *DD* subgoals could be used to generate feedback. However, since the *DD* subgoals are typically represented in a regular-expression-like form, labels are needed to make them meaningful and usable for students in programming environments.

3. METHOD

This work presents and evaluates a hybrid data-driven model for generating and detecting subgoals in a block-based programming exercise (explained in Section 3.1). To evaluate our hybrid data-driven approach, we applied our model on student data collected from an Introduction to Computing course, and we asked human experts to evaluate the accuracy of its subgoal detections (explained in Section 3.2.2).

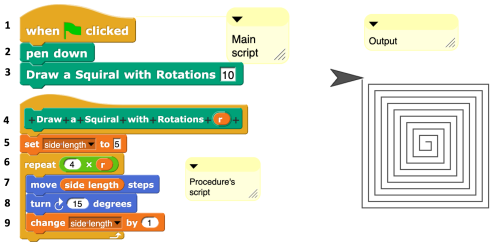

Figure 1: One possible solution for Squiral with line numbers on the left, and the script's output on the right.

We use this dataset to provide examples of how our approach works, but we also discuss how it can be generalized. We compared our hybrid model against its underlying data-driven (DD) model described above in Section 2.4, as well as state-of-the-art supervised learning models (explained below in Section 4.1).

3.1 Dataset

Our data is collected from a CS0 course for non-majors in a public university in the United States that uses Snap*!*, a block-based programming environment [22]. This programming environment logs all students actions while programming (e.g. adding, deleting or running blocks of code) with the *time* taken for each step. These student logs (i.e. actions) can also be replayed as a *trace* of code snapshots of all students' edits – allowing us to detect the time and the code snapshot where a subgoal is completed *during* student *problem-solving process*.

In this work, we collected students' logs from one homework exercise named *Squiral*, derived from the BJC curriculum [22]. *Squiral* requires a visual output, where students are asked to write a procedure that takes one input `'r'` to draw a square-like spiral with `r` rotations. Figure 1 shows a possible correct solution of *Squiral* that requires procedures, variables, and loops. We collected a training dataset from 3 semesters: Spring 2016 (S16), Fall 2016 (F16), and Spring 2017 (S17), which includes data of 174 students, that has a total log data of 29,574 student actions

3.2 Hybrid Data-Driven Subgoal Detection

Our hybrid data-driven model is based on two main things. First, the *DD* model is used to generate data-driven subgoals. Second, expert-authored constraints are added to improve the quality of these subgoals and the accuracy of their detection. We implemented our hybrid approach by conducting the following 3 high-level steps:

1. We used the *DD* model to generate an initial set of subgoals, consisting of clusters of code shapes. We then presented these clusters to experts in an interpretable form, who *combined* them to create a concrete set of meaningful subgoal labels.

2. We integrated *DD* subgoal detection model into the students' programming environment, allowing students to see when the *DD* algorithm detected completion of each subgoal. We then collected student programming log data along with *DD* detections, and asked experts to evaluate the accuracy of the *DD* detections.

3. We used human expert insights to fix code shapes that led to false subgoal detections; and then combined them again to create a modified set of hybrid subgoals and evaluated its new accuracy.

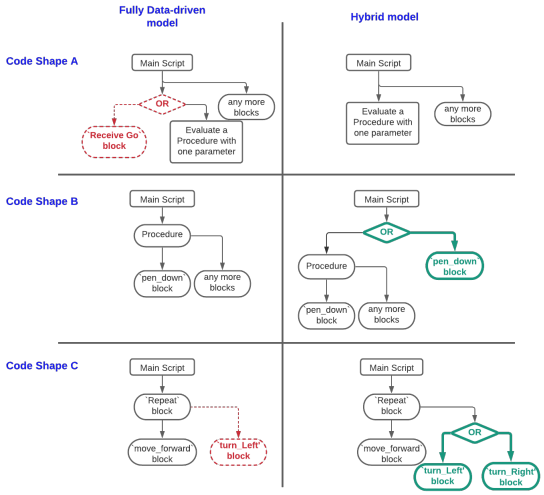

Figure 2: Three code shapes A, B, C, in both the data-driven and hybrid models. Each code shape represents a false detection and its fix by human experts. Red dashed nodes are removed and green bold nodes are added.

3.2.1 *Step 1: Interpreting and Editing Data-Driven Subgoals*

The goal of this step is to generate data-driven subgoals using the *DD* model and present them in an interpretable and editable form. We applied the *DD* model (described in Section 2.4) on S16, F16, and S17 student datasets to generate a number of clustered code shapes. Column 1 in Table 1 shows the description of 7 subgoals corresponding to code-shape clusters generated from *correct* solutions (n = 52). We evaluated each cluster by displaying its code shapes separately and *interpreted* their code behavior. For example, code shape A in Figure 2, on the left, represents a decision shape that requires student to use the `'ReceiveGo'` block (i.e. the hat block in Figure 1, line 1, which is used to start a script) in their main script, **or** to evaluate a procedure with one parameter, which is done by creating and snapping a procedure in the main script (as shown in Figure 1, line 3). We treated each cluster as a subgoal, and for a subgoal to be detected, the *DD* model requires all of its code shapes, and exactly one component of its *decision* shapes, to be present in student code.

While the data-driven clusters can represent appropriate subgoals, we combined some of them to create a shorter list of higher-level subgoals similar to the programming task rubric. Column 2 in Table 1 show the combined subgoals. It is worth noting that we also took the insights of two instructors of the CS0 course on how meaningful these subgoals are for students to understand. Additionally, because

one of our goals is to use these data-driven subgoals in learning environments, we asked human experts to label them to make them easily understandable by students, and instructors. For example, the human label of subgoal 1 is: "Create a procedure with one parameter, and use it in your code", as shown in Table 1. We then developed a data-driven subgoal detector that takes student code as an input, and outputs the status of each subgoal. For example, if the input is code C and the output is `{1, 0, 0, 1}`, this means the subgoal detector detects the completion of subgoals 1 and 4, and the absence of subgoals 2 and 3 in C.

3.2.2 Step 2: Investigating Data-Driven Subgoals

The goal of this step is to investigate the correctness of the *DD* subgoal detections. In Spring 2020 (S20), we integrated the *DD* subgoal detector into the Snap*!* programming environment for the *Squiral* exercise to provide students with subgoal feedback [39]. In Snap*!*, students could see the subgoal labels (shown in Table 1), colored gray to start, green when the subgoal was detected, or red when it became broken. We collected 4,480 edit logs from 27 student submissions with an average of 166 edits per student in S20. For each student edit, we recorded the *DD* subgoal detection state (e.g. `{1, 0, 0, 0}` for subgoal 1 being complete). We asked human experts to manually replay each student's trace data and evaluate whether the subgoal labels, as shown to students, were achieved at the specific timestamps when the *DD* algorithm detected them. Importantly, we asked experts to report when the expert-authored *labels* for each subgoal (which students saw) were achieved. Since these labels do not *precisely* match the code shape combinations that the *DD* subgoal detector used, it was very possible for the *DD* model to be "wrong." In other words, we asked experts to determine when each student achieved "Create a *Squiral* procedure with one parameter and use it in your code," and compared that to when the *DD* detector marked this subgoal label as complete.

We classified each evaluated instance as either `Early`, `onTime`, or `Late`. An instance is classified as `Early` if the *DD* detection is *before* the human expert detection timestamp, `OnTime` if they coincide, and otherwise `Late`. For example, if for student S_j, the human expert detected the completion of subgoal `i` (SG_i) at time `t` $= 5$; while the algorithm detected it at `t` $= 2$, then we label SG_i for S_j as `Early` detection. Then we sorted students in descending order based on the percentage of false detections in their log data, and we took the first 66% of this data ($\sim$ 18 students as a data sample) to investigate the reasons for false detections. We did not use the full set of false detections, since our primary goal was to fix the most common mismatches, without overfitting to the dataset.

We then focus on false detections that occured due to new, correct solutions, in the S20 dataset, that had no matching code shapes in the training dataset (S16, F16, and S17 datasets). We do not investigate expected false detections that occured due to known limitations in the *DD* algorithm (e.g. the *DD* algorithm does not differentiate between variable names).

We found three reasons for false detections for subgoals 1, 2, and 4. Inspired by the design of the constraint-based SqlTutor by Mitrovic et al. [41], we introduce 3 fixes (or constraints) to resolve them.

Subgoal 1 false detection. As shown in Table 1, subgoal 1 label requires a student to create a procedure with one parameter, and use it (or evaluate it) in the main script. However, subgoal 1 code shapes consist of the creation and evaluation of a procedure, ***or*** the use of a `'ReceiveGo'` block (the hat block used to start a script). This means that whether a student created and evaluated a procedure, *or* added a `'ReceiveGo'` block in the main script, the *DD* model will detect the completion of that subgoal, but experts did not interpret the 'ReceiveGo' block as meeting this subgoal, yielding a false detection. To fix this false detection, we simply removed the 'ReceiveGo' block as an option for this subgoal. Code shape A in Figure 2 shows the code shapes of subgoal 1 of the *DD* model (on the left), and how it is fixed in the hybrid model (on the right).

Subgoal 2 false detection. As shown in line 6 in Figure 1, subgoal 2 requires a student to use a 'repeat block that iterates 4 times the number of rotations to draw a *Squiral* with the correct number of sides. While code shapes of this subgoal satisfy this definition, they also include a code shape of adding a 'pen down' block, which is necessary to draw, but *only* inside a procedure. Therefore, if a 'pen down' block is used outside of a procedure, subgoal 2 will not be detected. To fix this false detection, we added a disjunction code shape to detect the presence of `'pen down'` inside *or* outside a procedure, as shown in code shape B in Figure 2.

Subgoal 4 false detection. As shown in lines 6-9 in Figure 1, subgoal 4 requires the use of 'move', 'turn', and 'change - by -' blocks (which increments a value of a variable), inside a 'repeat block'. We found that code shapes of subgoal 4 only include the `'turnLeft'` block; however, if the student solution contains a `'turnRight'` block (which does the same 'turn' functionality but from a different direction), the subgoal will not be detected. To fix this false detection, we modified all the code shapes that require the use of `'turnLeft'` block to accept either `'turnRight'` or `'turnLeft'` blocks, as shown in code shape C in Figure 2.

These three false detections show that prior solutions in S16, F16, and S17 datasets often used a `'ReceiveGo'` and `'turnLeft'` blocks, and used `'pen down'` inside a procedure; but this was not always the case in the S20 data. This shows that investigating the accuracy of a model, either data-driven or expert, is necessary since it is impossible to predict how students will behave in practice or how the data will change from one class to another.

3.2.3 Step 3: Improving the Data-Driven Subgoals with Human Insights

The goal of this step is to apply the human expert constraints (explained in Step 2) to mitigate the false detections of the *DD* algorithm. To do so, we developed a tool that iterates over each code shape of the data-driven subgoals, and allows humans to edit code shapes (i.e. add, delete or modify) to apply the three constraints (i.e. fixes) explained in Step 2. Because this tool modifies the code shapes, we then use the original *DD* algorithm to re-cluster all code shapes to ensure that the most similar code shapes remain

Table 1: Data-driven subgoals (composed of code shape clusters) with their corresponding human labels that were used when presented to students.

Data-Driven Code Shape Clusters	Combined Clusters	Subgoal Human Label
C1: Evaluate a procedure with one parameter on the script area OR Add a 'ReceiveGo' block.	C1 + C2 = Subgoal 1	Create a Squiral procedure with one parameter and use it in your code.
C2: Create a procedure with one parameter.		
C3: Have a 'multiply' block with a variable in a 'repeat' block OR two nested 'repeat' blocks.	C3 + C4 = Subgoal 2	The Squiral procedure rotates the correct number of times.
C4: Have a 'pen down' block inside a procedure		
C5: Add a variable in a 'move' block inside a 'repeat' block.	C5 = Subgoal 3	The length of each side of the Squiral is based on a variable.
C6: Have a 'move' and 'turnLeft' block inside a 'repeat' block.	C6 + C7 = Subgoal 4	The length of the Squiral increases with each side.
C7: 'Change' a variable value inside a 'repeat' block.		

clustered together. Figure 2 shows an example of three code shapes before and after they have been edited by human experts, that fix false detections that existed for subgoals 1, 2, and 4, respectively.

In summary, our hybrid model **humanizes** data-driven subgoal detection models through a series of important steps. First, we apply a data-driven model to correct, historical student solutions to generate a set of human *interpretable* code shape clusters. Second, a human expert labels the subgoals these clusters represent, in a way that is meant to align with the original programming assignment. Third, we collect data from students solving the same task using a programming environment augmented with subgoal feedback (i.e human labels with colors) based on the *DD* subgoal detector. Fourth, we had experts examine code traces with the *DD* subgoal feedback to determine when the displayed subgoal labels were actually achieved. Fifth, human experts modified the code shapes that led to discrepancies between the data-driven and expert detections for the displayed subgoals. This series of steps leverages the natural cycle of a frequently-offered CS0 class to bootstrap the creation of *DD* subgoal detectors in the programming environment.

4. EVALUATION

In this experiment, we applied both the hybrid and the *DD* models to detect subgoals in students' S20 code submissions. We also asked two human experts to evaluate the presence or absence of each subgoal in a subset of students' code snapshots (sequential states of student code, corresponding to their code edits, e.g., the addition or deletion of code blocks) using the subgoal labels (shown in Table 1) as rubric items (with 1 for the subgoal's presence and 0 for its absence), resulting in an *expert (or gold standard) subgoal state*.

Because S20 data consists of 4480 code snapshots, it is not feasible to evaluate the models on every timestamp for two reasons. First, students mostly need feedback on a given subgoal when they are making edits towards finishing *that subgoal*, not after every single edit they make. Second, students break and recomplete subgoals frequently, even when they are not working on a particular subgoal, and therefore it is not meaningful to have an expert label at every single datapoint. As a result, we evaluate the models at the most meaningful times when a student is close to finishing a subgoal, including: (1) the first time a student completed a subgoal, according to a human expert, (2) up to five code edits before that subgoal is completed, and (3) any time when either model (i.e. hybrid, or *DD*) suggests a *change* in a subgoal's status. While these changes may or may not be true, we wanted to have experts evaluate the correctness of how the algorithms may have detected subgoal changes at these points.

For each subgoal, two human experts evaluated 150, 163, 178, and 196 student snapshots for subgoals 1, 2, 3, and 4, respectively, making a total of 687 labeled snapshot datapoints. The experts used the subgoals as their rubric; and they started the labelling process by evaluating *the first time* a subgoal is detected. To do so, they divided the data (27 students * 4 subgoals = 108 datapoint) into a set of 6 rounds, where the first round consists of 2 students and the remaining 5 rounds consists of 5 students. The two experts collaboratively evaluated the first round together to make sure they have a clear understanding of the rubric subgoals. Then for the next two rounds, they evaluated the logs independently and after each, they met to discuss and resolve conflicts. For these 3 rounds, the two experts had a moderate to substantial agreement with a Cohen's kappa ranging from 0.5 to 0.67. The reason why the kappa values are low is that we considered any disagreement even if it was a difference of *one* timestamp, but it does highlight how subgoal detection can be subjective, which is a challenge for measuring the accuracy of subgoal detection. As a result, for the remaining data, the two experts continued to evaluate it independently and then met to discuss and resolve conflicts to produce relatively objective *gold standard* expert labels. We used these labelled logs as ground truth to compare the accuracy and F1-scores of both the *DD* and the hybrid models. We also calculated the agreement between the expert detections and those generated by the hybrid and *DD* models.

4.1 Supervised Learning Models

We also compared our hybrid humanized model with supervised machine learning models as another form of baseline. The supervised models were trained and tested on the S20 dataset, using the same 687 expert-labeled snapshots described above. We trained separate models to detect each of

the subgoal labels (using training/testing splits discussed below). This allows us to directly compare these supervised methods, which require *labeled* training data, to the *DD* model, which does not, and to our hybrid approach, where the expert uses *some* of the labeled data to improve the model. While we discuss some limitations to this comparison in Section 7, these baselines help contextualize the performance of our subgoal detectors.

The baseline supervised machine learning models we have chosen are two shallow models (SVM [14] and XGBoost [9]) and one deep learning model (code2vec [4]). We used the same edits for predictions as the *DD* and hybrid models, and extracted the term frequency–inverse document frequency (TF-IDF) features from the models, thus a vector representation of an edit is generated, and used for training the two models. We performed grid search cross validation for both models. For SVM, we used a parameter space of linear kernel and Radial Basis Function (RBF) [60] kernel, and searched the regularization parameters from 1 to 10. For XGBoost, we searched the subsampling space of 0.1 to 1, with the number of estimators from 5 to 100, stepping by 5. Ten-fold cross validation is performed to search the parameter spaces. The training, validation, and test sets are split by students to make sure that no students used for testing will have an edit in training, since edits from one student would be very similar, and using samples similar to the testing set in training would lead to an unfair comparison.

We selected one state-of-the-art deep learning model, code2vec [4], for comparison as well, as the model has recently been applied in educational code classification tasks [53]. Instead of using a vector of term frequency to represent edits, code2vec uses the structural representations from ASTs to represent the code, and the representation is learned from training a neural network[1]. We used early stopping to avoid overfitting. To ensure the robustness of our results, we ran 20 times with resampling for all supervised baseline models, and reported average metrics (e.g. F1-score, accuracy).

5. RESULTS

RQ1a: *How well does a hybrid model perform compared to a data-driven model without expert augmentation?*

The prediction results for each subgoal from the *DD* model and the hybrid model are shown in Table 2. Our hybrid model achieves higher accuracy and F1-scores on all subgoals than the *DD* model. In particular, it reaches > 0.8 accuracy for all subgoals, and it reaches > 0.9 accuracy for 2 out of the 3 subgoals that were modified (i.e. subgoal 1 and 4) with expert constraints. It is worth noting that the hybrid model achieves higher accuracy in subgoal 3, which was not modified with expert constraints. This is possible because after we modified code shapes for the *other* subgoals, we reclustered the code shapes (as described in Section 3.2.3), and the new code shapes for subgoal 3 were changed. This is likely because, after reclustering, some code shapes moved to subgoal 3, resulting in higher recall.

We also measured the agreement between human experts, *DD*, and hybrid model subgoal detections. For the four subgoals, we find low to moderate agreement over all student logs between *DD* and human expert detections, with Cohen's kappa values ranging between 0.25-0.581. However, we find substantial or better agreement between the hybrid model and human expert detections, with Cohen's kappa values ranging between 0.6-0.84. It is worth noting that this agreement is higher than that achieved between the two human experts (described in Section 4). These results showed that the addition of just three human constraints to a data-driven model succeeded in improving its accuracy, making the hybrid model agree *more* with the gold standard (that the experts co-constructed), than the experts' original agreement with one another.

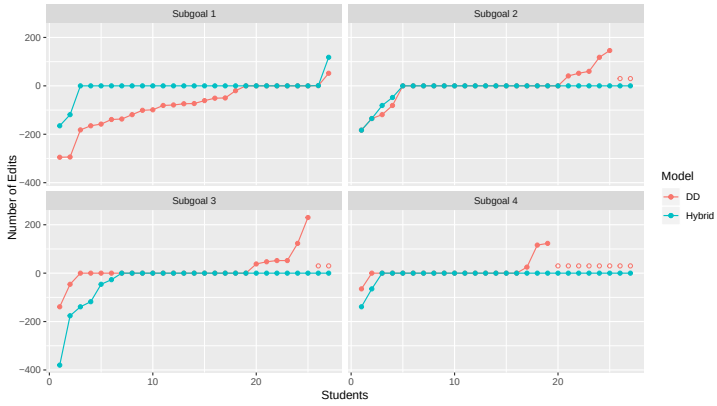

Figure 3: The number of code edits (y-axis) that occurred between gold standard expert subgoal detections, and detections by the DD and Hybrid models, for first-time subgoal detections for each student trace (x-axis).

We also determined the number of false detections (i.e. `Early` and `Late` detections, as described in Section 3.2.2) for both the hybrid and *DD* models. We found the *DD* model detected 40.66%, 10.66%, 5.62% and 5.10% `Early` detections, and 2%, 13.5%, 12.36%, and 15.31% `Late` detections for subgoal 1, 2, 3, and 4, respectively. However, our hybrid model detected 1.33%, 13.5%, 10.67% and 4.6% `Early` detections, and 8%, 5.52%, 1.7%, and 2.81% `Late` detections for subgoal 1, 2, 3, and 4, respectively. To visualize these false detections, Figure 3 visualized these false detections by presenting the distance (i.e. how many edits) between the `Early` and `Late` detections by both the *DD* and hybrid models, and the gold standard human expert detections of the *first time* a subgoal is completed. The x-axis presents the students ($n = 27$), and the y-axis presents the number of edits a student makes until they complete a subgoal. We used a negative number to indicate how much *earlier* the models were than the gold standard detection, 0 to show when models *agree* with the gold standard, and a positive number to show how much *later* the models were. We also used *empty* circles to indicate instances where a subgoal is *never* detected by the models but it was detected by human experts. While Figure 3 shows *only* how early/late the model is in detecting when a subgoal is *first* completed, this is likely the most important detection. Our results suggest a high agreement between the hybrid model's detections with the gold standard, and a strong improvement over the *DD* model.

[1]We applied code2vec using the process described in [53].

Table 2: Precision, Recall, F1-score and Accuracy observed with Supervised, Data-Driven (DD) and our Hybrid Models.

	Precision					Recall					F1-score					Accuracy				
	SVM	XG-Boost	Code2vec	DD	Hybrid	SVM	XG-Boost	Code2vec	DD	Hybrid	SVM	XG-Boost	Code2vec	DD	Hybrid	SVM	XG-Boost	Code2vec	DD	Hybrid

RQ1b: *How does a hybrid model perform compared to supervised learning approaches that leverage expert subgoal labels?*

We show our comparison of supervised learning models and the hybrid model in Table 2. On all subgoals, except one, the hybrid model has higher accuracy and F1-score than code2vec, SVM, and XGBoost models, outperforming them by 0.10, 0.06 and 0.15 percent of F1-score, respectively. In subgoal 1, we found that code2vec achieved a higher F1-score than all the other models, and a relatively similar accuracy to the hybrid model (0.903, 0.906). One possible explanation for this is that subgoal 1 is the simplest subgoal, requiring only that the student has defined and used a procedure, regardless of its content, and this simple code pattern may have been easier for the supervised approaches to learn. These results show that a hybrid model iteratively constructed through cycles of student data collection, machine learning, along with human labeling and correction can be used to create accurate automatic subgoal detections on a novice programming task. Furthermore, these supervised learning models, that were mostly outperformed by our hybrid model, were learned using labels from snapshots that were *strategically chosen* to reflect important decision points for the model, suggesting that the supervised models' performance may suffer if a random selection of snapshots were used to create an expert-labeled training set instead.

5.1 Case Studies

In this section, we present case studies to highlight ways the hybrid model improved upon the original *DD* model, as well as the hybrid model's limitations. These case studies come from the 33% of students who were *not investigated* when the expert identified false detections in S20 from the original *DD* model, as discussed in our methods (Section 3.2.2). These students also used the original *DD* system, but their data did *not* inform our hybrid model. These case studies, therefore, help us understand the ways our hybrid model might help new students, as well as limitations of the model. Though our prior work suggests the *DD* subgoal detections overall were often useful to students [39], our post-hoc analysis here shows that the *false detections* may have negatively impacted student programming behavior, suggesting the need for our hybrid model's improvements.

5.1.1 Case Study 1 (Em): Inaccurate Data-Driven Subgoal Feedback

We present here a case study of the student Em[2] when they received an inaccurate subgoal detection based on the *DD* model, and how the hybrid model could have mitigated this false detection.

Em started solving *Squiral* by snapping the 'when green flag clicked block' (i.e. 'ReceiveGo' block) on the main script as shown in Figure 4A, and the system *falsely* detected subgoal 1. Em then proceeded to work on subgoal 2, *without* creating the required procedure, and created a loop using the 'repeat' block nested with 'move' and 'turnLeft' blocks (shown in Figure 4B). This time, the system was correct in not detecting subgoal 2 because the loop was not in a procedure, and does not iterate on the 'rotations' parameter. Afterwards, Em correctly created a procedure with one parameter as shown in Figure 4C; however, the system shows no change, since it already falsely detected subgoal 1 earlier, and therefore, no change in the feedback is given to the student. Em then destroyed the procedure, without ever making it again. Em kept working for the rest of the time on creating a number of redundant loops, similar to the one in Figure 4C, with constant values to manually draw the *Squiral* shape (rather than using a variable to vary its length).

Em spent a total of 55 minutes to draw *Squiral* in an iterative manner. While the *DD* system accurately detected subgoals 2-4 as incomplete, this case study highlights potential harm that may have arisen from the false detection of subgoal 1. When subgoal 1 was detected early, Em skipped over creating a procedure. Later, when she did create the procedure correctly, she got no additional feedback (since the subgoal was already detected), and promptly deleted it. Preventing these unneeded deletions is a primary role of correct, positive subgoal feedback. However, had Em been using the hybrid model, subgoal 1 would not have been detected early because the expert edited the faulty code shape. We argue that this might have allowed Em to keep working on creating a procedure (as shown in snapshot C in Figure 4), which would have been detected as complete by the hybrid system only at this time. It is also possible that receiving inaccurate feedback at the very beginning may have led to Em's mistrust in the system, since prior work shows that incorrect feedback can reduce students' willingness to use it [48].

Note that, we do not believe this incorrect *DD* detection

[2]We provide anonymous names for students.

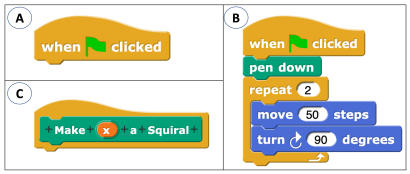

Figure 4: Code snapshots A, B, and C, implemented by student Em in Case Study 1.

means the full data-driven system should not be used since our prior work shows the system can be helpful to students [39]. However, we need to explore how to present subgoal feedback in a way that promotes students to question the feedback since any such program will inevitably fail to recognize some correct variants of a subgoal solution.

5.1.2 *Case Study 2 (Jo): Cases when Hybrid Subgoal Detections could be Incorrect*

We present here a case study where the hybrid model would *not* have provided accurate subgoal feedback. As evidenced by the model's high overall accuracy (Table 2), these instances were rare, but understanding them highlights the affordances and limitations of our approach. Specifically, we investigated subgoal 1, where the hybrid model had the lowest F1-score.

Student Jo correctly created a procedure with a parameter; however, since Jo had not yet used the procedure in their main script, subgoal 1 was not detected (accurate detection). Jo continued programming and completed subgoals 2 and 3, which were accurately detected by the system. Afterwards, Jo added a procedure call to the main script, and subgoal 1 was detected as complete (accurate detection). However, Jo then added a 'pen up' block underneath the procedure call, where unexpectedly, the hybrid model changed subgoal 1's status back to incomplete (incorrect detection).

This false detection in the hybrid model was due to an overly-specific code shape. Specifically, the code shape required the procedure call to be the *last block* in the main script (which was true for 94% of students, but not Jo), leading to the false detection. This case confirms the importance of iteratively investigating and refining data-driven subgoal detections to keep improving their accuracy, which is a common process in expert-authored models as well. While this false detection has a straightforward fix, similar to the ones presented in Section 3.2.2, it shows one limitation of the hybrid model: creating these fixes requires the expert to find and address the false detections in the first place, which is dependent on finding the bugs in the data inspected. This is also one reason why the hybrid model performance of subgoal 1 has a lower F1-score than the code2vec model (as shown in Table 2).

6. DISCUSSION

6.1 Automated Subgoal Detection

The key contribution of this paper is tackling the critical challenge of *automated subgoal detection* during programming tasks. Our results show that a hybrid data-driven model meaningfully addresses this goal, with high accuracy and F1 score when detecting subgoals at key moments during students' work. Our results show that this is a challenging task: even a state-of-the-art supervised learning approach with access to labeled data struggled to identify some subgoals (F1 score as low as 0.64). This agrees with prior work using expert-authored [13, 38] and supervised learning models [53], showing that immediate feedback on subgoals is a hard problem.

While automatically detecting subgoals is challenging, research suggests that the ability to provide automated, immediate feedback on subgoals can significantly improve students' motivation and learning. Providing subgoals for novices can improve student learning by breaking down the programming task into smaller subtasks, which is a challenging task for novices [36, 38]. In human tutoring dialogues for programming, tutors provide a combination of corrective and positive feedback, increasing students' motivation and confidence in programming [8, 33, 17]. Automatic subgoal detection could be used to provide similar corrective and positive feedback during programming. We know of only 3 systems that can afford such immediate feedback, that is not based on unit tests, during programming, that have been shown to promote learning, confidence and persistence for linked lists [21], database queries [42], and block-based programming [38]. It is perhaps uncommon to make such systems due to the difficulty in anticipating all student approaches, paired with the high potential for inaccuracies and student reactions to them. Our accuracy results suggest that our hybrid, humanized approach can be used to build similar automatic subgoal detection systems that could be deployed and more easily scaled across problems in real classrooms.

6.2 Affordances of Data-driven, Hybrid and Expert models

Our results suggest that the hybrid model has good potential for solving the problem of automated subgoal detection. Here we discuss the advantages and trade-offs of the hybrid approach, compared to data-driven and expert models.

6.2.1 *RQ1.a: Hybrid versus Data-Driven Models*

Our results show that a hybrid, iterative model that leverages data-driven subgoal extraction, human labeling, and expert refinement based on labeled student data, can *greatly* improve model performance compared to a purely data-driven (DD) model. The expert constraints improved F1-score of the data-driven model by 0.14-0.25 points, as shown in Table 2. Based on our analysis, the hybrid model, reduced the number of `Early` and `Late` subgoal detections and increased the `onTime` detections, when compared to the original *DD* model, as shown in Figure 3. This is a critical improvement, since prior work shows that the quality of feedback affects novices' programming behavior [48, 51], but also their self-perceptions, and trust in the learning environment [48].

The hybrid model creation does require additional labelling effort needed to evaluate the models; however, this effort seems well worth it, and is needed to evaluate the accuracy of any data-driven model before deployment. Compared to prior work, our iterative hybrid model shares similar benefits of "human-in-the-loop" methods in machine learning [56, 30] and also represents data-driven rules in an interpretable and

editable form that simplified the process of merging human insights into the model. In prior work, Diana et al. found, qualitatively, that their generated data-driven rubrics are considerably similar to human-generated rubrics [19]. Similarly, in our work, not only did instructors agree with the hybrid model subgoal detections, we also found these detections have substantial or better agreement with the human expert gold standard than the *DD* model. From these results, we conclude that **a hybrid model can be used to iteratively improve and humanize data-driven subgoal detection.**

6.2.2 RQ1b: Hybrid versus Supervised Learning Models that Leverage Expert Subgoal Labels

Our results show that **a hybrid model can surpass the performance of supervised learning models.** The steps we used to create our hybrid model were to: (1) apply a data-driven model, (2) add expert constraints, and (3) determine interesting datapoints consisting of times when subgoals might be achieved. The steps we used to create supervised learning models leveraged the interesting datapoints from step 3 of our hybrid model, hand-labeled them, and used them to build supervised learning models. We highlight this to point out that it is hard to determine what labeled data to use in a supervised learning model for subgoal detection, since there are hundreds of potential snapshots from each student. As a result, it is unclear whether the supervised model would have performed as well, compared to one learned from a labeled dataset selected at random or regular timestamps. Our results show that, even after using carefully selected labelled data to train the model, the SVM and XGBoost baselines did not achieve the level of accuracy of the hybrid model for all subgoals. Even code2vec, the state-of-the-art supervised learning model [53], has lower performance for all subgoals, except subgoal 1, than the hybrid model. Perhaps the code2vec performed worse due to the size of labelled dataset (687 datapoints), though recent results suggest the model is still effective with small datasets [52].

6.2.3 Hybrid versus Expert Models

Our hybrid approach offers distinct advantages and trade-offs compared to expert-authored models for subgoal detection. Traditional expert-authored models (e.g. constraint-based tutors [42]) have the advantage of high accuracy and high confidence, but the trade-offs of considerable domain expert time for creation and the potential failure to anticipate some student strategies and misconceptions. Our hybrid model has the advantage of incorporating actual student strategies and misconceptions, and primarily requires human effort to *label data* and identify errors, tasks which can potentially be done by non-experts and distributed across multiple people. A domain expert is only needed to edit the automatically extracted rules and is afforded the chance to do so with actual student data available. A significant tradeoff of the hybrid model is its reliance on data - so the quality of the dataset will directly impact the quality of the subgoal detectors. Furthermore, both models are likely to need refinement as students use them, and this process is already built into the hybrid model creation and refinement cycle.

7. LIMITATIONS & CONCLUSION

This work has 5 main limitations. First, while the *DD* model can capture small differences in solution approaches in *Squiral* (like having whether a 'turnLeft' or 'turnRight' block), we have not tested it in programming tasks with larger space of solution approaches. Therefore, it is not known how well the accuracy results will generalize to other types of programming tasks or languages. However, the iterative process of data collection, *DD* subgoal extraction, labeling, and collection of data from students using the subgoal labels and detectors, could be applied for other programming problems, of the same level as *Squiral*, and repeated until the models achieved high accuracy. Second, some of S20 data that was used for models' evaluation was also used to inform expert constraints in the hybrid model. However, this was only 66% of the data, and we discussed above how the added constraints are generalizable, which should have helped in any semester (see Section 5.1). Additionally, our case studies in Section 5.1 show examples of how the hybrid detector performed on unseen data, though there was insufficient data for a quantitative evaluation.

Third, we used only the labelled S20 data to train the supervised baseline models, but we also used 3 other semesters of *unlabeled* data to train the unsupervised *DD* and hybrid models. However, we argue that this ability to leverage a larger unlabeled dataset is an advantage of the unsupervised methods, rather than a limitation of our analysis. Fourth, some of the datapoints that were labeled for the evaluation of all the models were selected in part by using the hybrid and *DD* model detections, as discussed above, and this might have biased the results. However, all the models were evaluated on these same datapoints that were *strategically* chosen for their importance, and there are instances where some of the supervised models outperformed the original *DD* model. It is not clear how a different data selection strategy would have affected the results, and we argue that training and testing the supervised models on a dataset of the same size with randomly selected snapshots would likely decrease the performance of supervised models. Finally, we did not compare the hybrid model to a purely expert-authored model, and we did not measure time taken by experts to modify the data-driven rules. We argue that these comparisons require hiring experts to author rules and performing time analysis, which is beyond the scope of this paper.

In summary, this work proposes a new paradigm for 'humanizing' data-driven subgoal detection for novice programming. Specifically, we proposed to humanize data-driven subgoals in an iterative refinement process. We (1) extract data-driven subgoals from student work, (2) give them human labels, (3) collect more data from students programming with the labels and subgoal detectors, (4) present experts with the labels, and interpretable detectors, along with student behavior data so they can add expert constraints. This process ensures that humans are involved in every step of the creation of automatic subgoals, offering the advantages of reflecting real student behaviors, and limiting and focusing expert authoring time. Our results show that this hybrid humanized model outperforms fully data-driven models and state-of-the-art supervised learning models. This proposed paradigm can be used to create humanized automatic subgoal detection for tasks where it may be too expensive to create full expert models for, but that are important for student learning, motivation, and retention.

ABSTRACT

As Computer Science has increased in popularity so too have class sizes and demands on faculty to provide support. It is therefore more important than ever for us to identify new ways to triage student questions, identify common problems, target students who need the most help, and better manage instructors' time. By analyzing interaction data from office hours we can identify common patterns, and help to guide future help-seeking. My Digital Hand (MDH) is an online ticketing system that allows students to post help requests, and for instructors to prioritize support and track common issues. In this research, we have collected and analyzed a corpus of student questions from across six semesters of a CS2 with a focus on object-oriented programming course [17]. As part of this work, we grouped the interactions into five categories, analyzed the distribution of help requests, balanced the categories by Synthetic Minority Oversampling Technique (SMOTE) , and trained an automatic classifier based upon LightGBM to automatically classify student requests. We found that over 69% of the questions were unclear or barely specified. We proved the stability of the model across semesters through leave one out cross-validation and the target model achieves an accuracy of 91.8%. Finally, we find that online office hours can provide more help for more students.

Keywords

Office Hour, Computer Science Education Research, Text Analysis, help-seeking request

1. INTRODUCTION

Over the past decade the popularity of CS majors has increased and enrollments have skyrocketed [2]. This has created challenges for instructors with increasing demands for individual support, collaborative learning, and automated guidance [12, 2, 16, 15]. As the size of courses and cohorts have increased, the demand for office hours has begun to exceed the time that instructors and staff have available [12, 13]. To address these needs instructors have adopted a wide range of innovative support models including virtual office hours [10], peer support [7], and ticketing systems for help-seeking interactions [13]. The last approach is exemplified by My Digital Hand (MDH) [21], an online support system for office hours which allows students to queue for office hours, post questions in advance, and record the outcome of interactions. MDH assists students in structuring their help-seeking interactions with teaching staff. It also assists instructors and teaching assistants (TA) in managing their courses, by allowing them to triage student questions and target their effort during office hours to be efficient and meet group and individual needs. MDH also tracks help-seeking and interaction data throughout the whole semester. Using this data, we can identify patterns in students' help requests and automatically classify the questions. One common challenge for help-seeking interaction on large classes arises when many students ask the same or similar questions but must be dealt with separately thus eating up limited instructor time. One approach to address this is to develop automated Q&A systems which can leverage common problems. In order for this to work however, students must provide sufficient information about their problems so that they can receive targeted support.

Our goal is to develop analytical methods to understand what kinds of help students seek during office hours, how they frame their questions to the instructors, and whether or not we can automatically classify questions to support guidance and time management. By analyzing students' help requests across course offerings we can better understand what kinds of challenges the students are facing, and how the teaching staff can better anticipate students' needs and target their limited support. Moreover, by automatically classifying help requests we can help teaching staff to efficiently triage student questions and identify common problems that may be solved with group support or peer assistance. Over the long term we will develop summary

Zhikai Gao, Collin Lynch, Sarah Heckman and Tiffany Barnes "Automatically classifying student help requests: a multi-year analysis". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 81-92. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

statistics which can be used to support instructors in course management, and we will augment our existing ticketing system with support for automatic categorization.

In this paper we will address four specific research questions in the context of a CS2, object-oriented-focused course:

- RQ1: What types of questions do students ask on MDH during office hours and how do they formulate their description?
- RQ2: How can we automatically classify student help requests and tickets?
- RQ3: How robust is our classification model across different offerings?
- RQ4: Compared to regular office hours, does online office hours provide more benefits?

In order to address RQ1 we analyzed our dataset to identify common patterns of student questions and to classify them into five categories. We then address RQ2 and RQ3 by training an automated classifier for student questions with the goal of evaluating its' stability across semesters. Due to the COVID-19 pandemic, all courses are operating online in Fall 2020, which gives us an opportunity to study the advantages and disadvantages of hosting office hour online. Therefore we analyzed and compared the data pattern on Fall 2020(F20) with other regular semesters in RQ4.

1.1 Background

Prior researchers have analyzed student help requests with the goal of understanding student behaviors. Xu and Lynch, for example applied deep learning approaches to classify student question topics in MOOC discussion forums [24]. In that work Xu and Lynch collected student posts from two offerings of a MOOC on Big Data in Education. The authors classified student questions into one of three types (Course Content Question, Technique Question, and Course Logic Question) and developed an automatic classifier using Recurrent Neural Networks to divide questions' into those three categories. While the models were successful within a single offering they Xu and Lynch, found that they did not generalize across offerings. Thus, the system suffered from a cold start problem on each semester.

Vellukunnel et al. in turn collected Piazza posts from CS2 courses offered at two institutions and analyzed the type and distribution of the questions students asked [22]. As part of this work they manually partitioned the questions into five categories and then analyzed the impact of students' question types on their final grades. They concluded that asking constructive questions can help students to develop a better understanding of the course materials and in turn receive better grades. This analysis has informed our own work. However the Piazza platform, unlike MDH, is designed to support interactive discussion and online peer support through the use of threads and replies. By contrast the MDH system is focused on initial help seeking and not on collaborative dialogue. Therefore it is unclear whether our results will align with theirs.

Prior researchers have also studied how instructors manage office hours and how to make face to face support time more efficient and effective. Guzdial, for example, argued that office hours should incorporate diverse teaching techniques including pair programming, peer instruction, and backward design. These approaches, he argued, would potentially work to reduce wait times and support enhanced learning outcomes [8]. In order to provide more convenience for students, Harvard University introduced virtual office hours to an introductory programming course CS50 so that students can interact with teaching staff online [14]. However, they found that those virtual sessions were often inefficient and took more time to address the students' problems. This research is complicated by the fact that students frequently avoid seeking help from teaching staff when they need it [1]. Some of the factors behind this help-avoidance include a lack of trust in the tutor's abilities, inaccessibility of office hours due to timing or other constraints, and a desire for independence in learning [18]. While our research provides some guidance on the design of office hours and the need to reach out to students, the impact of how students frame their help requests has not yet been analyzed extensively. One notable exception is the work of Ren, Krishnamurthi, and Fisler, who designed a survey-based method to help track the students' help-seeking interactions during office hours in programming-based CS courses [20]. While informative, their approach is difficult to generalize as it depends on requiring the teaching staff to complete a detailed form *after* every interaction. In MDH, by contrast, we collect much of the data upfront as an integral part of the process.

2. METHODS

2.1 MDH system

My Digital Hand (MDH) [21], is a ticketing system for office hours that was developed to facilitate large CS courses. Students using MDH request help during office hours by "raising a virtual hand", that is creating a ticket which lists the topic they need help on, describes the issue they are facing, and the steps they have taken to address it. Once the ticket is created it is visible to the teaching staff who can then use it to prioritize interactions or even group students together for help. Once the interaction is complete the teaching staff can close the ticket and describe how the interaction played out. Students are also given the opportunity to evaluate the help received. These feedback questions are configurable and set by instructors at the start of the semester.

This data allows instructors to identify common issues facing students and to track the time it takes for students to receive support from the teaching staff as well as the duration of each help session. A prior analysis of MDH data, Smith et al. found that 5% of students in a course accounted for 50% of office hour time, and that long individual interaction times, representing students who needed long and detailed guidance, served to delay many other short questions [21]. They concluded that a small but critical group of students are reliant on individual tutoring via office hours, while other students who need intermittent help are often unable to obtain support. These findings have motivated our own focus on developing analytical tools which can be used to analyze, prioritize, and manage help requests so that high-demand students do not shut out their peers.

2.2 Data Collection

We analyzed data from seven semesters of a typical second-semester Object-Oriented programming course [17] at a research-intensive public university in the south-eastern United States. Basic descriptive statistics for the dataset are shown in Table 1. Students produced an average of 1477 tickets per semester with higher volumes in the fall semesters due to larger class sizes. The number of tickets also increased year over year due in part to larger class sizes, greater emphasis on tool use by the course instructor, and higher per-capita demand for office hours.

The course is structured as a single lecture section with 12 small-group lab sessions which are held weekly. Over the course of the semester students complete weekly lab assignments, 2-3 individual or team Projects (C-Projects), and 3 separate Guided Projects (G-Projects). The G-Projects are designed to provide a review of prerequisite materials and introduce students to new concepts. The C-Projects are generally structured as two sub-assignments, one focused on design and system testing, and the other on implementation and unit testing. Students manage their code via the GitHub platform with integrated support for the Jenkins automation testing server. When students commit code they receive automated testing results from instructor-authored test cases as well as test cases that they supplied. The students use feedback from test failures to guide their work and their help-seeking.[6]

In Fall 2020, this course was moved fully online due to the pandemic. All office hours were hosted through zoom meeting where students can share their screen with the teaching staff to show their code or any problems.

Table 1: Number of tickets and students for each semester (F= Fall, S=Spring)

	F17	S18	F18	S19	F19	S20	F20
tickets	1146	609	1224	860	1650	1401	3452
students	208	157	259	174	256	191	303

The interaction data is the most important for our current analysis. The format of the interaction records, along with selected examples is shown in Table 2. For this analysis each ticket consists of three major parts: the participants, time and duration of interaction, and the context.

2.3 RQ1: Categorization of Questions

Our primary focus in RQ1 is to identify the types of questions the students are asking and to understand how they describe their work. MDH allows students to frame their question topic or description in any way that they wish. The platform does not provide a list of suggested topics or mandate content beyond the basic text. This, in turn, lead students to vary widely in the descriptions and content that they provide. We therefore studied two features of the questions with the goal of supporting classification, the students' topic, as contained in the `"I'm working on"` field. And the longer problem description, as stated in the `"my problem is"` field.

2.3.1 *Classified by Topic*

Table 2: Attributes of the interaction data

Attributes	Content Explain	Example
interaction id	Id for each ticket	30072
student id	Id for the student who raised this ticket	1950
teacher id	Id for teacher who deal with the ticket	20810
time raised hand	Timestamp for each tickets that are asked	2019-03-08 19:34:09
time interaction began	Timestamp for each tickets began	2019-03-08 19:38:39
time interaction ended	Timestamp for each tickets ended	2019-03-08 20:01:02
I'm working on	Topic for the question of each ticket	Program1Part1
my problem is	Detail statement for the question of each ticket	Null Pointer on TS test
I've tried	The solution the student tried before they raised the tickets	Debugging

Rapidly identifying, or even anticipating, students' question topics would allow teaching staff to anticipate the kinds of issues they should be prepared for and may also allow them to set up mini-groups within office hours to deal with problems assignment by assignment, or to separate code questions from conceptual ones. We therefore performed a manual analysis of the topics in our study dataset over all semesters with the goal of determining how students label their topics, and whether it is possible to either anticipate or sort their posts as they come in.

Our preliminary analysis showed that in most cases the students simply entered the name of their current assignment or an abbreviation of it and provided no other details. Moreover, due to the structure of the course deadlines almost every help request in a given session was focused on the same assignment. In the newest version of MDH, the question is now a check box and the instructor can set the assignments. As a consequence we decided to omit this from our classification task and focus on the types of help being sought.

2.3.2 *Classified by Description*

In the description section ("my problem is"), the students can provide a rich summary of their problem including a text description, bug reports, or even code snippets. If it is possible to automatically classify student posts then we can use that approach to triage student questions as they come in, perhaps separating long questions from short. We therefore performed a manual analysis of the description content as well with the goal of identifying useful categories of posts. We also sought to examine how complex the problem descriptions were. In our prior discussions with the teaching staff they reported that many students provide too little information in the description (e.g. a single word such as "Errors"), provide too much (e.g. a full execution dump and error log), or they simply type gibberish with the simple

goal of securing a place in line. All of these strategies are problematic either because they provide too little information to effectively triage posts, or because the dump is too complex and likely out of date before the student reaches the head of the line. In our analysis we analyzed both the length and structure of the students' submissions as well with the goal of understanding whether we can provide automatic scaffolding for useful posts, and automatic triage of the submissions.

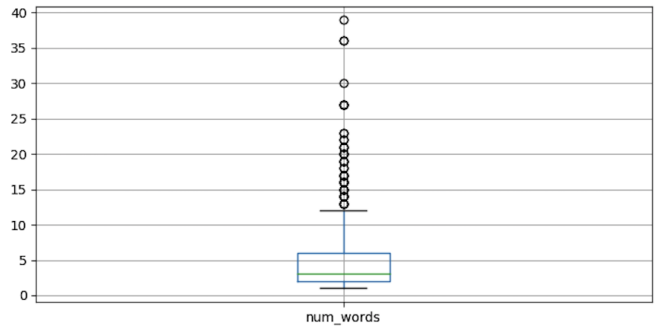

Figure 1: Distribution of the number of words in the questions' description

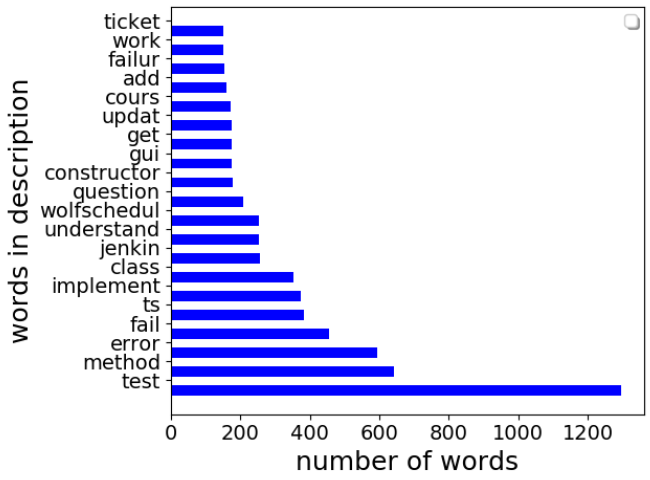

Figure 2: Top 20 Popular words in question description

We examined the length, content, and complexity of the students' problem description including the specific `my problem is` prompt. We also grouped common words to find keywords that are associated with specific types of submissions. We then used this information to inform our understanding of the students' posting behavior and to inform the design of the posting categories. This preliminary analysis was consistent with the experience described by the teaching staff. Figure 1 shows that the average description was less than five words long. When reviewing those short posts we noted that many students preferred to use keywords to indicate their question topics and problems rather than spelling their issues out. For example, when encountering an error in implementing an `add()` function, they often put "add()" as the problem description assuming that the method name, together with the assignment information, provided enough context for the help request.

This led us to focus on the specific terms that students use in their problem description. In this analysis, we grouped words by stemming and ignored stopwords to focus on the primary content information. The top 20 words are shown in Figure 2, top among them being `test`. This is consistent with the design of the assignments where students were provided with tests and required to develop their own. It is also consistent with the teaching staff's observation that many students focus on the tests as a guide for their progress and for where they need help. Upon closer examination of questions using this word we found that most interactions were focused on failed test cases; a typical description for a question of this type was "2 test case fail". It would be difficult for instructors to interpret these without reviewing the code and the test results in more detail but such a review takes time. Another closely-related word that was common in this dataset is `error` which was used primarily when students encounter bugs or other failures. In these cases in particular, the teaching staff noted that some students would simply paste the crash report into the question with little other context. This kind of behavior is rare in the data but was also useful for instructors, we therefore used it as an additional factor.

Based upon this preliminary analysis we defined five categories of help requests based upon the problem descriptions. These categories are shown in Table 3. We then labeled all interactions related to the problem manually. For each question, we also ranked the clarity or comprehensibility of student questions based upon the description provided. As we discuss below, most of the questions provided *insufficient* information to diagnose the problem. However as Figure 1 shows, some students did elaborate on their problem thoroughly as measured by the number of words in the problem description.

2.4 Labeling Process

2.4.1 Code book

To investigate the distribution of the above five categories in our data, we first need to set up a standard to categorize our data and apply it. All seven semesters' data was labeled by one researcher by the following rules:

- Check if there is any text that is clearly an error message copied from the compiler or a test failure. If so, label it as Copied Error. Notice that if the student describes the error message in their own words, then it should also be classified as Sufficient.
- Check if there is any text indicating that this is a test problem, no matter if the description gives you the detail of their test error or not. If you are sure that it is a test problem, label it as Test. If it also qualifies as Copied Error, classified as Copied Error
- If the text does not provide any information about their question and you cannot understand or deduce anything that related to their question, classify as Useless

Table 3: Explanation and example for all five categories we developed

Category	Explanation	Example description(my problem is)
Useless	The description contain nothing related to the question	I would like to check of it
Insufficient	The description contains partial information about the student question, but not enough for instructors to understand the details.	TicketManager getInstanceOf
Sufficient	Contains enough detail on the question for instructors to understand. Usually a very clear sentence.	CourseRecordIOTest, I seem to be failing reading the files, at the moments it is testing the size of the ArrayLists, but I am passing writing the files
Copied Error	Contains a copied error from the compiler.	I got this error: TypeError: barh() got multiple values for argument 'width'
Test	Test case fail related problem	2 test cases failed

- If the text does provide what or where the problem is, but not enough for you to fully understand or identify what is their question, marked as Insufficient
- If the text only contains one or multiple words of the method name associated with a problem, it can help to localize the problem but provides no additional details. It should be classified as Insufficient
- If the text is in a form of "I don't understand xxxx" without further explanation of which part they do not understand or other details, classify as Insufficient
- If the text is in a form of "I don't understand xxxx" with some further explanation, classify as Sufficient
- If the text tells you what their question or describes how they encounter this problem, classify as Sufficient

2.4.2 Inter rater reliability

After all data was labeled, we randomly generated a subset of 150 unique questions(30 for each category) and sent it to another researcher to rate. In this subset, we reveal the label of 10 questions for each category as example data and the rater classifies the remaining questions based on those example data and the code book. Then we compare the result with the original labels and calculate Kappa to represent the inter rater reliability. Kappa[4] is widely applied for measuring the agreement between two coders that accounts for chance agreement. Generally a score higher than 0.8 is considered acceptable. In our cases, the final unweighted Kappa value is 0.815 which is acceptable.

2.5 RQ2: Modeling

In addressing RQ2 we drew on our basic categorization developed in RQ1 to train automatic classifiers that can triage posts by topic and content. We used the first six semester data as training data to train our model and the last semester (F20) as the testing set to evaluate our model. To train our classification model, we first extracted training features from the problem descriptions across our dataset. The features included content features such as the keywords described above as well as meta-text features such as length, the number of stop-words (as a general proxy for specificity), the punctuation, and the character case. These meta-text features have the advantage that they are easy to extract automatically and can therefore be used for automated triage. Length, for example, is a suitable proxy for completeness and coherence while punctuation and case shifting are common in error messages. The full list of these features is shown in table 4.

We represented the text features as a tf-idf [19] matrix and basic word count matrix over the content. The word count matrix is simply a 2D Array which describe how many times each term appears in each question text. The tf–idf matrix is the product of two statistics, term frequency and inverse document frequency. The term frequency uses the raw count of a term in a text. The inverse document frequency is a measure of how much information the word provides. Some common words like "is" or "that" do not provide much information but they do usually have a high term frequency. Those words should have less inverse document frequency(idf). We can calculate the value as:

$$idf(t) = ln(\frac{Total\,number\,of\,documents}{Number\,of\,documents\,with\,term\,t\,in\,it}) \quad (1)$$

In our preliminary analysis we found that the matrices performed poorly in classification due to the fact that both were extremely sparse. We therefore opted to compress them so that they can be compatible with the dense feature approaches. To that end we built a Naive Bayes model [9] using the tf-idf sparse features and then use the predictions features. From this model we generated five shallow prediction features which correspond to the probability that the question belongs to each category. We followed this same approach with the word count vector and used those features as probabilities. The final list of extracted features is shown in Table 5.

2.5.1 Model Training

We trained our classification models using LightGBM [11], a Gradient Boosting Decision Tree (GBDT) algorithm provided by Microsoft. GBDT is an ensemble model of decision trees trained in sequence. In each iteration, GBDT learns the decision trees by fitting the negative gradients

Table 4: Text meta features list

Feature name	Explanation	value example
length	number of words in the problem description	12
character	number of characters in the problem description	12
stop words	number of stop words in the problem description	2
punctuation	number of punctuation in the problem description	0
uppercase	number of uppercase words in the problem description	0

Table 5: Text content features lists

Feature name	Explanation	value example
prob-tf-useless	the probability of this tickets belong to category "useless" using tf-idf	0.75
prob-tf-ins	the probability of this tickets belong to category "insufficient" using tf-idf	0.82
prob-tf-suf	the probability of this tickets belong to category "sufficient" using tf-idf	0.77
prob-tf-error	the probability of this tickets belong to category "copied error" using tf-idf	0.99
prob-tf-test	the probability of this tickets belong to category "test" using tf-idf	0.65
prob-cnt-useless	the probability of this tickets belong to category "useless"using using common word count	0.75
prob-cnt-ins	the probability of this tickets belong to category "insufficient" using common word count	0.82
prob-cnt-suf	the probability of this tickets belong to category "sufficient"	0.77
prob-cnt-error	the probability of this tickets belong to category "copied error" common word count	0.99
prob-cnt-test	the probability of this tickets belong to category "test" common word count	0.65

(also known as residual errors). To reduce the complexity of GBDT, LightGBM utilize two novel techniques to improve the algorithm: Gradient-based One-Side Sampling and Exclusive Feature Bundling. This method also utilizes a Leaf-wise Tree Growth algorithm to optimize the accuracy of the model and it applies a max depth of the trees to overcome the over-fitting problem that it might cause. Further, it optimizes the speed of training by calculating the gain for each split and uses histogram subtraction. LightGBM is known for its outstanding performance and relatively good speed. Thus, many researches applied this method to machine learning tasks.

The implementation code for LightGBM was provided by Microsoft[11] in 2013 and we are utilizing its Python library for modeling process. We applied features and the label of training data by LightGBM to train a model, and fit that model on the testing data to predict each question in those data. By calculating the accuracy of the prediction, we can evaluate the performance of this model. We ran a series of 20 preliminary experiments to explore the space of parameters before we settled on the values listed in Table 6. A list of crucial parameters people generally need to tune to improve classification model performance is also in Table 6. Since our goal is to achieve better Accuracy, we will tuning toward larger max_bin, smaller learning_rate with larger num_iterations, larger num_leaves and larger max_depth each experiment until the accuracy is not improving.

2.5.2 SMOTE

During the modeling process, another issue we faced is that the categories are highly imbalanced. Over half of the questions are in the *Insufficient* category and the *Copied Error* category contained fewer than one percent of questions. To address the problem, we applied SMOTE method which over-samples examples in the minority class. SMOTE [5], first selects one minority class instance at random, create a synthetic instance by choosing one of the k nearest neighbors at random and connecting those two instance to form a line segment in the feature space. We applied this method with k=5 and oversampling the data to generate the training datasets and testing datasets for further model training.

2.6 RQ3: Model stability over semesters

For a trained model to be useful however, it must be stable across semesters or else we suffer from a *cold-start problem* [3]. In order to assess the model stability we ran a series of experiments where we assessed the relative utility of the models by applying a leave-one-out validation strategy on a semester-by-semester basis. Showing that all models perform at a comparable level provides a strong indication that the models themselves are consistent and useful, even early in the semester.

2.7 RQ4: Online Office hour analysis

In Fall 2020, all the office hours were held online, which provided valuable data about online office hours interactions. We are very curious to analyze and see whether the students behavior changed with the move to online office hours and if we should keep some online office hours sessions once we resume in-person instruction.

We first analyzed whether the online session attracted more students to seek help during office hours. For an in-person session, students need to physically find the teaching staff in the office and physically stay in line. For online sessions, students only need to click the link to join the meeting with teaching staff. With online office hours, the friction of physically going to a campus location has been removed. However, online office hours have additional overhead in creating a connection between parties and transitioning between students. To better understand online office hour help-seeking, we calculated the average number of tickets per student and the percentage of students who used office hour in each semester and compared earlier semesters with in-person office hours to the Fall 2020 semester with online office hours.

Table 6: LightGBM common training parameters and the final optimal value after tuning our model

parameter	meaning	final optimal value
num_leaves	number of leaves in one tree	1000
max_depth	Specify the max depth to which tree will grow.	10
max_bin	max number of bins to bucket the feature values.	150
learning_rate	learning rate of gradient boost	0.1
num_iterations	number of boosting iterations to be performed	32
num_class	number of classes. used only for multi-class classification	5

Table 7: Distribution of labeled questions on those five categories in all seven semesters

Useless	Insufficient	Sufficient	Copied Error	Test
3.01%	69.02%	12.04%	0.10%	15.83%

Table 8: Average interaction time(in minutes) and standard deviation of each semester

	Useless	Insufficient	Sufficient
AVG	19.7	21.9	18.3
STD	125.3	237.0	103.6
	Copied Error	Test	
AVG	11.5	24.8	
STD	67.5	208.2	

However, online office hours could have an impact on the efficiency of communication. When teaching staff and students meet online, it creates more challenges for teaching staff to indicate problems to the students and to help explain why their code is failing. Screensharing allows the staff to view the students' work, but physical interactions like pointing to a portion of the screen to indicate which button to click is lost. The teaching staff member needs to verbally describe the debugging process and ask students to follow it. Therefore, we calculated the interaction time and the wait time for each ticket. The we compare the distribution of interaction time and wait time of F20 tickets with the rest of tickets. Additional overhead is incurred when connecting to a meeting. There is a lag when a student joins a meeting for their audio to set up to start the conversation.

3. RESULTS

3.1 RQ1: Categorization Results

Table 7 shows the distribution of question categories across our dataset. As the figure shows, the most common category is *Insufficient* which occupies over 69 percent of the questions. The *Test* category coming next at 15 percent. Approximately 12 percent of the questions belong to the *Sufficient* category while 3 percent were rated as *Useless*. Surprisingly, despite comments from the teaching staff, the least common category was *Copied Error* with at most 10-15 questions per semester falling into this group. As our results show, the students tended to use the system primarily as a way of getting in line and typically provided little useful information for the teaching staff. These results also highlight the significance of testing tasks for the assignments and for students' help-seeking given the high proportion of help tickets that are triggered by them.

To assess the stability of these results we also examined the frequencies within each semester. Figure 3 shows this breakdown. We found that the relative distribution is generally similar across semesters while the absolute percentages vary. In more recent semesters the students have authored more *Sufficient* tickets than in prior years suggesting that there has been greater effort by the instructional staff to encourage good communication. Yet the persistence of the other ticket type suggests that automatic classification and triage remain an important feature.

Table 8 shows the average and standard deviation of interaction time (the difference between when the interaction began and it was closed) of each category across the semesters. For this calculation we did not consider tickets with an interaction time less than 10 seconds in length or which were longer than one hour. Our discussion with teaching staff and the instructors showed that the former were cases that were never seen as the student set a placeholder but fixed their problem before their turn came up or changed their mind, while the latter represents cases where the teaching staff offered help but did not close the ticket, often until well after the tutoring session was over. The *Useless*, *Insufficient* and *Sufficient* categories averaged around twenty minutes in length with no meaningful difference in their interaction times. The *Copied Error* category was slightly shorter on average which may reflect the specificity of the students' problems while the *Test* category had a slightly longer average interaction time. This may indicate that this kind of question is more complex or more substantive relative to the others. Overall these results indicate that the amount of information provided does not necessarily affect the speed with which the issue can be addressed.

3.2 RQ2: Modeling Results

To evaluate the performance of our model, we trained the model using the first six semesters' data and tested it on Fall 20 data.The training dataset applied SMOTE method to oversampling the minority categories and result in each category having the same amount(5037) of questions in training dataset. The model achieved an overall accuracy of 91.8%. We then conducted a more detailed analysis of the performance for precision, recall, and F-score on each question type. The results are in Table 9. As our results show the model is relatively balanced across the categories with the exception of the Test category which had substantially higher precision and lower recall. This indicates that it was far more likely for other categories to be erroneously classi-

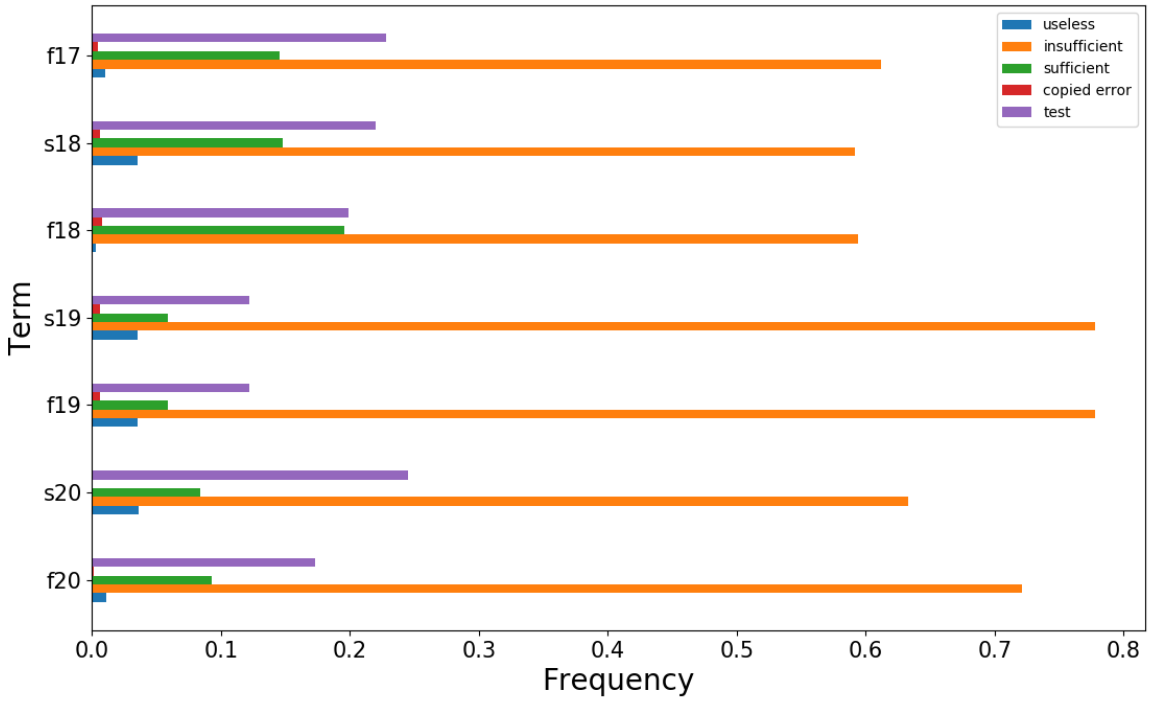

Figure 3: Frequency of each category for each semester

fied as *Tests* when the student submitted other information. One comment that triggered this error was: "Jenkins errors".

Table 9: Precision, Recall and F-measure for each category

	Useless	Insufficient	Sufficient	Test	AVG
Precision	0.902	0.915	0.913	0.967	0.922
Recall	0.901	0.903	0.905	0.877	0.901
F-measure	0.896	0.894	0.901	0.914	0.901

3.3 RQ3:Leave One out Results

Having shown that the model is relatively balanced across categories we then analyzed the relative accuracy of the model on each semester. The results are shown in Table 10. With the exception of Fall 2019, the model achieved an accuracy of at least 0.91 across each semester. Fall 2019 was the largest and busiest semester in our training dataset which may indicate that students were more diverse in their habits or posting behavior but even still we achieved an accuracy of 0.899. In light of these results we believe that our modeling method is sufficiently stable to assist in processing unseen semesters without a cold-start problem.

Table 10: Leave one out accuracy result

left-out semester	F17	S18	F18	S19	F19	S20
accuracy	0.913	0.915	0.908	0.907	0.899	0.912

3.4 RQ4: Online Office Hour Analysis Results

Table 11 shows the various summary measures associated with office hours interactions for the semesters studied. The Fall 2020 semester had the highest number of average tickets per student and the largest percentages of students utilizing office hours. Additionally, the average tickets per student in Fall 2020 is nearly twice the average tickets per students in Fall 2019. This suggests that online office hours supports increased student participation in office hours interactions. However, this increment could be explained by other factors. The data shows that in general more students take advantage of the help each year. This is consistent with the increasing class sizes but it is important to note that there are other patterns as well such as regular dips in each spring. Overall it serves to highlight the need for better course management. Secondly, since the course lecture also holds online in F20, the increase of office hour usage supports a general expectation that students are facing additional challenges with online classes however we still believe that online office hours are a practical means to minimize the cost of help-seeking and thus encourage more students.

The distribution of interaction times shown in Figure 4 indicates that the teaching staff generally took slightly longer to support students in Fall 2020 than other semesters. The median interaction time of Fall 2020 is 8.78 minutes while other semesters are 8.17 minutes. We believe that this is caused by the inconvenience of remote instruction and debugging. Additionally, the high percentages of interactions within one minute in all semesters are usually caused by teaching staff forgetting to open the tickets when the interaction begins. In Fall 2020, the percentage of short tickets was much higher suggesting the teaching staff were more likely to make such mistakes because they are working with both MDH and the online interaction tool. After notify the student, the teaching staff has to waited in the zoom until

Table 11: Statistic Analysis for each semester

	F17	S18	F18	S19	F19	S20	F20
total tickets	1146	609	1224	860	1650	1401	3452
total students	208	157	259	174	256	191	303
students use office hour	104	63	141	84	158	108	209
average tickets per student	5.51	3.88	4.73	4.94	6.44	7.34	11.40

(a) (b)

Figure 5: Histogram of wait time (time difference between open time and raised time) for tickets in (a) Regular semesters and (b)Fall 20

the student actually join the zoom meeting to start the interaction. It is very common for the teaching staff just start the interaction in zoom without open ticket in MDH. The wait time in Fall 2020 is much longer than regular semesters, as shown in Figure 5. While we had 37 hours of regular office hour time each week for 17 TAs and 2 instructors, the increased demand in office hour help-seeking did have impact on student wait time and throughput. We additionally observed an increase in the number of canceled tickets. While online office hours lowers barriers for student attendance, additional resources to support demand are needed to ensure timely support. As we transition back to in-person instruction, the course instructor will continue to offer some online office hours to support access to help-seeking.

4. CONCLUSIONS

The results of our analysis in RQ1 show that students' use of the MDH platform does vary substantially from the developers' intentions. Far from using it to write complex help requests many do use it merely to reserve a place in line. Of the five categories, our labeling showed that most of the help tickets submitted lack sufficient detail to be clear what the student is asking about while those that do provide detail are most commonly focused on test cases which constitute a major feature of the class. Contrary to our initial expectations, the students rarely use the system to enter specific error messages, even if they have them. Thus the teaching staff have relatively little to go on when triaging questions. Clearly the proportion of useful information in the tickets increased in more recent years of the course but insufficient detail remains the most common feature. Despite this however, our results also show that there are clear categories of use that we can build upon to assist teaching staff. And our results show that it may be possible to extend the system with minimal automated interventions such as detectors for word counts or grammar that can be used to scaffold, or simply enforce, good posting behavior.

Informed by our analysis, we were able to address our modeling questions, RQ2 and RQ3 by developing accurate and robust classification models that achieved an overall accuracy of 92.6% and individual accuracy of 0.899% to 0.91% . Moreover, the results are robust on a per-category basis. While these results are not perfect, they show that we have the potential to use models of this type for effective triage of student questions as well as to provide scaffolding and immediate guidance for students as they author help tickets. While such guidance has not been evaluated for its' educational impact prior work on self-explanation (e.g. [23]) leads us to conclude that it may help students to diagnose their own challenges.

For RQ4, the comparison between an online session semester and regular semester shows both the strength and weakness of online office hours. The advantages of hosting office hours online is that it can encourage students to utilize the help-seeking resources; However, the large amount of help-seeking requests can be overloaded for teaching staff and the remote debugging through screen sharing is clearly less efficient than face-to-face interactions.

5. LIMITATIONS

There are several limitations to our work that must be acknowledged. While our results span semesters, they are still taken from a single course with a single instructor. As a consequence our results are necessarily dependant on the training that students have received and it is not yet clear whether this stability will be apparent in models created from interaction data for other courses, particularly those that are not as large, do not use the same assignment structure, or rely so heavily on tests.

Additionally, for our analysis toward online office hour, we did not consider the influence of teaching lectures online could raise more challenges for students and thus increase the usage of office hour. Our conclusion of online office hour encourage students to seek help is based on the assumption that there is no significant difference of academic difficulty between F20 and other semesters.

6. FUTURE WORK

This research can support future instructors in course management and the automatic categorization for MDH system. We therefore plan to address these limitations, expand our dataset, and build upon the models that we have obtained. First, we plan to conduct a more robust process of tagging and classifying our tickets with the goal of assessing the stability of our categories with other evaluators and of identifying other important ways of grouping the tickets themselves.

Second, we will extend My Digital Hand to take advantage of these trained models in supporting both the students and instructors. We will support instructors by providing automatic triage approaches that can help to guide their planning. And we will use automated guidance to prompt students to produce better tickets in the first place.

Third, we also plan to investigate other aspects of the office hours that are captured in the MDH data. These include: whether students in the same office hours post similar tickets, thus highlighting the potential of peer feedback; and the presence or absence of serial ticketers; that is students who keep multiple follow-up tickets going to monopolize support. We plan to build models for these features with the goal of understanding how help time is being used and by extension how to better coordinate limited support.

Finally, we plan to apply our models to provide automated scaffolding for students when they provide insufficient comments or errors. Specifically, we will integrate this model to the MDH system and every time a student raise a hand, we will use our model to predict the question category. If their description is insufficient or useless, then we can immediately notify them to revise it. This will help students to better frame their questions, and it will help the teaching staff can be better prepared to answer the students' question. This initial filter can be followed by additional models to suggest debugging steps or common answers based upon their revised question.

7. ACKNOWLEDGEMENTS

ABSTRACT

Recent years have seen significant interest in multimodal frameworks for modeling learner engagement in educational settings. Multimodal frameworks hold particular promise for predicting visitor engagement in interactive science museum exhibits. Multimodal models often utilize video data to capture learner behavior, but video cameras are not always feasible, or even desirable, to use in museums. To address this issue while still harnessing the predictive capacities of multimodal models, we investigate adversarial discriminative domain adaptation for generating modality-invariant representations of both unimodal and multimodal data captured from museum visitors as they engage with interactive science museum exhibits. This approach enables the use of pre-trained multimodal visitor engagement models in circumstances where multimodal instrumentation is not available. We evaluate the visitor engagement models in terms of early prediction performance using exhibit interaction and facial expression data captured during visitor interactions with a science museum exhibit for environmental sustainability. Through the use of modality-invariant data representations generated by the adversarial discriminative domain adaptation framework, we find that pre-trained multimodal models achieve competitive predictive performance on interaction-only data compared to models evaluated using complete multimodal data. The multimodal framework outperforms unimodal and non-adapted baseline approaches during early intervals of exhibit interactions as well as entire interaction sequences.

Keywords

Museum learning, visitor engagement, adversarial domain adaptation, early prediction, multimodal learning analytics.

1. INTRODUCTION

Visitor engagement is critical in museum learning [21]. Engagement defines how visitors experience museums, including how they move between exhibits, form and express interests, and acquire knowledge and understanding. Developing computational models of museum visitor engagement holds significant promise for identifying salient patterns of visitor behavior as well as providing insight into how specific exhibits can be designed to enhance engagement. For example, visitor analytics show potential for enabling adaptive learning experiences tailored to the preferences and tendencies of the visitors, leading to highly engaged interactions with the exhibit. Visitor interactions with museum exhibits are inherently *multimodal*. Visitor engagement manifests through a variety of behaviors such as facial expression, touch, eye gaze, and body posture. As such, multimodal learning analytics can model museum visitor engagement by capturing and analyzing visitor behavior from several different perspectives [2, 16]. Multimodal models of learner engagement have been shown to be effective in a range of environments, including laboratory [8, 22] and classroom settings [1, 6, 7]. More recently, multimodal learning analytics have been the subject of growing attention in informal education settings, such as museums [16, 20], but this line of investigation is still in its nascent stages.

Given the multimodal nature of visitor interactions in museums, the use of multichannel data provides important benefits for modeling visitor engagement. In particular, multimodal models can be used to predict visitor engagement early during a visitor's interaction with an exhibit [16]. This shows promise for enabling visitor-adaptive technologies that provide adaptive support for fostering engaged learning experiences with an exhibit or for notifying museum educators to inform decisions about staffing the museum floor. In predictive modeling, it is important that the multimodal visitor engagement models be evaluated in terms of both predictive accuracy and the minimum amount of time that the models require to achieve robust predictive performance.

Multimodal modeling of visitor engagement in museums also poses significant challenges. Interactions with exhibits are highly variable due to the free-choice nature of museum learning [12, 25, 28]. Additionally, multimodal frameworks often utilize physical sensors (e.g., video cameras, motion sensors, eye trackers), which introduce questions about scalability, privacy, and mistracking. Intrusiveness is also a concern, as suites of multimodal sensors may be impractical in some settings, or they may adversely affect the natural behavior of visitors [32].

Transfer learning presents itself as a natural solution to this issue, as the various modalities in a multimodal modeling framework share a common predictive task. In particular, recent years have seen an increased emphasis on domain adaptation, a type of transfer learning that investigates the predictive capacity of models that are pre-trained on one domain (*source* domain) and are subsequently reweighted to perform similarly on another domain with a different distribution (*target* domain) across a single common task [39]. A

primary objective of domain adaptation is to obtain a domain-invariant representation of the salient features extracted from the two distinct data sources, where the shared feature space allows for improved predictive performance on data points from the target domain while still maintaining strong performance on data from the source domain. Examples of recent domain adaptation research include adapting across images extracted from different domains [34, 42] or across modalities captured from different data channels such as RGB-to-depth image translation [33, 42].

In this work, we investigate the use of domain adaptation as a method of translating unimodal, interaction-based data to a domain-invariant representation that can be used with predictive models previously trained on multimodal data. We demonstrate the effectiveness of a multimodal domain adaptation framework for making early predictions of visitor dwell times at an interactive museum exhibit. Our multimodal analytics framework is designed to operate in museum settings where sensor-based data capture may be restricted or otherwise impractical. We adopt an adversarial approach to generating domain-invariant representations of multimodal data (exhibit interactions and facial expression serving as the *source* domain) and unimodal data (exhibit interactions serving as the *target* domain) that are encoded using stacked denoising autoencoders. Empirical results of evaluations of the framework suggests that the use of adversarial discriminative domain adaptation allows for a unimodal target encoder to be trained to share a latent feature space with a multimodal source encoder [42]. The framework achieves higher performance than an interaction-only baseline model in terms of early prediction and visitor-level prediction of dwell time, a proxy indicator of visitor behavioral engagement with an exhibit. Dwell time has been frequently used to quantify visitor engagement in museum settings [5, 23]. The framework offers the potential to accurately predict visitor dwell time in museums, while also allowing for operation with reduced availability of physical sensor data, or even when no physical sensor data is available.

2. RELATED WORK

Visitor engagement is a critical aspect of learning in informal learning environments, such as science centers and museums [21]. Engagement shapes how visitors proceed throughout a museum, and interact with various exhibits [16]. There has been substantial work on modeling engagement in formal learning environments such as classrooms [19] and laboratories [8], and this focus has expanded in recent years to informal learning environments. This includes research efforts focused on analyzing engagement in groups of visitors around interactive tabletop exhibits [5], investigating the effectiveness of interventions for enhancing group engagement at different diorama exhibits [23], and predicting visitor dwell time [16]. However, devising computational models of museum visitor engagement remains a relatively unexplored area and presents distinctive challenges due to the free-choice nature of visitor learning in museums, creating a need for data-rich engagement modeling techniques.

Multimodal engagement modeling has shown significant promise as an engagement modeling approach due to its capacity to provide a data-rich multi-dimensional perspective on learner behavior [2]. In many cases, multimodal models lead to improved performance compared to models that utilize a single modality [19, 22, 32, 49]. Multimodal models have often utilized several diverse data channels when deployed in formal learning environments, including facial expression, posture, eye gaze, dialogue, and interaction trace data [40]. Facial expression data is commonly used in multimodal learner models of student affect [7] and performance [44]. Posture data has also been used for affect detection [22] as well as predicting learners' levels of engagement with Massive Online Open Courses (MOOCs) [9]. Eye gaze data has been combined with facial expression and head pose data to train models for continuous emotion prediction [48], while dialogue data has been utilized to predict dropout in online K-12 courses [26]. Finally, interaction trace logs and keystroke data have been used in conjunction with facial expression data to detect confusion in students engaging with an introductory computer science education learning environment to provide adaptive feedback and support dynamic adjustment of exercise difficulty levels [6]. While recent work has investigated multimodal approaches to modeling visitor engagement in museums [16], multimodal approaches to museum visitor modeling poses significant challenges, as these frameworks often necessitate physical, sensor-based data capture. This introduces various ethical and logistical concerns and may be impractical or prohibitive in certain informal learning environments.

Computational methods such as transfer learning, and particularly domain adaptation, provide a way to harness the predictive capacities of multimodal learning analytics while allowing visitor modeling frameworks to operationalize a reduced number of more intrusive modalities. Domain adaptation and transfer learning have shown significant potential in a variety of implementations, and have been utilized within educational contexts for tasks such as confusion detection in online forums for different online courses [50] and automated essay scoring across different prompts [35]. Additionally, domain adaptation has been investigated within multimodal contexts such as RGB and depth images [42], as well as video and audio modalities [36]. To our knowledge, adversarial domain adaptation has not been applied to unimodal and multimodal data to model learner engagement in museums.

Recent domain adaptation work has focused primarily on an unsupervised or semi-supervised variation of this problem, where deep learning models trained on a labeled source dataset are transferred to share latent representations alongside a target domain that may contain little or no previously labeled data. The issue of missing labels for the target domain data is addressed by obtaining a domain-invariant representation through minimizing the distance between the learned data representations between the two domains [17, 41, 42]. While prior efforts accomplish this task through statistical measures such as the Maximum Mean Discrepancy (MMD) [43] or the deep Correlation Alignment (CORAL) [39], other work has taken an adversarial approach, with the simultaneous goals of learning a data representation that is predictive of the source domain labels while also being indistinguishable to a domain discrimination model [27, 42]. One approach involves reversing the gradients of a domain discrimination model to maximize the model's loss and guide the learning to explore a domain-invariant representation [17]. Other approaches train a source encoder to reduce the source domain data to a latent representation and use a domain discriminator to adversarially train a target encoder to produce a latent representation of the target domain data that is indistinguishable to the discriminator [42]. The trained target encoder is subsequently used to process unlabeled data from the target domain to be classified by a model pre-trained on source data. Another approach is the Co-GAN approach, which involves two Generative Adversarial Networks (GANs) that generate source and target data, respectively [27]. The high layer parameters of the two GAN models are tied together, allowing the generators of the models to co-learn a shared latent representation while possibly sharing a common input noise vector.

Early prediction is an important component of visitor modeling because it can drive run-time adaptive support to enhance visitor interest and engagement with interactive exhibits. A critical objective in early prediction is to reach a certain accuracy threshold in a timely manner. Early prediction has been investigated in the context of formal learning environments, such as predicting middle-grade learner engagement with a game-based learning environment [47], evolving learning goals throughout students' interaction trajectories [31], and student success in novice programming tasks [29]. Early prediction has also been the subject of prior work on museum learning, such as automatic detection of visitors' social behavioral patterns [13, 24] and multimodal regression-based modeling of visitor engagement in science museums [16].

The primary contributions of this work are as follows: (1) we demonstrate improved predictive performance of multimodal models of museum visitor dwell time using facial expression and interaction data compared to interaction-only baselines, (2) we evaluate the effectiveness of adversarial discriminative domain adaptation as a means of enabling the use of previously-trained multimodal models with unimodal data, and (3) we investigate the performance of each visitor engagement model using convergence-based early prediction metrics and standard predictive performance measures. Domain adaptation has been relatively underexplored with educational data, and this is especially true of data from informal learning environments such as museums. Furthermore, there has been limited work investigating domain adaptation in the context of early prediction of learner engagement. Our work shows that domain adaptation is effective at enhancing prediction of visitor dwell time by harnessing the capacities of multimodal visitor modeling, which leads to higher predictive accuracy when compared to unimodal models.

3. FUTURE WORLDS EXHIBIT

To investigate multimodal predictive models of museum visitor engagement, we use data collected from visitor interactions with a game-based museum exhibit, FUTURE WORLDS, which is designed to introduce visitors to concepts about environmental sustainability (Figure 1). FUTURE WORLDS runs on a multi-touch display, enabling visitors to interact with the virtual environment through touch and gestures on the screen. Visitors are faced with the challenge of improving the conditions of the virtual environment's biosphere through a series of changes such as farming practices and energy sources within the game. FUTURE WORLDS and its integrated educational content are targeted towards learners ages 10-11.

Visitors can tap or swipe on the screen to perform certain actions such as reading about a particular aspect of the virtual environment and its impact on sustainability or modifying an in-game element and observing the broader consequences of this decision on the environment. Upon making a change to the virtual environment, the visitor is given immediate feedback regarding the positive or negative impact of the gameplay action. A visitor can "win" by making the correct decisions to certain in-game elements that maximize the environmental sustainability of the virtual environment. Afterwards, the visitor is presented with the option to restart the game or continue interacting with the virtual environment in its completed state. Additionally, a visitor is able to leave the FUTURE WORLDS exhibit having not completed the game beforehand. Prior work with FUTURE WORLDS found that visitors improved their understanding of environmental sustainability

Figure 1. Gameplay of the FUTURE WORLDS interactive exhibit, including (A) 3D virtual environment, (B) selecting an element to modify, (C) viewing information about the selected element, and (D) correctly solving the in-game problem.

concepts, while also demonstrating high levels of engagement throughout their interactions with the exhibit [37].

4. MULTIMODAL DATA COLLECTION

To track visitor engagement and behavior with FUTURE WORLDS, the exhibit was instrumented with several sensors to collect the real-time behavior of visitors' interactions with the exhibit, as shown in Figure 2. We first describe the visitor population for study participants and then introduce the two modalities used for the domain adaptation approach (facial expression, exhibit interaction trace logs), and the features extracted from each input data channel.

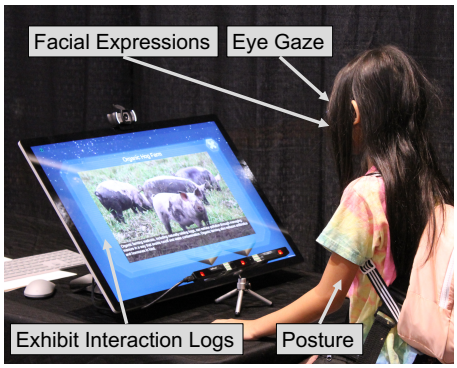

Figure 2. Visitor interacting with FUTURE WORLDS.

4.1 Study Participants and Procedure

We conducted a study of visitor interactions with the FUTURE WORLDS exhibit at the North Carolina Museum of Natural Sciences in Raleigh, North Carolina. The data were collected over a series of three sessions with different school groups of visitors aged 10-11 (M=10.4, SD=0.57). The school groups came from different socio-cultural backgrounds (e.g., race/ethnicity), and each school served student populations where 70% of the students are from low-income families. In total, 116 visitors interacted with FUTURE WORLDS. There were 47 female and 55 male participants, with 14 participants who did not provide data on their gender. The visitors were 32.4% Hispanic or Latino, 21.6% African American, 11.8% American Indian, 8% Asian, 7.5% mixed race, 3% Caucasian, and 15.7% preferred not to respond. Before interacting with the exhibit, visitors were asked to complete a series of surveys and questionnaires, including a demographic survey, sustainability content knowledge assessment, and the Fascination in Science scale [11]. Afterward, visitors interacted with the exhibit until they wanted to stop or after approximately 12 minutes had elapsed (M=5.8, SD=2.4, Min=1.8, Max=11.8). Visitor dwell times were captured by the game's internal logging functionalities. Once visitors finished their interaction with the exhibit, they were asked to complete a sustainability content knowledge assessment, engagement survey, and a short debrief interview. Several visitors were missing one or multiple data channels (e.g., facial mistracking), requiring the removal of their data from the final dataset for analysis. The final dataset that was used for the predictive models in this paper consisted of multimodal data from 79 visitors.

During the data collections, the visitors' body movement, eye gaze, facial expression, and interaction data from the exhibit were captured. For this study, we focus exclusively on the exhibit interaction data and the facial expression data. We selected the exhibit interaction data due to its unintrusive nature and its relative ease of data capture, as the trace data is captured in the background with the exhibit software and does not require any physical sensors or calibration. We selected facial expression data because of its predictive utility in previous work on unimodal and multimodal models of learner engagement [14, 15].

4.1.1 Facial Expression

Facial expression is an important indicator of learner emotion, and it has been widely used in previous studies on modeling learner engagement [46]. In this work, visitor facial expression was captured using video data from an externally mounted Logitech C920 USB webcam. In real time, the video data was processed by OpenFace, an open-source facial behavior analysis toolkit to detect facial landmarks, estimate head pose, recognize facial action units (AUs), and estimate eye gaze [3]. The OpenFace software automatically detects and analyzes 17 distinct AUs for each visitor's face captured within the camera's field of view.

4.1.2 Interaction Trace Logs

FUTURE WORLDS includes built-in logging functionalities to capture fine-grained logs of visitor interactions with the exhibit. The interaction trace logs consist of sequential records (at the millisecond level) of physical interactions with the multi-touch display (e.g., taps, swipes, and gestures), as well as specific in-game learning events (e.g., altering the virtual environment and accessing an embedded informational resources). The interaction trace logs are used to investigate how visitors interacted with the exhibit and progressed through the game.

4.2 Multimodal Features

Using both visitors' facial expression and exhibit interaction behavior, we distilled two sets of features to serve as predictors of visitor dwell time. Many of the extracted features for each modality were chosen based on their predictive performance in prior work on multimodal learning analytics [16].

4.2.1 Facial Expression

Using the processed AU data from OpenFace, we calculated the duration that each AU was exhibited throughout the visitor's interaction with FUTURE WORLDS. We first standardized each visitor's observed AU intensity values and then calculated the duration of each AU during time intervals where consecutive AU intensity values were at least one standard deviation greater than the mean of that particular visitor-specific AU feature. This filtering process ensured that only spikes relative to the specific visitor's AU values contributed towards the calculation of the total duration. To further filter the AU durations, we only recorded the duration if the AU was present for longer than 0.5 consecutive seconds. This avoided possible micro-expressions that could add noise to the overall data channel [38]. We performed this filtering process for all 17 AUs tracked by OpenFace. In addition, we generated the standard deviation and maximum AU values across the visitor's interactions up to the current timestamp. In total, we extracted and distilled 51 facial expression-related features.

4.2.2 Exhibit Trace Logs

We distilled eight features from the exhibit interaction data: (1) the total number of times a visitor tapped the FUTURE WORLDS multi-touch display, (2) the total number of times a visitor tapped informational tiles about environmental sustainability concepts, (3) the total duration of time an informational tile was open, (4) the total duration spent with labeled sustainability images displayed onscreen, (5) the total duration of time that a visitor spent directly interacting with the 3D simulated environment in FUTURE WORLDS, (6) the total number of times a visitor swiped the interface to explore alternative options for modifying the simulated

environment, (7) the total number of times the simulated environment was modified, and (8) a binary feature that indicated whether a visitor had successfully solved the current environmental problem scenario in FUTURE WORLDS.

5. DOMAIN ADAPTATION

In this work, we present an unsupervised, adversarial discriminative domain adaptation approach that enables the use of multimodal visitor engagement models in settings where only unimodal data streams are available. In unsupervised domain adaptation, two datasets are extracted from two separate domains: (1) a source domain (s), from which data samples X_s and associated labels Y_s are drawn, and (2) a target domain (t), which contains unlabeled data samples X_t. It is also assumed that there exists a classifier C_s that has been previously trained on the source data X_s and source labels Y_s by learning a latent mapping M_s. The primary objective of the unsupervised domain adaptation approach is to learn a latent mapping M_t so that $M_t(X_t)$ can be correctly classified by C_s despite the absence of any associated labels for X_t.

The purpose of adversarial training within the domain adaptation framework is to learn a domain-invariant data representation that minimizes the distance between $M_t(X_t)$ and $M_s(X_s)$. This is accomplished through a separate binary discriminator, D, that is trained to distinguish between latent representations of the source domain and the target domain. The discriminator is optimized according to a standard cross-entropy loss function (Equation 1):

$$\mathcal{L}_{DISC}(X_s, X_t, M_s, M_t) = -\mathbb{E}_{x_s \sim X_s}\left[\log D\left(M_s(X_s)\right)\right] - \mathbb{E}_{x_t \sim X_t}\left[\log\left(1 - D\left(M_t(X_t)\right)\right)\right] \quad (1)$$

Adversarial domain adaptation focuses on two primary objectives implemented within a minmax framework: the discriminator attempts to accurately classify a latent data representation as either from the source domain or the target domain, while a target encoder attempts to learn a mapping $M_t(X_t)$ that deceives the discriminator, thus finding a latent representation that is domain-invariant but retains enough salient characteristics to provide predictive value to a source classifier C_s. To implement an adversarial loss function within the framework, a common practice is to simply invert the loss term when training the target encoder. This essentially reverses the gradients for the target encoder but can consequently lead to premature convergence and vanishing gradients [17]. A more stable training method is to invert the labels used to train the target encoder. This creates two distinct convergence objectives for the two elements of the adversarial framework [42]. The discriminator loss term remains the same as stated in Equation 1 above, while the loss term for the target encoder becomes:

$$\mathcal{L}_{TAR}(X_s, X_t, D) = -\mathbb{E}_{x_t \sim X_t}\left[\log D\left(M_t(X_t)\right)\right] \quad (2)$$

This process is analogous to the process utilized by generative adversarial networks (GANs) [18]. A GAN attempts to emulate a fixed data distribution by adversarially training a discriminator to distinguish between "fake" data, which was produced by a generator that aims to generate data that is synthetic but realistic looking using a random noise vector, and "real" data that is extracted from the prior fixed data distribution. While GANs have been utilized in domain adaptation tasks [27], they are typically effective when the source and target domains are relatively similar. GANs have shown convergence issues in scenarios involving a high degree of domain shift [42]. As our work involves a domain shift from a multimodal source domain to a unimodal target domain, we opt to utilize a non-generative approach for this work and focus exclusively on discriminative adversarial methods. It is assumed that a pre-existing distribution of multimodal data (i.e., interaction trace logs + facial expression) is available to train the source encoder and the source classifier, while the target distribution consists of unlabeled unimodal data (i.e., interaction trace logs). This is intended to simulate scenarios where visitor engagement models have been previously trained on multimodal data but are deployed in situations where only interaction trace log data is available to generate new predictions of visitor engagement.

While much prior work in adversarial domain adaptation involves source and target domains of similar or identical dimensionality (e.g., image-to-image translation), the multimodal aspect of this work presents a distinct challenge, as the multimodal data in the source domain inherently contains more features than the unimodal target domain. To enable the pre-trained multimodal classifier to handle unimodal data as input, stacked denoising autoencoders [45] are used to reduce the multimodal and unimodal feature vectors to the same dimensionality. An autoencoder is an unsupervised method of using feedforward neural networks to reduce an input vector X to a latent data representation using an encoder that contains a mapping function M. The autoencoder then attempts to use a decoder that uses mapping function N to reconstruct $M(X)$ to its original input. The encoder and decoder components of the autoencoder are both optimized by minimizing the reconstruction loss between X and $N(M(X))$. A stacked autoencoder is a variation in which each component contains multiple hidden layers of autoencoders. A denoising autoencoder builds on the same concept but corrupts the input vectors using random noise injection, which allows effective model regularization [45]. In this work, we use a corruption level of 0.25 on each feature in each input vector, where a value is set to 0 when the input feature is corrupted. After input vector X undergoes random noise injection to produce X', the denoising autoencoder attempts to reconstruct X from $N(M(X'))$. This allows the autoencoder to become more robust against random noise within the input features while also preventing the autoencoder from overfitting or simply learning the identity function. Following the optimization of the autoencoder, the decoder component is discarded while the encoder component is retained for dimensionality reduction within our data processing pipeline. A denoising autoencoder is shown in Figure 3.

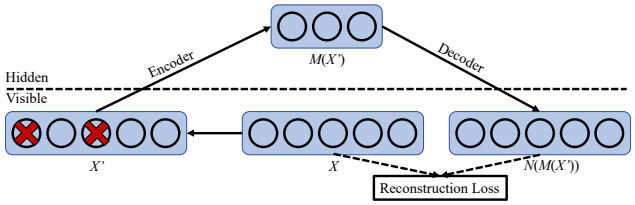

Figure 3. A denoising autoencoder.

Our adversarial domain adaptation process is shown in Figure 4. Figure 4A illustrates the initial training of the classifier and the source encoder. The features from the facial expression and interaction modalities are concatenated together and then used to train a stacked denoising autoencoder. Following this process, the trained source encoder is then used to reduce the multimodal input data to a latent representation that is then used to train a classifier. The classifier receives the latent data as input and is trained to predict the target variable, visitor dwell time. To enable the adversarial training of the target encoder and discriminator (Figure 4B), the weights of the pre-trained source encoder are fixed, and the target encoder weights are initialized using a pre-trained autoencoder optimized on the unlabeled, interaction-only data. An

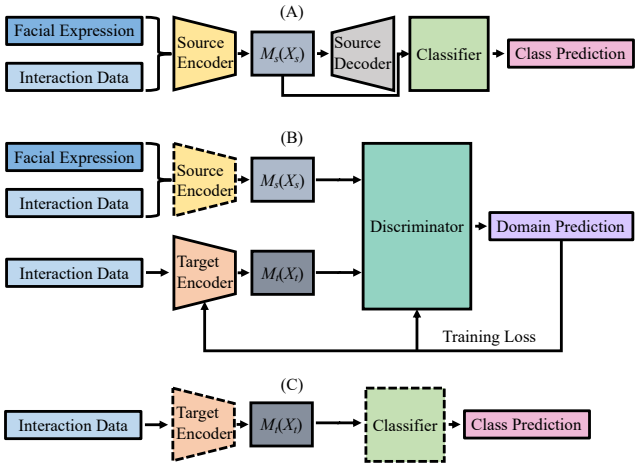

Figure 4. Domain adaptation process, including (A) the classifier and source encoder training, (B) adversarial training of the target encoder and discriminator, and (C) evaluation of the adapted target encoder on the classifier. Dashed lines indicate fixed model weights.

alternative approach is to initialize the target encoder weights from the source encoder. However, this can only be accomplished if the feature vectors extracted from the source domain are the same dimensions as the target domain. In our work, the multimodal feature vectors from the source domain have a higher dimensionality than the unimodal feature vectors from the target domain, since we remove the facial expression modality from the training data for the target encoder. The source and target encoders are used to produce latent representations of the multimodal and unimodal features, respectively. These representations are assigned labels of either 1 if the sample originated from the source domain, and 0 if the sample originated from the target domain. The data/label pairs are then used to train a feedforward network serving as the discriminator model. The discriminator is trained to distinguish between latent data from the source domain and from the target domain, while the target encoder is simultaneously trained to produce latent data from the target domain that consistently deceives the discriminator. To evaluate the target encoder (Figure 4C), unimodal data is passed through the encoder, and the resulting encoded data is then forward propagated through the trained classifier shown in Figure 4A. This procedure provides a way to evaluate the predictive performance of a multimodal classifier on unimodal data. It is important to note that some amount of multimodal data must be present prior to deploying our adversarial approach in order to train the multimodal classifier as well as the multimodal autoencoder.

6. METHODOLOGY

In multimodal models of learner engagement, some modalities that are highly predictive of engagement can also be impractical or undesirable in certain educational settings, such as sensors that require a cumbersome calibration process or expensive specialized equipment. Modalities that involve the capture of video data can raise concerns about privacy. However, eliminating physical sensors and exclusive reliance on sensor-free modalities may result in decreased performance on some tasks and settings. We propose a solution to this issue that (1) allows the predictive capacities of multimodal models to be retained, and (2) allows for the reduction in use of physical sensors. This work operates under the assumption that multimodal data is available in at least some capacity to facilitate the training of multimodal models prior to adversarial domain adaptation. As a result, the ideal setting for the proposed framework is after an initial multimodal data collection has taken place, enabling pre-trained multimodal models to be deployed. Below we describe the methods used to preprocess the multimodal and unimodal data, the feature selection process utilized to select the data used in the prediction and adversarial tasks, and the approach to training and validation of the visitor engagement models. Finally, we present the early prediction convergence metrics used to evaluate the final classification models and the domain encoders.

6.1 Data Preprocessing

6.1.1 Temporal Feature Engineering

To facilitate early prediction of visitor engagement, sequential representations were produced from the features engineered from the two modalities as described in Section 4.2. To accomplish this, feature vectors were engineered for every subsequent 10-second interval in a single visitor's interaction session with the exhibit. For each feature, the average or sum of all values from t=0 to t=10n seconds was calculated, where n is the number of 10-second intervals that have elapsed for that feature vector. For example, if a visitor engaged with the exhibit for one minute, then n=6, and the feature vectors are generated across time intervals of 10, 20, 30, 40, 50, and 60 seconds from the beginning of their session. This allows each feature vector to be a representation of a visitor's behavior over their entire interaction with an exhibit up to that point. Additionally, this approach solves the issue of the temporal alignment of the separate data channels caused by differing sampling rates of the facial expression modality and the interaction-based modality. As a result, the early prediction models are able to make predictions at a consistent frequency across every visitor's exhibit interaction trajectory (i.e., every 10 second). To ensure that the additive nature of the features does not contribute to artificially inflated model performance, each feature is scaled by the elapsed time up to the current timestamp. After this process is complete, 2,279 data samples were generated for 79 visitors.

6.1.2 Visitor Dwell Time

The beginning of a visitor's dwell time takes place after a calibration process with the eye gaze sensor is completed, and prior to when they are presented with an on-screen information dialogue box explaining the problem to be solved. The visitor's session can end one of three ways: (1) the visitor opts to end their session prior to completing the problem-solving task in FUTURE WORLDS, (2) the visitor solves the problem and chooses to end their session, or (3) the visitor solves the problem, opts to continue interacting with the virtual environment, and later chooses to end their session. Each visitor's dwell time was captured in total seconds (M=268.83, SD=137.48, Min=77.11, Max=657.48) and was recorded by the FUTURE WORLDS exhibit's built-in logging functionalities. For the purpose of this work, the dwell time prediction task was converted to a classification problem by splitting dwell time into three tertile groups and assigning approximately one-third of the visitors to each group. We use this classification approach instead of regression analysis due to the relatively low number of visitors in the dataset and to accommodate the use of early prediction convergence metrics. The visitors in the dataset were assigned to one of three possible groups according to their dwell time d: low (d <= 193.54, N=26), low (193.54 < d <= 318.82, N=27), and high (d > 318.82, N=26). We take this approach as a way to prevent a significant class imbalance while still retaining a higher level of granularity than a median split. The distribution of visitor dwell times, including the ternary groups, is shown in Figure 5.

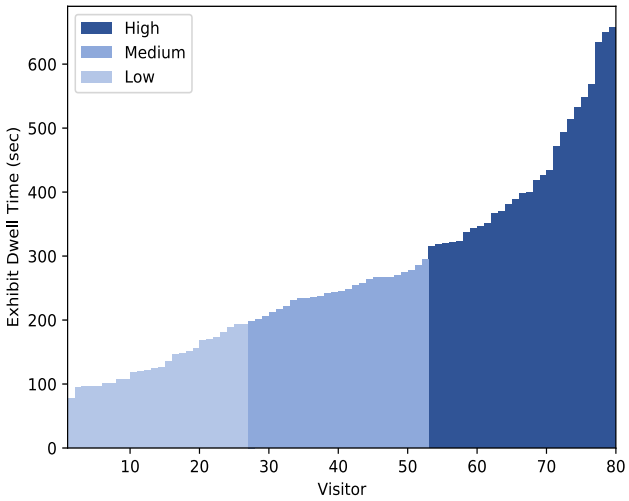

Figure 5. Distribution of visitor dwell times and ternary groups.

6.2 Feature Selection

Because of the large number of features in the multimodal data (51 facial expression features and 8 exhibit interaction features), we implemented forward feature selection to eliminate features with little or no predictive value and to reduce potential noise. Forward feature selection iterates through a list of features in a greedy manner, training a model on a single feature and continuing to add features if their inclusion increases the performance of the model on the target variable. This process continues until a predetermined number of features are selected or until all available features have been evaluated. This process has a few shortcomings. Due to the greedy nature of the algorithm, the features that are evaluated first have a higher chance of being selected. For example, the first feature that is evaluated is always retained, regardless of its true contribution to the predictive performance of the model. One approach to mitigating this issue is to perform forward feature selection for every possible combination of features, but this is often prohibitive as the number of combinations increases exponentially as the number of features increases, which imposes significant computational requirements. To mitigate the issue of bias in greedy feature selection while avoiding an exhaustive search across all feature combinations, we perform forward feature selection across a randomized ordering of all available features. We used a support vector machine (SVM) as the predictive model for each feature combination due to its effectiveness in high-dimensional spaces and relatively small computational overhead. This process was repeated for 100 separate iterations and randomizations to ensure that each feature had an equal probability of being placed at a specific point within each feature ordering. Following this process, the features were sorted according to the frequency that each feature was selected across all 100 iterations. To compensate for the difference in the number of features for each data channel, we performed forward feature selection on the facial expression modality and selected the ten most frequently selected features.

It should be noted that because we selected the ten most frequent features from the facial expression modality, and the interaction-based modality contained only 8 total features, each feature from the latter modality was included in the data modeling process. (We perform forward feature selection on the interaction-based features for analysis purposes only.) Because certain features such as AU durations and tile durations increase monotonically throughout a visitor's exhibit interaction trajectory and can lead to indirect data leakage with regard to the target variable (dwell time at the exhibit), the features were scaled by the total elapsed time up to the current timestamp, so these features were converted to proportional representations of the elapsed time at each time interval.

Table 1. Most frequent features from forward feature selection (interaction)

Feature	Frequency
Proportional Tile Duration	0.637
Proportional Open Tile Count	0.561
Proportional Info Duration	0.557
Proportional Info Taps	0.554
Proportional Taps	0.511
Proportional Swipe Tiles Count	0.416
Proportional Modify Tile Count	0.341
Beat Game	0.272

Table 2. Most frequent features from forward feature selection (facial expression)

Feature	Frequency
AU05 Max	0.317
AU10 Max	0.276
Proportional AU10 Duration	0.257
AU02 Max	0.237
Proportional AU01 Duration	0.227
AU26 Std	0.218
AU25 Max	0.214
Proportional AU17 Duration	0.208
Proportional AU45 Duration	0.206
Proportional AU26 Duration	0.196

This feature selection process took place within each cross-validation fold, and as a result, each fold produced a different combination of selected features. We calculated the frequency of the features across all cross-validation folds and present these in Table 1 and Table 2.

Based on the results in Table 1, features related to general interactions (proportional number of times any tile was opened, proportion of time any tile was open) were the most predictive interaction-based features. The features related to opening and viewing embedded graphical and textual science materials were also frequently selected features. The features representing the frequency a visitor modified the in-game virtual environment were less frequently selected as predictive features, as was the binary indicator of whether the visitor correctly solved the problem at that particular timestamp.

The most predictive features from the facial expression modality were primarily maximum values and proportional durations of certain AUs. AU05 (upper lid raiser) and AU10 (upper lip raiser) were the most predictive facial action units, followed by AU02 (outer brow raiser) and AU01 (inner brow raiser). AU25 (lips part) and AU26 (jaw drop) were moderately predictive, followed by AU17 (chin raise) and AU45 (blinking). Multiple representations

of AU10 and AU26 were frequently selected during the feature selection process as well. It is notable that the overall frequency of the facial expression features is significantly lower than many interaction-based features. This is likely a result of the large number of facial expression features compared to the interaction-based features.

6.3 Model Evaluation

The models were evaluated using 10-fold cross-validation, with the splits for each fold occurring at the visitor level to ensure that a visitor's data was contained only within a single training, validation, or test set. The dataset was standardized within each cross-validation fold by dividing each feature by subtracting the feature's mean and dividing by the feature's standard deviation, as determined by the training data. This rescales the data to have a standard deviation of 1 (unit variance) while centering the mean to be 0. Following this process, class imbalances within the training data were resolved using Synthetic Minority Oversampling Technique (SMOTE) [10]. SMOTE is a common upsampling approach that resolves class imbalances through a randomized K-nearest neighbor approach, which brings the class balance to a uniform distribution while avoiding duplication of any data points. The upsampled, standardized training data is then used for forward feature selection as described in Section 6.2.

After feature selection, a classifier model was trained on the multimodal data and the visitor dwell time labels in each cross-validation fold to provide a comparison point for the domain-adapted models. The tertile labels for the target variable were encoded as one-hot vectors for each model output. We evaluated five different models: SVM, logistic regression, naïve Bayes, random forest, and a feedforward neural network. We performed hyperparameter tuning using a 3-fold nested cross-validation within the training set for each outer cross-validation fold. The hyperparameters that were varied for each model included the regularization parameter and kernel (SVM), regularization parameter (logistic regression), number of estimators (random forest), and number of layers and nodes (feedforward neural network). Additionally, the architecture of the autoencoder used to train the source encoder was evaluated during the hyperparameter tuning phase. The autoencoder was a feedforward neural network, and the hyperparameter values that were evaluated were the number of layers and nodes in the hidden layers within the encoder and decoder, as well as the number of latent dimensions. The feedforward neural network achieved the optimal performance as the classifier for visitor dwell time, using two hidden layers with 64 nodes each. The source encoder contained three hidden layers with 64, 32, and 16 nodes, respectively, with a latent output of 10. Additionally, all feedforward neural network models used a learning rate of 0.001, a dropout rate of 0.5 in the last hidden layer, and sigmoid activation functions. The loss function used for each model was categorical cross-entropy. Early stopping was implemented for each model using the validation data during the nested cross-validation to protect against overfitting. As a baseline, we follow the same process previously described, except using only the interaction modality. We evaluate both a unimodal and multimodal baseline in order to demonstrate the improved performance of the multimodal model of visitor dwell time as compared to the unimodal model, and to show the improved performance using the domain adaptation framework in situations where only unimodal data is available.

After the optimal classifier and source encoder for adversarial domain adaptation were trained for each cross-validation fold, the models' weights were fixed to evaluate the classifier performance on interaction-only data and to encode the multimodal data within the adversarial framework, respectively. The adversarial framework used a target encoder that is a feedforward neural network whose architecture and weights were pre-determined using the interaction-only baseline model. Although the source encoder and target encoder weights were not tied together as is common in other adversarial domain adaptation work [27], there was an imposed restriction that the latent dimensions be the same for both domains due to the fixed input size of the discriminator. The discriminator in the adversarial framework was a feedforward neural network with two layers of 64 nodes each. The learning rate of both the discriminator and the target encoder was 0.001, with a dropout rate of 0.05 in the last hidden layer and hyperbolic tangent activation functions. The loss functions for the discriminator and target encoder were based on binary cross-entropy as shown in Equations 1 and 2, respectively. The adversarial domain adaptation took place within each cross-validation fold to prevent data leakage from the test set.

To evaluate the predictive performance of the domain-adapted representations of the target data, the trained target encoder was used to encode the interaction-only data from the held-out test set within each cross-validation fold, and the encoded data was passed to the classifier model trained with the source data. The predictive performance of the classifier on this data was used to confirm that the use of multimodal data to train the classifier induces higher performance than if the facial expression data was removed from the dataset entirely. As an additional baseline, the target encoder trained on the interaction-only modality was used to pass the encoded data directly to the multimodal classifier without the domain adaptation procedure, following the source-only baseline approach of Tzeng et al. [42]. This illustrates that any improvement due to our method can be attributed to the adjusted weights through the adversarial adaptation process instead of just compressing the latent representation of the target domain data to the source domain's dimensionality. This specific baseline is called *target-only*.

6.4 Early Prediction

To quantify the models' ability to accurately predict a visitor's dwell time early and consistently, we utilize two metrics: *standardized convergence point* [30] and *convergence rate* [4]. The *standardized convergence point* calculates an average point of model convergence to the correct labels, while a particular visitor's sequence not converged to a correct prediction is penalized. This metric extends the conventional *convergence point* metric to account for sequences that are ultimately predicted incorrectly and fail to converge by instituting a penalty term [4]. In this instance, standardized convergence point is greater than one. In cases of convergence, a sequence's standardized convergence point falls within the range [0, 1]. Equation 3 displays the formula used to calculate the standardized convergence point across all sequences, where m is the number of sequences, and n_i is the number of data points in the i^{th} visitor's sequence. The value of k_i is the number of data points after which the model makes consistently accurate predictions, otherwise k_i equals n_i+p_i, where p_i is the penalty term for the i^{th} sequence [30]. (p_i is set to 1 for all sequences in this work following the original work.) A lower standardized convergence point indicates that the model's predictive accuracy tends to converge earlier in a visitor's interaction with the exhibit, indicating better early prediction performance.

$$Standardized\ convergence\ point = \sum_{i=1}^{m} \frac{\left(\frac{k_i}{n_i}\right)}{m} \qquad (3)$$

The second metric that we use to quantify a model's early prediction performance is the *convergence rate*. Convergence rate is the percentage of observed sequences in which the final prediction is accurate. Any sequence that contains an accurate dwell time prediction at the last data point is considered to have converged. Therefore, a higher convergence rate is indicative of better performance.

7. RESULTS AND DISCUSSION

The results for the unimodal and multimodal models as well as the unimodal latent representations (i.e., target-only encoding) and domain-adapted representations are shown in terms of early prediction and visitor-level predictive performance in Table 3. To measure visitor-level performance, a single point estimate of the predictive performance for each individual visitor is obtained by averaging across the predictions for all data points. The results for Table 3 are shown in terms of standardized convergence point (SCP) and convergence rate (CR) for early prediction, and area under curve (AUC), Cohen's Kappa, accuracy, and F1 score for visitor-level performance. Although AUC is commonly used for binary classification problems, we use this metric for a multi-class approach using a "one vs. rest" method which treats the correct class as the "positive" group and combines all other classes as a single "negative" group. The total AUC for a single model is calculated by using the unweighted mean of the AUC values across all three groups.

Based on the results in Table 3, the adversarial domain adaptation allows the multimodal classifier to outperform all baselines in terms of early prediction and across all sequences for each visitor. As expected, the complete multimodal model achieved the highest performance, achieving an AUC value of 0.660, while also outperforming the other models in all other evaluation metrics. The model achieved a standardized convergence point of 64.58%, indicating that the model achieved and maintained its optimal predictive performance approximately 64% into a visitor's total dwell time at the exhibit, while converging to the correct predictions more often than other baseline approaches. The interaction-only modality produced noticeably lower performance, achieving a convergence point of 75.95%, while also reaching a 0.574 AUC across all sequences. The adversarial domain adaptation allowed the classifier to achieve higher performance on the interaction-only data, with an early prediction performance of 67.42% and a visitor-level AUC of 0.585, similar to the full multimodal model while also outperforming the interaction-only baseline across all evaluation metrics.

The classifier's performance on the latent unimodal data (without domain adaptation) was notably poor, achieving an AUC that was slightly worse than random chance (0.500). This result is not surprising, as we are evaluating the model's performance using latent representations from a domain that has not been used to train the model beforehand. Although similar baseline approaches can achieve moderate performance in instances where the source and target domains are relatively similar, other work that investigates cross-modality adaptation or adaptation across dissimilar domains achieves much lower performance for this specific baseline [42].

While the adversarial domain adaptation proved more effective than the interaction-only and latent unimodal data baselines, the performance of our framework did not achieve the same performance as a framework that contained the full multimodal data. This could be attributed to the significant difference between the interaction and facial expression domains. The majority of the interaction-based modality is comprised of discrete, monotonically increasing features, which inherently are not as data-rich as the features from the facial expression modality. Because there are multiple features for each AU, this modality provides multifaceted perspectives on multiple AUs, leading to a relatively high number of continuous features. Adapting between two data channels with such a discrepancy in dimensionality may be a contributing factor to the framework's performance. Second, the relatively small number of visitors in the dataset may also be a contributing factor, as the performance of the models could be at risk for overfitting the classifier, source encoder, or target encoder. Contributing to this potential issue is the loss induced in the domain adaptation process. The size of the dataset may prevent the adversarial framework from reaching optimal convergence. Third, because there is no restriction regarding how long the visitors could remain at the exhibit, the target variable has a relatively wide range of values, approximately from one minute to more than ten minutes. Although this issue is addressed through the use of a tertile split, additional data could provide further evidence of behavioral patterns that are able to induce higher performance with more granular target variables.

Because timestamped interaction trace logs are the basis of one of the modalities used in this work, the design of the museum exhibit may play a role in the performance of the visitor models in terms of early prediction. During the early stages of FUTURE WORLDS, visitors are prompted to read an information dialog box explaining the premise of the game and a summary of the problem to be solved in the virtual environment. Because this event occurs at the beginning of every visitor's interaction sequence, it is likely that more indicative behaviors that allow the classifier to differentiate between groups occur at later stages of learner interactions with the exhibit. This is a potential explanation behind the early prediction performance of each model, as the standardized convergence point occurs after 60% of the overall exhibit interactions across all models.

To further investigate the impact that domain adaptation has on the predictive performance of the multimodal classifier, confusion matrices based on the target-only encoder and the adversarially-trained encoder are shown in Figure 6 as is the confusion matrix for the interaction-only classifier. The purpose of this analysis is to determine if adversarial domain adaptation results in any changes relative to the classifier's sensitivity to certain dwell time groups.

Table 3. Visitor-level predictive performance (all sequences)

	Early Prediction			Visitor-Level Prediction			
Encoding	Classifier	SCP	CR	AUC	Kappa	Accuracy	F1 Score
Interaction-Only	Unimodal	75.95%	34.18%	0.574	0.085	0.392	0.355
Multimodal	Multimodal	**64.58%**	**48.10%**	**0.660**	**0.278**	**0.519**	**0.511**
Target-Only	Multimodal	73.79%	34.18%	0.499	0.015	0.342	0.338
Domain Adaptation	Multimodal	**67.42%**	**43.04%**	**0.585**	**0.203**	**0.468**	**0.468**

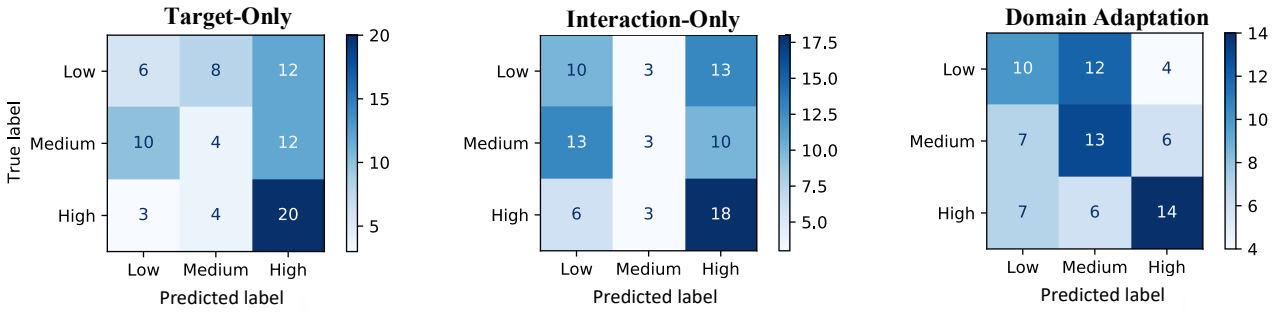

Figure 6. Confusion matrices for classifiers using target-only, interaction-only, and domain adaptation-based representations.

Based on the confusion matrix for the target-only classifier (i.e., the multimodal classifier evaluated on the interaction data without domain adaptation), the classifier appears to primarily predict high dwell times for a majority of visitors. The model also appears to frequently predict visitors with medium dwell time as having low dwell time. As this particular model performed similarly to a random chance classifier, it is likely that the interaction-only data representation was not easily identifiable to the classifier, leading it to primarily predict a single class and not classify the lower two groups accurately. The classifier that was trained and evaluated on interaction-only encodings performed slightly better and appears to become more accurate in cases of lower dwell time in visitors. However, it is notable that the model still does not appear to accurately predict instances of medium dwell time. This indicates that the interaction-based modality contains salient features indicative of noticeably low or high engagement but interactions from visitors with medium dwell time are not easily distinguishable to the model. Low dwell time may be characterized by a relatively low number of taps or interactions in the virtual environment, while high dwell time may be indicated by greater or more frequent tapping or interactions with the virtual environment. Additionally, visitors that have a higher dwell time are more likely to beat the game or read a higher number of information dialogs. However, this information may not be predictive enough with the ternary split, causing the interaction model to overfit to the two extremes.

The multimodal classifier that processes the modality-invariant data representations performs noticeably better for visitors with medium dwell time and continues to maintain fairly accurate performance on visitors with high dwell time. This may indicate that facial expression captures physical cues that allow the model to more easily distinguish between the medium group and the other groups, and the domain adaptation allows these features to be integrated into the interaction-only representations. By implementing this approach across the two modalities, it appears that the multimodal model retains its robustness to visitors with a medium dwell time in particular, while being able to achieve this performance using only features from the interaction data. This is significant because it appears that the interaction-only model does not appear to induce high performance on the medium dwell time visitors, so it remains important to utilize the multimodal data representations obtained through domain adaptation as pre-training for accurately predicting the visitor dwell time.

8. CONCLUSION

Modeling visitor engagement is an important task in museum-based learning. However, visitor engagement modeling presents significant challenges, as visitors' patterns of engagement with museum exhibits can vary widely. Multimodal frameworks show promise for the prediction of visitor engagement in museums because they capture information about visitor behavior that cannot otherwise be captured through interaction trace logs or similar unimodal data channels. Although multimodal sensor systems give rise to concerns about privacy, feasibility, and intrusiveness, the complete removal of sensor data from visitor engagement models may result in diminished predictive performance. To address this issue, we have introduced an adversarial domain adaptation approach to generating modality-invariant representations of interaction data and facial expression data from visitor interactions with the FUTURE WORLDS museum exhibit. The domain adaptation approach enables multimodal models to be induced in a pre-training phase while being deployed and evaluated with modality-invariant representations obtained using interaction-based data exclusively. We investigate the models' ability to predict visitor dwell time during the early stages of a visitor's interaction with the museum exhibit. Results indicate that the domain adaptation approach to modeling visitor engagement achieves higher performance than a visitor modeling approach using only a single modality. The domain adaptation approach also outperforms the unimodal baseline during early sequences of a visitor's interaction trajectory as well as across all sequences while demonstrating competitive performance compared to classifiers utilizing multimodal data.

There are several promising directions for future work. Alternative techniques for modeling visitor engagement should be evaluated, including sequential models like long short-term memory (LSTM) networks, to improve models' predictive accuracy and early prediction. Alternative approaches to the adversarial learning component of this framework include the use of generative models such as GANs or variational autoencoders. Attaining reliable training convergence continues to be a challenging problem within adversarial learning and investigating solutions to this issue may enhance the benefits of domain adaptation. The generalizability of the domain adaptation framework should be evaluated using larger and more diverse visitor populations on different exhibits and museum settings. Additionally, the domain adaptation framework should be evaluated using additional combinations of modalities (e.g., posture, gaze, speech), and extended to include three or more modalities simultaneously. Finally, this framework should be evaluated at run-time by integrating visitor engagement models into a museum exhibit to enable visitor-adaptive interventions to enrich visitor engagement and enhance museum-based learning experiences.

ABSTRACT

Knowledge Tracing (KT) is a task to model students' knowledge based on their coursework interactions within an Intelligent Tutoring System (ITS). Recently, Deep Neural Networks (DNN) showed superb performance over classical methods on multiple dataset benchmarks. While most Deep Learning based Knowledge Tracing (DLKT) models are optimized for general objective metrics such as accuracy or AUC on benchmark data, proper deployment of the service requires additional qualities. Moreover, the black-box nature of DNN models makes them particularly difficult to diagnose or improve when unexpected behaviors are encountered. In this context, we adopt the idea of black-box testing / behavioral testing from Software Engineering and (1) define desirable KT model behaviors to (2) propose a KT model analysis framework to diagnose the model's behavioral quality. We test-run the framework using three state-of-the-art DLKT models on seven datasets based on the proposed framework. The result highlights the impact of dataset size and model architecture upon the model's behavioral quality. The assessment results from the proposed framework can be used as an auxiliary measure of the model performance by itself, but can also be utilized in model improvements via data-augmentation, architecture design, and loss formulation.

Knowledge Tracing, Deep Learning, Behavioral Testing, Model Validation

1. INTRODUCTION

Assessment is a central task in Education, as it is involved in meta-cognition [17], tracing the skill trajectory, recommendation of contents [36], adjustment of tutoring strategy [14], and grading [3, 24, 33, 35]. With the advent of online educational platforms, there is an increasing demand in building assessment models using the interaction history data of users. One approach to track the skill of users is Knowledge Tracing (KT), which is the task to model students knowledge based on their coursework interactions within an Intelligent Tutoring System (ITS) [7].

To tackle the KT problem, the recent EdNet Challenge in Kaggle has gathered a total of 3,406 teams, 4,412 participants, to submit 64,678 models. Participants trained KT models on the EdNet KT dataset [6], and the models were evaluated by the Area Under the Receiver Operating Characteristic Curve (AUC). The AUC of the top 5 models were 0.820, 0.818, 0.818, 0.817, 0.817, which are very similar, and all models were based on the Transformer Neural Network structure [38]. While neural network structures are usually designed to appropriate human intuitions, most models lack interpretability compared to classical models. Therefore, when evaluation results for black-box models do not vary significantly, it becomes unclear how to choose the best model for deployment. Also, while small quantitative difference in the objective function or model AUC might not hurt the users' perception of the model reliability, few adversarial decisions of the black-box model can dissuade the user's faith. [34] also note that the performances of black-box models that are trained for general metrics such as classification accuracy or AUC(Area Under receiving operator characteristic Curve) can be overestimated.

As a result, Deep Learning based Knowledge Tracing (DLKT) models are not frequently implemented in the education community due to potential risks arising from the lack of model interpretability. In this study, we propose behavioral testing as an approach to alleviate this problem. The contribution of this work are summarized as follows:

- We propose a novel testing framework to validate DLKT models using a test on behaviors. The idea is to define consistent and convincing behaviors to be desired on DLKT models.
- As an example of applying the framework, we benchmark three state-of-the-art DLKT models from the

proposed validation framework. Positive results highlight the reliability of DLKT models and encourages the model's adoption, while negative results point out the limitations of DLKT models and show spaces for improvement.

- We introduce methods to utilize evaluations from the framework to design and improve DLKT models.

2. RELATED WORKS

2.1 Knowledge Tracing

Knowledge Tracing (KT) is the task to predict the expected correctness of an interaction of a student to a question by modeling the student's knowledge from past interactions [7]. In this study, we formulate the KT task as follows: the interaction sequence of a user is denoted as $X^u = \{x_1^u, x_2^u, \cdots, x_T^u\}$ where $u \in U$ is the user index. To simplify the notations, we omit the user index u unless specified. Each interaction $x_t = (q_{i_t}, c_t)$ at step t is defined by the pair of question $q_{i_t} \in Q$ and correctness $c_t \in \{0, 1\}$ where $Q = \{q_1, q_2, \cdots, q_n\}$ denotes the set of all questions and i_t denotes the question index of step t. A KT model predicts the correctness probability $P(c_t = 1 | x_1, x_2, \cdots, x_{t-1}, q_{i_t})$ of an unseen interaction X_t at step t, where $X_t = x_1, x_2, \cdots, x_t$ is the first t interactions of an interaction sequence X.

Notation	Description
$u \in U$	User index
X	Interaction sequence of a single user($= X^u$)
x_t	Interaction at time step t
$q_j \in Q$	Question
i_t	Question index at time step t
c_t	Correctness at time step t for question q_{i_t}
$c_t^{(q_j)}$	Correctness at time step t for question q_j
X_t	Interaction sequence of X up to time step t

Many KT models utilize domain specific tags such as skill components of questions [27, 8, 31, 43, 42], difficulty of questions [32, 10, 37], or knowledge graphs [4]. Item Response Theory (IRT) [32] models the correctness probability of a student responding to a question using custom designed models, and fits the model parameters using maximum likelihood. For instance, the 4-PL model predicts the correctness probability of a user with skill level θ solving item i by

$$p_i(\theta) = c_i + \frac{d_i - c_i}{1 + e^{-a_i(\theta - b_i)}},$$

where a_i, b_i, c_i, d_i are parameters that model discrimination, difficulty, pseudo-guessing, and slip of item i [23].

Another prominent approach is Bayesian Knowledge Tracing (BKT) [27, 42], which uses Markov process to model difficulty of the question items and learning capability of the students. Another well known approach is Deep Knowledge Tracing (DKT) [31], which is the first Deep Learning based KT model (DLKT). Since the introduction of DKT, many researchers have worked on different network structures to capture the complex aspects of the knowledge state. There are a variety of models based on different structures such as DKVMN [43], DKT+ [41], SKVMN [1], SAKT [30], GKT [28], EKT [21], KTM [39], DHKT [40], SAINT [5], AKT [13], and PEBG [22].

While there exist a variety of different KT models, [12] performed a major experiment on the accuracy of three groups of KT models (Markov process, Logistic Regression, Deep Learning) on nine real-world datasets. While deep learning models do show better AUC and RMSE on some datasets, other linear models including the authors' proposed BestLR approach yielded comparable or superior performances on most datasets, which also provided better model interpretability as well.

2.2 Behavioral Testing in Other Applications

To alleviate unexpected behaviors of black-box models, [2] introduces behavioral testing (also known as black-box testing) to test different capabilities of a system in the software engineering perspective. Many studies work on effectively designing test cases [18, 25, 26]. [29] gives a detailed review on the behavioral testing method applied in various software testing domains. In Natural Language Processing, [34] apply the behavioral testing framework to validate the behaviors of general NLP models. They introduce *CheckList*, which is a task agnostic methodology for testing NLP models. *CheckList* is a list of general linguistic capabilities and test type baselines for NLP tasks. It is also a software tool to generate test cases for NLP models.

2.3 Behavioral Studies in Knowledge Tracing

The expected behaviors of the KT models have been discussed in some studies, which point out the adversarial behaviors of KT models and propose new models to alleviate the problem. DKT+ [41] raises two problems of the Deep Knowledge Tracing (DKT) model [31], which are increasing correctness probabilities from false responses, and wavy prediction transition by time. However, these behaviors can naturally occur from the educational effects embedded in the interaction, which we discuss in detail in Section 3.1. The authors add three regularization terms in DKT+ to enhance the consistency of the predictions of DKT, and introduce extra performance measures.

The authors of [19] lists some desirable behaviors based on the monotonicity of the KT models to improve the general ability of the models. Then, they perform three types of novel data augmentation techniques(replacement, insertion, and deletion) and apply them to the training of KT models.

As examined in these relevant studies, the adversarial behaviors and low interpretability of DL models hinders the AIEd society to adopt Deep Learning based KT (DLKT) models and sustain on adopting interpretable models based on BKT, IRT, or Cognitive Diagnosis Models [9]. In this study, we provide a validation framework of DLKT models and conduct an extensive set of experiments on the desired behaviors of DLKT models. Good results highlight the reliability of DLKT models and encourages the model's adoption on most datsets. On the other hand, bad results point out the limitations of DLKT models on some datasets and show spaces for improvement.

3. BEHAVIORAL TESTING FOR KNOWLEDGE TRACING

We propose a black-box behavioral testing framework for knowledge tracing task. First we define the knowledge state (KS), and then elaborate on desirable behaviors of KT models' KS representation. Finally, in Subsection 3.2, we introduce specific experiment setups to assess whether DLKT models satisfy those behaviors.

We define the ***knowledge state*** to be a vector representation of a user's correctness probability on a set of questions Q' at a specific time point. Given the first t interactions $X_t = x_1, x_2, \cdots, x_t$ of a user, we define the user's knowledge state as:

$$KS_t = \left[P(c_t^{(q_j)} = 1 | X_{t-1}, q_j)\right]_{q_j \in Q'} \quad (1)$$

$c_t^{(q_j)}$ represents the Bernoulli indicator for the event when the user answers correctly to question q_j at time step t, as defined in Table in Section 2.1, which is updated along the provision of the user interaction sequence. Note that a KS is the collection of prediction values of questions, which either is responded or not. We describe the desired aspects of DLKT models in the following section.

3.1 Expected Behaviors of Traced Knowledge State

First we introduce two properties on the ***change*** ΔKS of the knowledge state KS with respect to an atomic change ΔX of the interaction sequence X, which is an insertion or a deletion of single interaction record.

First, **monotonicity** insists that the model's knowledge state should be updated to a more knowledgeable state when the student adds another correctly answered question (positive interaction) or when an interaction record with incorrect response (negative interaction) of the student is deleted. If the Δ is applied in the middle of the interaction record, all changes after the perturbation should hold the property as well. Second, **robustness** insists that a little perturbation in the interaction history should not yield a dramatic change in future knowledge states. The details of the two properties are introduced below.

- **Monotonicity**: If ΔX is a correctly responded interaction $(q_{i_{t_p}}, \mathbf{1})$ at perturbation time t_p, then we can track the relation of $P(c_t^{(q_j)} = 1 | X \cup \Delta X, q_j)$ and $P(c_t^{(q_j)} = 1 | X, q_j)$ depending on how q_j and ΔX are correlated. In many cases, a positive correlation in correctness probabilities is desired due to the relation of knowledge states:

  $$P(c_t^{(q_j)} = 1 | X \cup \Delta X, q_j) > P(c_t^{(q_j)} = 1 | X, q_j)$$

  for $t > t_p$ and $q_j \in Q$.

  However, there can also be negatively correlated questions which could be consequences of factors such as limited learning resource. For instance, a college student might sacrifice her studying time on one subject over another when both subjects' examinations are scheduled too closely with each other. This type of circumstance might cause the model to fit a non-monotonic relationship between the two fundamentally unrelated subjects. In most ITS's, however, the target study domain is usually restricted to a single subject, or a set of knowledge components where the student's comprehension on the components is usually positively correlated. Another case is when a negative response increases the correctness probability of a problem as described as an adversarial behavior in [41]. However, the educational effect of consuming a question can give positive feedback on the knowledge state even if the interaction response was wrong. Therefore, we assume the described monotonic behavior in general knowledge tracing environments while simultaneously keeping track of the opposite case in the experiments of Section 4.

- **Robustness**: For any black-box system, it is generally desirable that insignificant change in the system's input leads to limited change in the output. For a knowledge tracing model in an ITS, the input refers to the student's interaction record and the output refers to the model prediction on correctness probability for an encountered question or a set of questions. Therefore, we formulate the robustness of knowledge tracing model as below in a general sense, adopting the ΔX previously defined:

  $$|P(c_t^{(q_j)} = 1 | X \cup \Delta X, q_j) - P(c_t^{(q_j)} = 1 | X, q_j)| < \epsilon_t$$

  for some ϵ_t, a single interaction ΔX, $t > t_p$, and $q_j \in Q$. If we impose the inequality to always hold on $t = t_p + 1$ and fixed ϵ_1, then it is equivalent to imposing **continuity** on the knowledge state in terms of time-steps. We treat continuity as a specific case of **robustness** and introduce customized test for continuity separately from the test for robustness.

  However, consider a case when q_j and $q_{i_{t_p}}$ in ΔX assess similar concepts, or when the educational effect from the interaction with one question affects the student's correctness probability on the other question. Then an insertion or deletion of one question is prone to have a significant impact upon the predicted correctness probability value of the other for $t > t_p$. Therefore, the defined robustness / continuity need not be universally desirable for all pairs of questions. The impact of this property would eventually depend on the degree of dependency among the questions. Therefore, in the experiments, while assuming robustness for most question pairs, we also carefully track where some questions affect the prediction values of other questions in a notable amount.

Next we discuss what constitutes an expected ***value*** of knowledge state. Testing whether the knowledge state has accurately captured the user's interaction history is in line with the existing quantitative metrics (AUC, ACC) adopted in KT literature. However, the existing test methods focus only on a **single actual question** data provided per each time step whereas we propose to assess knowledge tracing model via its knowledge state on a **virtual question set** in order to provide a more holistic assessment via knowledge state representation.

Although tracing knowledge state on a set of questions would provide a more comprehensive picture of how the user's knowledge is traced, it lacks actual label of correctness on unseen questions at each time step, as discussed in Section 3.1. Therefore, we describe below novel measures to assess correctness of knowledge state under a few purposefully designed circumstances.

- Approximate Label of User-Independent **Initial Knowledge State**: At first prediction step, we approximate correctness label for *all* questions via their 'global difficulty'. The initial knowledge state for all users should represent the model's prior belief of question difficulty before encountering any user-specific interaction record data. It is reasonable to assess the quality of this value in terms of correlation of model's prediction on each question and the question's global difficulty. However, this is an approximation at best since the question's difficulty might not be accurately captured by simple average over its occurrences. If the actual interaction data generated from the ITS provides a very difficult question only after user's knowledge is significantly accumulated, simple average of question correctness labels would not be representative of the question's inherent difficulty. Model's prediction would be high.
- Ideal Value of Knowledge State after **Converged Interaction Data**: We generate obvious edge-case test cases where user's knowledge state on a set of question has converged to a value. We create this virtual dataset by simply repeating an identical interaction record on each question consecutively. The model's prediction value for the question in the repeated interaction should converge to the repeatedly provided label value.
- Approximate Label of Knowledge State in General: It's also possible to approximate a pseudo-label for unseen questions using rolling/expanding averages or IRT-like algorithms which demonstrate more stable and monotonic behavior by design. Although we conjecture such training methodology of DLKT models using pseudo-labels might provide regularization effect, we do *not* include this case in the scope of this work.

Table 1: Behavioral Test Summary

Behavior	Analysis Method
Monotonicity	**Perturbation Test**: Percentage of interaction samples of which model prediction changed in expected direction.
Robustness	**Perturbation Test**: Degree of impact from perturbation across time-steps.
Continuity	**Continuity Test**: Avgerage and maximum change in knowledge state score per step and throughout entire sequence.
Initial Value	**Initial Value Test**: Correlation between question correctness rate and initial knowledge state.
Convergence	**Convergence Test**: Convergence speed as in model AUC and average model output at different time-steps.

3.2 Behavioral Test Setups

Below we describe four behavioral testing setups for DLKT models. First, perturbation tests aim to test model's monotonicity and robustness given an atomic perturbation to the original interaction sequence data. Second, continuity test aims to check whether model's knowledge state representation is continuous along the interaction sequence. Third, initial knowledge state test checks whether the initial knowledge state reflects each question's corresponding difficulty measure. Fourth, convergence test checks whether the knowledge state converges to the expected value and how fast it converges. Following subsections elaborate each of the test setup in further detail. Table 1 provides summary of the tests.

3.2.1 Perturbation Tests

We examine monotonicity and robustness of the model by perturbation tests. We experiment three types of perturbations: insertion, deletion, and flip. For each original interaction sequence, we determine t_p, which is the index of interaction to be perturbed. For the insertion case, we add a new interaction between x_{t_p-1} and x_{t_p}. For the deletion case, we remove the interaction x_{t_p}. For the flip case, we flip the correctness of x_{t_p} from 1 to 0 and from 1 to 0.

In order to check monotonicity, we assess whether the model's predicted correctness probability in the following interaction sequence $X_{[t_p:]}$ changes towards the expected direction. For insertion / deletion / flip of an interaction to which user responded correctly, we examine whether the following future correctness probability $P(c_{t'+1} = 1|X_{t'})$, $\forall t' > t_p$ increases / decreases / decreases, respectively. In the experiments, we fix the perturbation point to be located halfway in the user's original interaction sequence, then measure the proportion of interactions which the model's predicted correctness probability changes towards the expected direction.

To assess the model's robustness, we visualize how the degree of impact from perturbation changes along the time steps from t_p. We expect the degree of impact from perturbation upon the model's prediction to decay gradually as more interactions are fed into the model after the perturbation point t_p.

3.2.2 Continuity Test

We test whether the knowledge state is continuous, in the manner described in the previous section 3.1. For every time-step, we provide the model with not only the original interaction at the corresponding time-step, but also a set of questions Q' simultaneously to construct knowledge state KS_t at the time-step. Although we don't have actual correctness label for those virtual interactions, we only inquire how the knowledge state or the model prediction on Q' evolves along the time-steps.

In the experiments, we approximate a **score** on the user's knowledge state by averaging the model-predicted correctness probability over the sample set of questions Q' to report: (1) average and maximum student score change per single time-step and (2) average student score change and range across 100 time-steps.

3.2.3 Initial Knowledge State Test

Table 2: Dataset Statistics

Dataset	Users	Items	Skills	#Intr.	%Crct.
ASSIST15	14228	100	100	656K	73
ASSIST17	1708	3162	411	935K	37
STATICS	282	1223	98	189K	77
Spanish	182	409	221	579K	77
EdNet-small	5000	13156	118	518K	65
EdNet-med	100000	13518	118	11M	64
EdNet	605763	13528	118	138M	66

We assess the quality of the prior knowledge state embedded by the model by the initial knowledge state test. Without any user-specific record, the prior knowledge state embedded in the model should accurately reflect the average difficulty of the question to all users. Thus, we check Spearman rank correlation and Pearson correlation between the question's average difficulty and the model-predicted prior belief for each question.

In detail, a trained DLKT model M's initial knowledge state for a question q_j can be represented as $P_M(c = 1|\cdot, q_j)$. We compare this with the question correctness rate over the entire dataset as in Eq 2 which is equivalent to the number of correctly responded q_j-interactions over the number of occurrences of q_j based on all user data.

$$\mathrm{gc}_{q_j} = \frac{\sum_{u \in U} |\{x_t^{(u)} | q_{i_t} = q_j, c_t = 1\}|}{\sum_{u \in U} |\{x_t^{(u)} | q_{i_t} = q_j\}|} \tag{2}$$

Consequently, we measure:

$$Corr\Big(\big[P_M(c = 1|\cdot, q_j)\big]_{q_j \in Q} \ , \ \big[\mathrm{gc}_{q_j}\big]_{q_j \in Q} \Big) \tag{3}$$

This initial knowledge state test pinpoints on whether the learned question embedding in the DLKT model alone has captured any information about the corresponding question's difficulty. Moreover, we emphasize the importance of the initial knowledge state since the state assumed by the model would likely affect the user's first impression on the system to make decisions.

3.2.4 Convergence Test

In convergence test, we assess whether the model's knowledge state value converges to a target value in a desired manner. We generate simple virtual interaction sequence data by repeating an identical interaction for 50 time-steps for each question for both correctness cases. Therefore, the virtual dataset would consist of virtual user interaction sequences of size twice of the number of questions.

In the experiments, we report the model's standard AUC metric at time-steps 5, 10, and 50. We expect significantly high figures as the inquired interaction sequence is extremely simple. We also visualize how the average model prediction value across the questions evolves throughout the 50 time-steps for each of the correctness case. We expect the values to quickly converge to 1 / 0 for interaction sequences of which correctness label is all correct / incorrect, respectively.

4. EXPERIMENTS

In this section, we benchmark three Deep Learning based Knowledge Tracing models DKT, SAKT, and SAINT on the proposed behavioral tests. First, we train optimized models for each architecture-dataset pair by searching hyper-parameters on the train and validation data split. Second, we report the classification accuracy and the AUC metric, which are commonly used for model assessments in the Knowledge Tracing literature. Third, we present the proposed behavioral test results of model instances on well-known datasets for Knowledge Tracing.

4.1 Datasets

We describe the datasets used in our experiments. All datasets are open to the public.

ASSISTments[11] is a dataset containing student interactions from an online tutoring system for solving Massachusetts Comprehensive Assessment System (MCAS) 8th Math test questions. We use the datasets ASSISTments 2015 (**Assistments15**) and ASSISTments Challenge 2017 (**Assistments17**).

STATICS is a dataset containing college student interactions on a one-semester Statics course. This dataset is available in the PSLC DataShop web site [16].

Spanish[20] is a dataset containing middle-school student interaction data for Spanish exercises.

EdNet[6] is the largest public benchmark education dataset containing user interaction data of an online tutoring system, for preparing TOEIC (Test of English for International Communication®). For ablation studies on the size of the dataset, we randomly choose 100,000 users for **EdNet-medium**, and 5,000 users for **EdNet-small**.

Table 3: Model Hyper-parameters

Model	Parameter	Tuning Details
Common	Adam learning rate	0.001, 0.003, 0.01
	Dropout rate	0, 0.25, 0.5
	Embedding dimension	64, 128, 256
	Maximum Seq.Length	100, 200, 400
DKT	# Recurrent Layers	1, 2, 4
SAKT	# Attention Layers	1, 2, 4
SAINT	Warm-up Steps	200, 400, 4000
	# Attention Head	1,4,8

4.2 Models and Algorithms

We perform hyper-parameter tuning on the training of models. For each configuration of hyper-parameters, we choose the model weights with the best validation AUC. In the training step, an early-stopping policy is applied with patience 30, which means that we stop the training process and save the best weights if there is no AUC improvement in the recent 30 validation steps. Among the best weights for each configuration, we choose the weight with the best validation AUC for each dataset, and evaluate the weights with an independent test set for test metrics.

4.2.1 Training Details

In this study, we use DKT, SAKT, SAINT in the experiments . DKT models the student's knowledge state using a Recurrent Neural Network (RNN) by compressing the interaction history in a hidden layer. SAKT is the first KT model that used self-attention layers, where in each layer the question embeddings are queries and interactions embeddings are key and values. SAINT is the first KT model based on Transformers. The sequence of questions is fed into the encoder, and the sequence of responses are fed into the decoder with the encoder output.

Our model hyper-parameters are shown in Table 3. We use the Adam optimizer [15] with default parameters. For SAKT and SAINT, we used the Noam scheme for scheduling the learning rate, and tune the number of warmup-steps.

The original SAKT implementation does not include residual connection from the query. This enforces the first prediction to a same number every time, regardless of the first question provided to the model. Since 3.2.3 becomes redundant, we use the modified SAKT architecture with residual connection. For SAINT and SAKT, the dimension of the feedforward network is set to 4×(model dimension). For SAINT, we use the same number of attention layers for the encoder and the decoder.

4.3 Results: Traditional Assessment

AUC and accuracy results are shown in Tables 4 and 5. The difference of these standard metrics is generally less than 0.01. For KT-based tutoring systems, this difference would be less important than behavioral performance. AUC shows the monotonicity of interactions by all users, and accuracy does not focus on the exact model prediction. On the other hand, behavioral tests can check the performance of model prediction for a single user, and analyze the impact of a single interaction.

Table 4: Standard AUC metric

4.4 Results: Behavioral Testing

4.4.1 Perturbation Tests

We report the test pass rate for insertion, deletion, and flip. The results are shown in Table 6, 7, and 8, respectively. Figure 1 describes the average impact on model prediction from insertion perturbation on each dataset (column) and correctness label of the inserted interaction (row). Figure 2 describes the degree of maximum impact over user sequences from insertion perturbation.

Table 6: Insertion Test Pass Rates(%)

Model	DKT	SAKT	SAINT

Assistments17	69.5	86.1	66.4
STATICS	93.4	92.9	84.7
Spanish	87.5	89.1	83.9
EdNet-small	75.2	95.0	95.8
EdNet-medium	87.8	94.8	95.5
EdNet	79.5	83.6	86.0
Average	81.4	91.1	86.7

- In general, deletion and insertion pass rates range from 60% to 80%, and flip pass rates range from 80% to 90%. Note that a flip can be interpreted as a combination of deletion and insertion. Therefore, the impact of perturbation is supposed to be larger, leading to higher pass rates as compared to insertion/deletion cases. From Figure 1, Figure 6 (Appendix), and Figure 7 (Appendix), we note that the degree of impact from replacement is twice of that from insertion or deletion.
- Robustness: From Figure 1, we observe that the degree of average impact from perturbation gradually decreases along the time-steps in general, and that the average impact is limited by only about 2%. Therefore, the desired robustness holds in terms of average impact.
- Monotonicity: From Figure 1, the average impact from positive/negative perturbation tends to remain posi-

Figure 1: Perturbation Test: Average Impact on Model Prediction from Insertion.

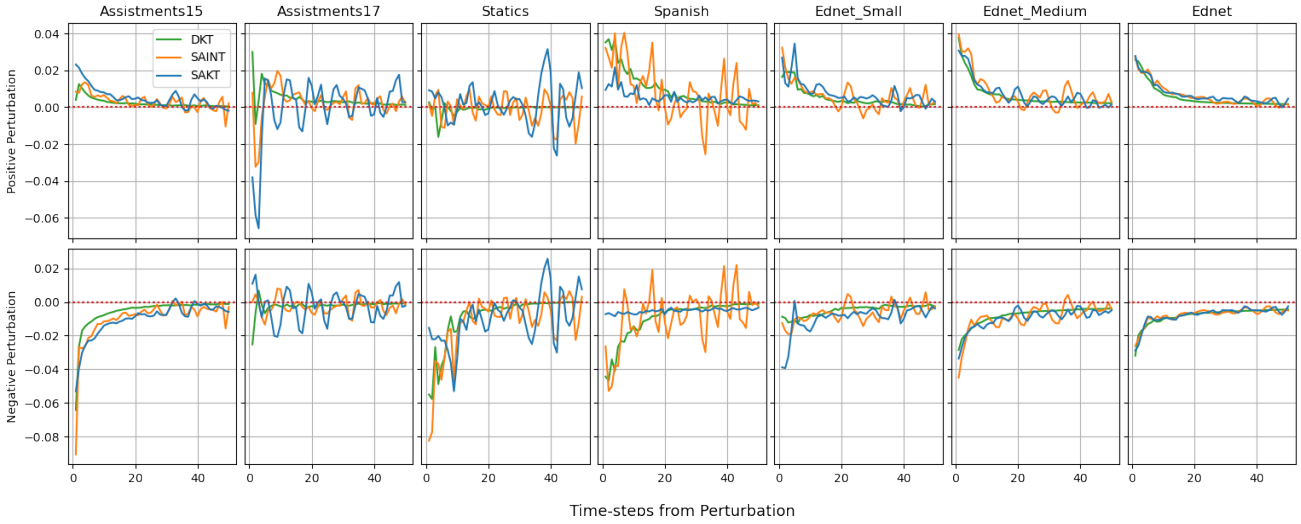

Figure 2: Perturbation Test: Maximum Degree of Impact on Model Prediction from Insertion.

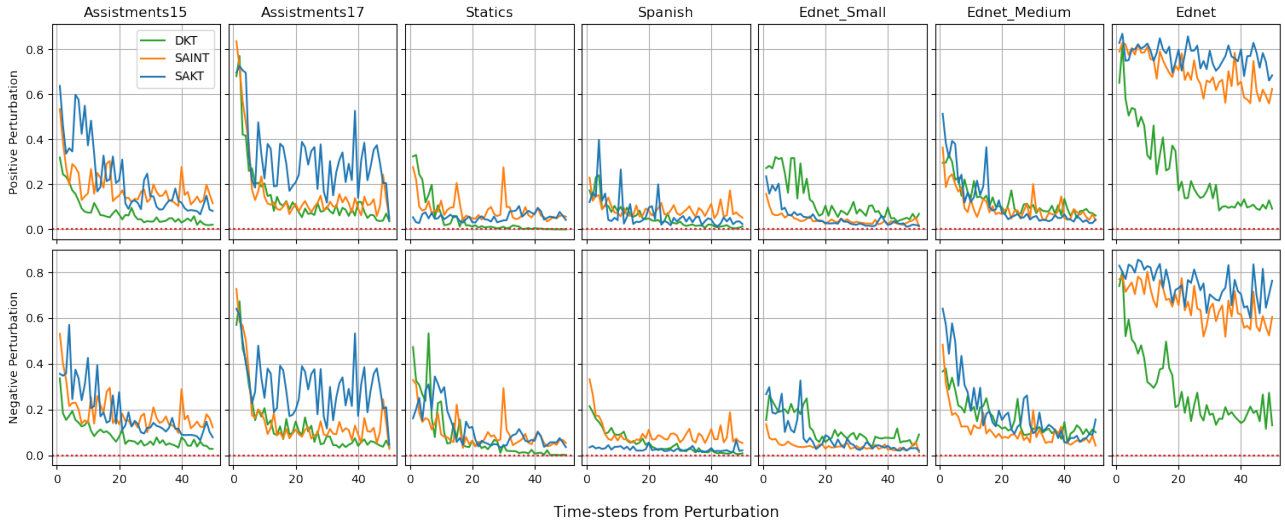

tive/negative, respectively, for Assistments15, EdNet-small, EdNet-medium, and EdNet datasets. On Spanish dataset, such trend is more noisy for SAINT network.

- On Assistments17 and Statics dataset, the expected monotonic behavior from SAKT and SAINT is not observed as the average impact oscillates across zero. This can be also seen from DKT's significantly higher pass rates on the two datasets in Table 6.
- From Figure 2, we note that there exists questions which persist to respond in a larger degree (even up to 80%) after 40 time-steps. Note that on the EdNet dataset, both transformer-based architectures SAKT and SAINT allow larger impacts from perturbations than DKT. This can be explained by the superior performance of the two models on EdNet data over DKT in terms of standard evaluation metrics AUC and ACC.

4.4.2 Continuity Test

We report average and maximum step-wise change in KS score over students in Table 9. Apart from the single-step change, we also measure final change of score from the first time-step to the last, and the total range of score explored throughout the time-steps, averaged over all students in Table 10. Sum of absolute change in KS coordinates, or Manhattan distance of KS's along time-steps (averaged over all students) is shown in Figure 3. EdNet-medium was omitted due to its similarity with the plot from EdNet-small.

- Except for Assistments17 and Statics, average score change per single time-step or an interaction remains reasonably low below 5% for all architectures. This suggests that the knowledge state is fairly stable across the time-steps.
- On Assistments17 and Statics, we observe significantly larger changes, especially in DKT. DKT's maximum

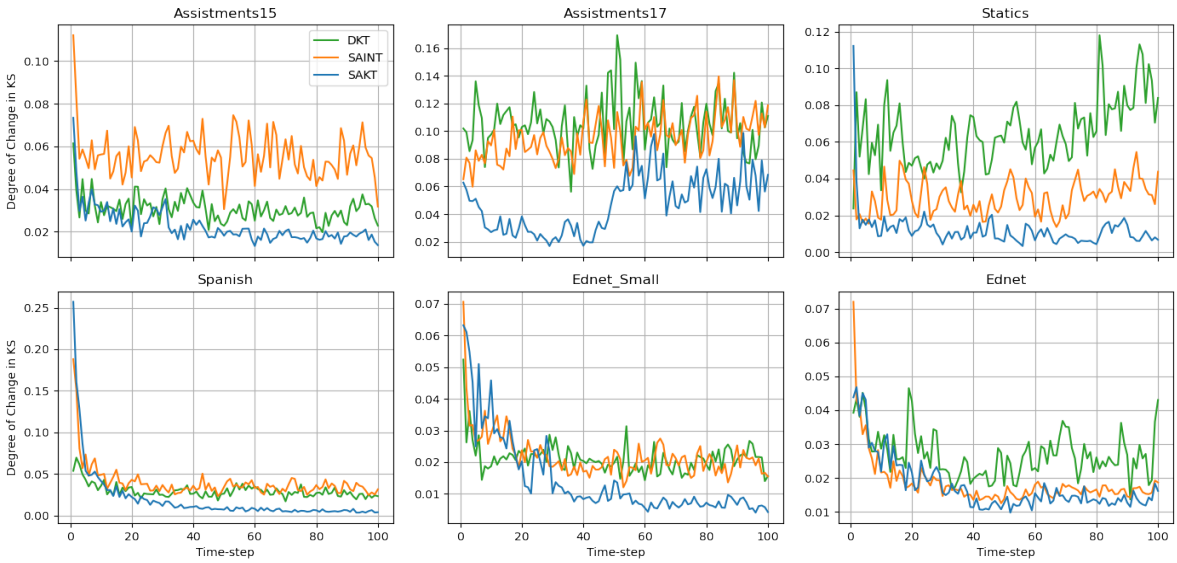

Figure 3: Continuity Test: Average Change in KS along Time-steps

Model		Assist15	Assist17	STATICS	Spanish	EdNet-small	EdNet-med	EdNet	Average
DKT	Diff	10.14	11.50	9.94	18.30	9.23	12.82	10.83	11.82
	Range	24.72	63.42	47.54	46.54	22.89	27.41	28.37	37.27
SAKT	Diff	15.96	13.97	15.67	18.36	10.48	13.00	8.95	13.77
	Range	30.98	40.16	22.08	53.33	23.70	23.80	20.69	30.68
SAINT	Diff	13.34	11.62	6.97	20.53	11.32	5.30	9.01	11.15
	Range	37.98	49.96	26.19	51.51	22.98	24.21	20.59	33.35

score change across a single time-step is as high as 85% and 65% for Assistments17 and Statics, respectively.

- In general, we observe decreasing marginal impact of each interaction data as time proceeds.
- From Figure 3 and Table 9, we note that SAKT's knowledge state changes significantly less than other models, consistently throughout all datasets. We also investigated whether this 'speed' of change affects total 'dislocation' of knowledge state in Table 10. Interestingly, SAKT's knowledge state moved by farthest on average (13.77%) while its range explored was the smallest (30.68%) on average. This suggests that SAKT's knowledge state evolution was least volatile.

4.4.3 *Initial Knowledge State Test*

To assess the validity of initial knowledge states embedded in the model, we measured the correlation of the predicted prior knowledge state and the global question difficulty as described in Section 3.2.3. The results are presented in Table 11. In the scatter plot of Figure 4, we choose the 200 most frequently answered questions from each data-set to show how the initial model predictions and question correctness rates are distributed and correlated.

- We observe from Table 11 that all models' initial knowledge states are positively correlated with the global question difficulty with statistical significance.
- The difference in correlation metrics among datasets is much more significant than that among models.
- Based on the three scatter plots of the first row in the figure, we note that the correlation becomes stronger as the size of dataset grows from EdNet_Small to full EdNet data. Table 11 and Table 2 also suggests that the number of interactions per unique question is positively correlated with the initial knowledge state test metric.

- From the scatter plot, we see that the three models occupy slightly different clustering regions in the plot. For instance, in EdNet_Medium and EdNet dataset, SAINT's initial prediction value is consistently larger than that of the other two models, which suggests ensemble of the models to reduce bias.

Table 11: Initial Knowledege State Test: Correlation(%)

Model	DKT	SAKT	SAINT
Assistments15	85.6	84.8	82.5
Assistments17	63.2	52.2	58.2
STATICS	56.1	58.1	54.6
Spanish	56.5	49.1	44.0
EdNet-small	39.0	38.5	31.6
EdNet-medium	75.1	74.2	74.4
EdNet	87.6	86.5	88.2
Average	66.1	63.3	61.9

4.4.4 Convergence Test

As the dataset we generate and use for the convergence test is extremely simple as described in Section 3.2.4, we expect the KT models' standard performance metrics to increase quickly along the time-steps. For instance, at the fifth time-step, the model would have already received four equivalent interaction record with the same question and the same correctness label for the virtual student. We report the model AUC at time-step 5, 10, and 50 in Table 12. In Figure 3 we also visualize the model's average response across different questions for each correctness label values assumed. We expect the average response plot to quickly converge to either 1 or 0 based on the assumed correctness label value.

- In general, all models show fairly high performance from early time-step of 5, except for Assistments17 dataset.
- Both Table 12 and Figure 5 suggest SAKT consistently achieves fastest convergence to a reasonable value close enough to either 1 or 0. DKT, however, consistently converges to a value farther from the two edges, as compared to the other two models. In particular, for the incorrect case (second row) of the Figure 5, we observe DKT converges to a value higher than 50% (red dotted horizontal line). For the positive case (first row), DKT converges to a correctness probability level around only 70% for Assitments17, EdNet-small, and EdNet-medium.
- DKT's convergence pattern is fairly monotonic while SAKT and SAINT's patterns go through fluctuation which likely pertains to noise.
- It is noteworthy that increasing dataset size from EdNet-small to EdNet-medium and EdNet significantly helps all three models' convergence behavior on both target correctness values, especially for DKT. DKT's convergence value moved signficantly closer to desired values of 1 and 0. For SAKT and SAINT, larger dataset size led to more stable response plot, reducing the degree fluctuation.
- Convergence in the incorrect case and the correct case is asymmetric. While the latter closely achieves the target value of 1, the former case converges around 30% level in most datasets. We attribute this to the tutorial content embedded in each of the interaction, along with the question item used for assessment in the dataset.

4.5 Overview of Experimental Results

Based on the proposed DLKT validation framework, we conducted a comprehensive investigation of three popular DLKT models on seven benchmark datasets to scrutinize the models' behavioral characteristics. The results highlight strengths and weaknesses of three DLKT models. Although DLKT models demonstrated stable and robust behaviors in line with expectation in most datasets, the results revealed few major disadvantages for each models: DKT showed better stability in perturbation tests while the other architectures occasionally presented volatile fluctuation in the response curve. In the continuity test, SAKT presented a significantly smoother evolution of knowledge state, but other models' knowledge state representations were seemingly volatile in a few datasets which strongly precludes DLKT's adoption. On the other hand, this suggests room for improving DLKT models based on the specific issue pinpointed by this framework. For instance, the volatility of KS could be alleviated by direct regularization of the change in the KS. On the other hand, the results from the convergence test showed that DKT was fragile even to simple edge-case data which undermines generalization capability of DKT, as compared to other attention-based architectures.

These behavioral characteristics identified from the proposed framework show that the two popular architectural paradigms, RNN and Attention-based, possess different strengths and weaknesses under KT environment. This also hints that an architectural combination or ensemble approach might alleviate the identified issues to improve both standard KT model evaluation metrics and behavioral characteristic.

5. CONCLUSION

In this work, we introduced the desired properties of knowledge tracing models and proposed a novel model validation framework for Deep Learning based Knowledge Tracing (DLKT) models. Using the framework, we conducted a comprehensive analysis of three popular DLKT models' behavioral characteristics and identify their strengths and weaknesses of the models in seven different benchmark datasets. We believe that the analysis on both strengths and weaknesses diagnosed by the framework would serve as a useful guideline for model enhancement. Also based on the findings from the proposed framework, a customized adoption of DLKT models fitting to the nature of the data and desired behaviors as well as accuracy would become possible.

We believe potential future work includes: (1) tackling the weaknesses of DLKT models identified in this work via architectural modification or model combination, (2) exploring the benefit of data augmentation using virtual edge-case data similar to converging interaction data used in the convergence test, and (3) extending the proposed testing framework beyond the task of knowledge tracing (i.e. student score prediction and item recommendation).

ABSTRACT

Predicting student problem-solving strategies is a complex problem but one that can significantly impact automated instruction systems since they can adapt or personalize the system to suit the learner. While for small datasets, learning experts may be able to manually analyze data to infer student strategies, for large datasets, this approach is infeasible. We develop a Machine Learning model to predict strategies from student data. While Deep Neural Network (DNN) based methods such as LSTMs can be applied for this task, they often have long convergence times for large datasets and like several other DNN-based methods have the inherent problem of overfitting the data. To address these issues, we develop a Neuro-symbolic approach for strategy prediction, namely a model that combines strengths of symbolic AI (that can encode domain knowledge) with DNNs. Specifically, we encode relationships in the data using Markov Logic and use symmetries among these relationships to train an LSTM more efficiently. In particular, we use an importance sampling approach where we sample the training data such that for clusters/groups of symmetrical instances (instances where the strategies are likely to be symmetric), we only pick representative samples for training the model instead of using the whole group. Further, since some groups may contain more diverse strategies than the others, we adapt the importance weights based on previously observed samples. Through empirical evaluation on the KDD EDM challenge datasets, we show the scalability of our approach.

Keywords

Intelligent Tutoring Systems, Learning Strategies, Neuro-Symbolic AI, Markov Logic Networks, LSTMs

1. INTRODUCTION

Intelligent Tutoring Systems (ITSs) [31] and more broadly adaptive instructional systems (AISs)[1] help a diverse population of students by adapting instruction to each learner thus accounting for different learning abilities, learning styles and education goals. Such adaptation leads to more engaging and effective learning. However, in order to build effective ITSs, it is important to understand how students learn and what learning and instructional strategies are most effective for whom and under what conditions. Specifically, students can follow several different *strategies* to learn the same content. For example, consider a simple math problem about solving a linear system of equations where $x+y+z = 9$ $x = y$ and $y = z$. One strategy is to perform systematic substitutions till there is an equation in terms of one variable and simply solve for that variable. However, another strategy could be to use transitivity to see that all three variables have the same value and use this to solve the problem. Depending upon the way a student thinks, one strategy could be easier or harder to grasp compared to the other. Thus, understanding the various ways in which students approach an instructional task will not only further our understanding of how learners learn, e.g., it may help identify the most effective learning strategies employed by top performers, but it will also enable ITSs to incorporate knowledge about these strategies in order to adapt appropriately and help students maximize their learning gains.

A student's choice of strategy is a complex function dependent on many factors such as experience with similar problems, general expertise in the topic, other cognitive abilities, etc. Human experts are exploring all these factors and how they are related to strategy use and learning. However, human experts are expensive and limited in the ability to analyze large data from thousands, tens of thousands, or millions of students. Advanced data science methods and access to large computing infrastructure such as the cloud offer new possibilities to analyze in-depth and at scale such large learner datasets with the promise of helping us discover, document, and benefit from the diversity of learning.

Indeed, with the growth of both data and advanced Machine Learning methods such as Deep Neural Networks (DNNs), we are able to successfully solve several challenging problems in domains such as natural language understanding [25] and visual processing [8]. However, the ability of DNNs to learn complex functions and representations comes at a cost. Specifically, DNNs require significant computational

[1]The main difference between Intelligent Tutoring Systems and Adaptive Instructional Systems at least in our view is that the former offer full-adaptivity, i.e., both micro- and macro-adaptivity, whereas the latter can offer any type, e.g., just macro-adaptivity.

resources to scale up to large datasets and at the same time, as data increases, they may not always yield expected results since they have a tendency to *overfit* the data. That is, they work well on the data on which they were trained but their generalization performance on unseen data severely degrades. A paradigm that is gaining significant attention in the AI/Machine Learning research community is Neuro-symbolic AI [7] where we augment DNNs with symbolic models to regularize the DNN. This helps in improving both scalability and generalization by allowing DNNs to learn from smaller datasets with higher accuracy. In this paper, we apply a Neuro-symbolic model to predict student strategies from structured student-interaction data.

Our model works on student data where the student interacts with an ITS in discrete steps. The strategy prediction task in this case can be formulated as a sequence learning problem where we want to learn to predict the sequence of steps a student is likely to follow for a given problem. Knowing this sequence will provide the ITS prior information that it can use to adapt, e.g., by better tailoring the available hints and feedback. Sequence learning is applicable to many tasks in general with one of the most popular applications being machine translation where the goal is to translate a sequence of words from one language to another language. A widely used traditional approach that has been applied in sequence learning is Hidden Markov Models (HMMs). However, this assumes a one-step dependency where each step depends only upon the prior step. Student strategies in problem solving though are much more complex where a student action in one step can influence several downstream steps. Long Short-Term Memory (LSTMs) [11] are DNNs that can model such long-term dependencies in sequences. However, LSTMs are known to take an extremely long time to train for large datasets [39]. To address this, we propose a Neuro-symbolic model where we combine the semantics of a symbolic AI model called Markov Logic [9] with LSTMs. Markov Logic encodes domain-knowledge using first-order logic formulas. The formulas establish relationships in the data that can be described in the form of a graph structure. Our approach learns symmetries between instances based on the graph structure and then uses these symmetries to train an LSTM more efficiently. Specifically, we use *importance sampling* to choose a subset of training instances to make learning more efficient. While importance sampling-based learning in DNNs has been used previously to scale up training [1, 13, 14], most existing approaches determine the importance of a training instance by estimating the gradient norm which is computationally expensive [14]. In our case, we determine importance of a training data instance based on symmetries in the MLN graph. Specifically, the idea is that if several strategies are likely to be symmetrical then we can learn more efficiently from a smaller subset of strategies instead of the whole training set. To do this, we learn an embedding such that problem instances which have symmetries in the graph have similar vector representations in the embedding. We then cluster the embedding vectors and sample instances from each cluster to train the model. The idea is to sample a subset with same overall distribution of strategies as the original dataset. That is, we end up with a smaller dataset the preserves much if not all the information in the original dataset. However, since the clustering is approximate, we may end up with some clusters where the strategies are likely to be more diverse than others. Therefore, we adaptively train the model by updating importance weights for the clusters in iteration $t+1$ based on the trained model in iteration t. Specifically, we sample more data instances from a cluster in $t+1$ when the model trained in iteration t has smaller accuracy for instances sampled from that cluster.

We evaluate our approach on the publicly available KDD EDM challenge datasets [34]. We compare our approach with HMMs and pure LSTM methods that do not use symmetries in training the data and show that our proposed Neuro-symbolic model is more accurate and scalable, where we obtain high prediction accuracy by focusing on a small fraction of the training data.

2. RELATED WORK

Ritter et al. [30] provide a comprehensive survey on different approaches used to identify student strategies. Model tracing based tutors [4] have been previously used to identify strategies. In such cases, strategies may be pre-specified and the tutor can recognize correct and incorrect strategies. Model-tracing based methods have also been adapted to recognize new strategies [29]. Sequence learning has been widely used for strategy identification. Specifically, in Open Ended Learning Environments such as Betty's brain [23], student activities were captured in logs and sequence pattern mining methods was used on these logs to extract action sequences which in principle are similar to sequences that we consider in this paper. Different types of strategies based on these sequences were analyzed in multiple studies [16, 17, 18] which also mapped these sequences to performances to compare and analyze strategies followed by high performers to those followed by low performers. Sequence learning has also been used to extract strategies for self-regulated learning [3]. More recently, a study performed large-scale sequence pattern mining in MOOCs platform to analyze activity sequences of learners [37]. Further, in the context of conversational tutors, tutorial dialogues can be treated as sequence of actions based on language-as-action theory [2, 33]. These sequences which are akin to strategies are mapped into a taxonomy by education experts [26]. Approaches have been developed to recognize these sequences from natural language interactions to help automated tutors understand successful strategies to guide a student. In particular, sequence learning methods have been used for this task as well [32, 24]. Symbolic models such as Markov Logic have also been applied for recognizing these sequences using joint inference [36]. In general, Neuro-symbolic models have gained prominence recently and have found applications in problems that have graph structure. In [22], the authors provide a detailed survey of Neuro-symbolic models using graph neural networks. In complex problems such as visual question answering that require connections between language and image processing, Neuro-symbolic models have performed better than pure neural network based methods [38]. Our proposed application in this paper is further validation that Neuro-symbolic AI is a promising direction to solve complex problems.

3. SEQUENCE LEARNING MODELS

Student strategies can be defined in different ways. In particular, the definition of what constitutes a strategy also

depends upon the type of interaction the student has with the AIS. In our case, we only consider structured interactions with discrete steps. Therefore, we define the student strategy as a function of the sequence of steps in the interaction. Each step is characterized by the central concept that is utilized to solve that specific step, i.e., the knowledge component [20] (KC) used in that step. Therefore, we define strategy in our case as a sequence of KCs used by a student in a problem solving session. Note that, this formulation of strategy as a sequence of discrete components is similar to the definitions used in prior work [30]. Formally,

DEFINITION 1. *Given a student s and a problem p, we define the strategy as $\bar{\mathbf{x}}_{s,p} = K_{s,p}^{(1)} \ldots K_{s,p}^{(n)}$, where $K_{s,p}^{(i)}$ is the knowledge-component that s uses to solve the i-th discrete step in p.*

We can now formulate a learning problem as follows. Given training data, $\{\mathbf{x}_{s_i,p_j}\}_{i=1,j=1}^{n,m_i}$, where n is the number of students and m_i is the number of problems solved by the i-th student, we learn a model $\mathcal{P}$ such that for a student s' and problem p', $\mathcal{P}$ generates a sequence of knowledge components $K_{s',p'}^{(1)} \ldots K_{s',p'}^{(k)}$. Note that students sometimes use more than one KC per step, in this case, we just unroll these multiple KCs by repeating the step with each of the KCs. Therefore, for the rest of this paper, we treat both multiple KCs in a step and single KC steps without distinguishing them. Also, to keep notation simpler, instead of adding the subscripts s_i, p_j each time, we denote the training input and output pairs as $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{N}$.

3.1 HMM Model

A popular model that is often used to learn from sequential data is the Hidden Markov Model (HMM), where we assume that every time-step is dependent on the previous time-step. HMMs are generative models represented using a dynamic Bayesian network. Each step in the time series is encoded by a *hidden-state* variable in the Bayesian network. We connect the hidden node corresponding to time-step j to the hidden node $j+1$ in the network and the observed feature at step j is also connected to the hidden node at step j. In our case, we encode the HMM as follows. Let O_t be the random variable representing the knowledge component at step t. We encode the knowledge component at step t as a vector $\mathbf{O}_t$ (the value of the random variable O_t) using a one-hot encoding. Let Z_t be the hidden-state variable corresponding to step t. The emission probability is given by $P(\mathbf{O}_t|Z_t)$ and the transition probability is given by $P(Z_t|Z_{t-1})$, i.e., the hidden state at time t depends only upon the hidden state at time $t-1$. The transition matrix is a $k \times k$ matrix that specifies transition probabilities to a state at time t given any other state at time $t-1$. Here, k which specifies the number of hidden states is pre-defined in the model.

The learning task in the HMM is to estimate the parameters of the HMM, namely, the transition matrix and the parameters of the emission probability distributions. Note that we need to estimate conditional probability conditioned on each possible state of the latent variable. To do this, we assume a Gaussian distribution represents the probability of each hidden state and the emission probabilities are also Gaussian distributions. Using the EM (Expectation Maximization) algorithm, we compute the parameters of the distributions using Max-likelihood estimation which has guarantees on convergence to a local optima. For predicting the strategy, we sample a KC at the first time step. Then, given a KC at any time step t, we generate the KC at time step $t+1$ as follows. Based on the observation, i.e., KC at step t, we predict an equivalent hidden state representation at step t and using the transition probability matrix, we sample the hidden state at time step $t+1$. We then predict the KC at time step $t+1$ using the emission probability.

3.2 LSTM Model

One of the problems with HMMs is that they have restrictive assumptions, i.e., each step depends only on the previous step. Ideally we would like to consider the student's activity across several steps to determine what his/her next step in the strategy is likely to be. For instance, suppose we have a student who works out a problem using a *divide-and-conquer* strategy, then there may be several small subproblems that the student solves before combining them together. In this case, a HMM model that simply looks at the previous step performed by a student may be able to capture the local strategy but will typically be unable to infer the global strategy since the dependencies may run across several steps. Therefore, to infer such advanced strategies, we need a more sophisticated model that captures longer-term dependencies. Long Short Term Memory (LSTMs) [11] are a variant of recurrent neural networks that have been used successfully for several problems like modeling text data. In particular, LSTMs can exploit longer range dependencies across words/sentences to learn a latent representation of sentences/documents. In our case, we apply LSTMs to learn a latent representation of the strategy.

Unlike HMMs, LSTMs are discriminative models that predict an output for step t based on the features observed in step t as well as a hidden state vector that summarizes the information up to step $t-1$. Note that a bi-directional LSTM can also consider information in steps succeeding t. To learn an LSTM for our task, we construct a tensor $T \in \mathbb{R}^{m \times n \times k}$, where m is the number of training instances, n is the number of steps and k is the dimensionality of features representing each training instance (s, p). Note that we can represent variable-length strategies using a special Start and Stop symbol in the LSTM to denote the start and end of strategies. The output of the LSTM for the t-th step is a vector representing the KC at step t. The final hidden state vector summarizes information for the full strategy for an input instance.

4. NEURO-SYMBOLIC MODEL

Though an LSTM can be directly used to learn a model for strategy prediction, it has certain limitations. LSTMs are known to converge very slowly for large datasets [39]. Further, LSTMs treat each instance in the training data as i.i.d (independent and identically distributed) which is limiting when there are underlying relationships among the instances. For example, problems are related to each other if solved by the same student, KCs used by the same student in similar problems are related to each other, etc. We address these limitations combining LSTMs with a symbolic model.

Neuro-symbolic AI [7], namely, combining symbolic AI mod-

els with DNNs has gained significant attention in tasks such as Visual Question Answering [38]. Neuro-symbolic models augment deep learning with knowledge from symbolic models. This can help learn deep models more efficiently even with limited labeled data [35]. Further, augmenting DNNs with symbolic models also controls overfitting. Specifically, since DNNs are highly expressive models, they are known to sometimes overfit the training data, particularly when the training data is non-diverse and in many problems such as image classification, data augmentation methods [5] seek to increase data diversity. In our Neuro-symbolic approach, we represent relationships in our dataset using the language of Markov Logic [9]. Based on symmetries in the relationships, we sample a smaller, more diverse training dataset to train the LSTM efficiently.

4.1 Markov Logic

Markov Logic [9] is a symbolic AI model designed as a representation and reasoning language for relational data. Markov Logic specifies relationships using the language of first-order logic. Each formula in Markov logic specifies a logical relationship using variables which can be substituted by symbols (also called constants or objects) from the data.

For example, we can model the fact that if two problems are similar then they require the same KC as a formula such as $\texttt{KC}(p_1, k) \wedge \texttt{Similar}(p_1, p_2) \Rightarrow \texttt{KC}(p_2, k)$. We can substitute this general formula using symbols in the data, say two problems P_1 and P_2 and KC K to obtain the formula, $\texttt{KC}(P_1, K) \wedge \texttt{Similar}(P_1, P_2) \Rightarrow \texttt{KC}(P_2, K)$. The formula that is substituted with the symbols is called a *ground-formula* using terminology from first-order logic. The predicates that are substituted with symbols are called *ground-atoms*, e.g., $\texttt{KC}(P_1, K)$ is a ground atom of predicate KC.

A Markov Logic Network (MLN) can be represented as a graph where the relationship encoded in each ground formula is represented by a clique in the graph. A clique is *activated* if the logical relationship specified by the ground-formula corresponding to that clique is evaluated to True in the data. For instance, in the above example, the clique corresponding to KC (P_1, K), Similar (P_1, P_2) and KC (P_2, K) is activated if the data asserts the logical relation that problems P_1 and P_2 use KC K and problem P_1 is similar to P_2. In MLN semantics, each activated clique represents a function parameterized by a weight attached to the ground formula. The full graph represents an undirected probabilistic graphical model [21]. For large datasets in real-world applications such as ours, the number of ground-formulas become very large resulting in an extremely large graph. In the standard use of MLNs, we learn parameters for the MLN based on Max-Likelihood Estimation (MLE). However, computing the gradient for MLE is infeasible when the graph is constructed from large datasets such as ours. Note that though, parameters for the MLN are required only if we want to use the MLN directly for probabilistic inference, i.e., when we want to answer queries using the MLN. While this is certainly desirable, it is well-known that MLN inference/learning algorithms cannot scale up to large datasets and perform extremely poorly in such cases [15]. Therefore, in our case, we make a simplifying assumption in the MLN that all the parameters for the graphical model have uniform weights. Thus, in our Neuro-symbolic model, Markov Logic is only used as a *language for knowledge representation (KR)* and not for inference/learning. That is, formulas specify relationships/connections in the MLN graph between different entities in our dataset (e.g. problems, students, etc.) while the actual learning and predictions are performed by an LSTM model. Note that in theory, other forms of KR such as Bayesian networks, arithmetic circuits or probabilistic programs can be used. However, the benefit of MLNs is that they specify relationships over large data using compact first-order formulas. Next, we describe the formulas in our MLN followed by how we learn symmetries in the graph to train the LSTM more efficiently.

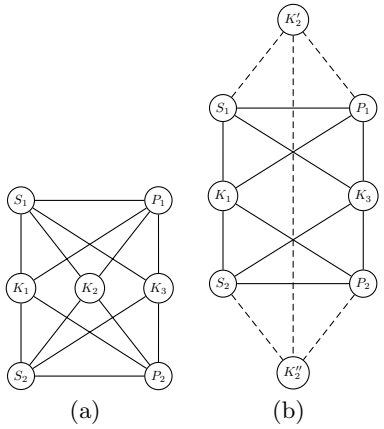

Figure 1: Illustrating symmetries in the MLN object graph. The graph represents symbols/objects in the MLN and the edges represent connection between variables, i.e., if objects appear together in a formula, they are connected in the graph. In (a) student S_1 can be exchanged with student S_2 and problem P_1 with P_2 to get an isomorphic graph. In (b) if the KCs K_1 and K_2 are similar, then the exchange is approximate.

4.1.1 MLN Structure

Our first set of MLN formulas relates the KCs to the problem and the student solving the problem.

$$\texttt{Student}(s) \wedge \texttt{Problem}(p) \wedge \texttt{PHierarchy}(p, h) \Rightarrow \texttt{KC}(s, p, t, k)$$

where s is a variable that denotes a student, p denotes a problem, t is a step, k denotes a knowledge component and h denotes the problem hierarchy which is the hierarchy of curriculum levels containing the problem, and PHierarchy(p,h) relates to the problem p in the hierarchy h where the hierarchy contains the curriculum unit name and the section name that the problem belongs to (e.g. Unit LCM, Section LCM-2).

Next, we encode the *homophily property* where the same KC is likely to be reused by a student for problems that are related to each other through a common problem hierarchy.

$$\begin{aligned}\texttt{Student}(s) \wedge \texttt{Problem}(p_1) \wedge \texttt{Problem}(p_2) \wedge \\ \texttt{PHierarchy}(p_1, h) \wedge \texttt{PHierarchy}(p_2, h) \wedge \texttt{KC}(s, p_1, t_1, k) \\ \Rightarrow \texttt{KC}(s, p_2, t_2, k)\end{aligned}$$

Next, we encode transitive dependencies between KCs by relating KCs that occur close to each other. Specifically, this encodes local dependencies across KCs (similar to a HMM model).

$$\texttt{KC}(s, p, t-1, k_1) \wedge \texttt{KC}(s, p, t, k_2) \Rightarrow \texttt{KC}(s, p, t+1, k_3)$$

4.2 Embeddings

Given the formulas, we can define the MLN object graph by connecting objects that appear in the same ground formula. For instance, consider an example MLN object graph shown in Fig. 1 (a) with two students (S_1, S_2), two problems (P_1, P_2) and three knowledge components (K_1, K_2, K_3). The edges indicate that in the graph corresponding to the MLN, there is a connection that relates the corresponding symbols. Note that S_1 works on P_1 and S_2 works on P_2, where P_1 and P_2 are related since they correspond to the same topic. Suppose both $S1$ and S_2 use the same strategy, K_1, K_2, K_3, then, we can exchange S_1 with S_2 and P_1 with P_2 to get an isomorphic graph structure. Now, suppose $S2$ uses a strategy K_1, K_2', K_3 that is slightly different from the strategy of S_1, say, K_1, K_2'', K_3, then we obtain a graph structure shown in Fig. 1 (b), where the new connections are shown by dotted lines. Now, exchanging S_1 with S_2 and P_1 with P_2 will not give us a graph structure that is isomorphic to the original graph. However, suppose that the knowledge components K_2' and K_2'' are similar to each other, i.e., there are many other problem instances where students use the KCs K_2' and K_2'' interchangeably, then exchanging S_1, P_1 with S_2, P_2 will yield an approximation that is still quite similar to the original graph. This means that using (S_1, P_1), it is reasonable to obtain a model that can predict the strategy for (S_2, P_2) and vice-versa. The set $\{(S_1, P_1), (S_2, P_2)\}$ is therefore an equivalence class consisting of approximately symmetrical instances. In general, if we group together approximately symmetrical instances in our training data, then we can train our LSTM model with diverse instances by sampling these groups since each group represents data that is likely to have a similar effect in training the model. We do this by learning *embeddings* for nodes in the graph structure.

Unfortunately, the size of the graph becomes very large as we increase dataset size and it is practically infeasible to construct the graph structure explicitly. Though several approaches have been developed that identify symmetries in MLNs using graph automorphism groups [27] using tools such as saucy [6], these approaches generally work directly on the graph structure. Further, it is possible to infer symmetries in graphs using other neural-network based methods such as Node2Vec [10] and Graph Convolutional Networks (GCNs) [19]. However, all these approaches work on general graphs and considering an MLN graph as a general graph is problematic since the graph becomes very large even for smallish datasets. This makes it hard to apply such approaches to our strategy identification problem since we expect to have an extremely large graph. Therefore, we instead use a recent, much more scalable Markov Logic graph specific approach called Obj2vec [12] that detects symmetries without explicitly constructing the graph. This approach is based on identifying approximate symmetries based on neighborhoods of a node using a neural network without constructing the actual graph.

4.2.1 Obj2Vec

Obj2Vec is inspired by skip-gram models [25] which are widely used to learn word embeddings. In skip-gram models, we learn an embedding for a word based on its *context*, i.e., the neighboring words that it typically appears with in text documents. For words which have similar contexts, we learn similar vector representations. Word2vec [25] is arguably the most popular skip-gram model, where we train a neural network for learning the embedding. Specifically, for each word w as input, the neural network learns to predict the context of w. Typically, The inputs and context words are encoded as one-hot vectors. The hidden layer in the neural network typically has a much smaller number of dimensions as compared to the input/output layers. The hidden-layer learns a dense, low-dimensional embedding, where similar words have similar vector representations. This is because, words that are similar typically have similar contexts in text documents and therefore the neural network learns a similar representation in the hidden layer for such words.

Obj2Vec extends the idea of word embeddings to MLNs. Specifically, recall that each ground formula of an MLN represents a clique in the MLN graph. For each activated ground formula, i.e., formula that represents a relationship that is supported by the data, we predict a symbol/object in the formula from other symbols/objects in that same formula. For example, suppose our data shows that *Alice* and *Bob* use the knowledge component `Slope-Intercept` across several problems. Then, all ground formulas that contain either *Alice* or *Bob* and the KC `Slope-Intercept` are activated. In this case, both *Alice* and *Bob* are said to share a common context. Therefore, we predict the symbol `Slope-Intercept` from both *Alice* and *Bob*. That is, we have an autoencoder neural network where the input is a one-hot encoding of *Alice* (or *Bob*) and the output is a one-hot encoding of `Slope-Intercept`. The neural network must therefore learn a common representation for both *Alice* and *Bob* since it needs to make similar predictions for both. Thus, suppose the hidden-vector representation (or embedding) for *Alice* is v_{Alice} and that for *Bob* is v_{Bob}, then $v_{Alice} \approx v_{Bob}$. Note that the embedding defines a continuous approximation of symmetries in relationships specified in the MLN graph. That is, the distance between the vectors v_{Alice} and v_{Bob} quantifies the symmetry between *Alice* and *Bob* based on relationships specified in the data.

4.3 Scalable Learning using Symmetries

The embedding vectors from Obj2Vec encodes relational knowledge from the MLN graph. Given the embedding vectors, we now train an LSTM to predict the student's strategy. Specifically, let our input instances be $\mathbf{x}_1 \ldots \mathbf{x}_N$, where each $\mathbf{x}_i$ consists of embeddings for a specific student s solving problem p, and the outputs are $\mathbf{y}_1 \ldots \mathbf{y}_N$, where $\mathbf{y}_i$ is a sequence of KCs used by the student s to solve the problem p. The LSTM training objective is given by,

$$\theta^* = \arg\min_{\theta} \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}(\psi(\mathbf{x}_i, \theta), \mathbf{y}_i) \quad (1)$$

where θ^* and θ represent the parameters of the LSTM, $\mathcal{L}$ is a loss function and $\psi(\mathbf{x}_i, \theta)$ is the sequence of KCs output

by the LSTM parameterized by θ for input $\mathbf{x}_i$. In general, a stochastic gradient descent (SGD) procedure can be used to minimize the objective in Eq. (1). In SGD, we sample the training instances to approximate the gradient. Typically, SGD assumes that all training instances are equally important, and therefore samples them uniformly. That is, the probability of sampling a specific instance in the training data is equal to $p = \frac{1}{N}$. However, this approach is expensive particularly if we repeatedly choose training instances that are similar to each other. For example, suppose all the training instances that we sample are likely to encode similar strategies, then our model may take a long time to understand diverse strategies. Further, since the underlying data encodes symmetries (from the MLN graph), the information in one training instance may be very similar to the information in another symmetrical instance. Therefore, we force the model to learn from instances with diverse relationships by imposing an importance distribution over the training data. Specifically, training instances with larger importance are more likely to be chosen as compared to training instances with smaller importance.

In general, to focus the training on more important data instances, we can modify the sampling distribution such that each instance is sampled with a non-uniform probability. This approach has been explored in prior work, where we scale up training by replacing the uniform distribution over the training instances with an importance distribution that quantifies how important a specific example is for the training process [14]. Previous work such as [14, 1, 13], have focused mainly on approximating importance as a function of the gradient norm which is hard to compute exactly. In [14], therefore, the authors propose an approximation to the gradient norm and use this to target important training examples. The focus in these approaches is to target the training examples that are likely to induce changes when updating the model parameters during backpropagation which can be shown to translate to a reduced variance in the gradient estimates. However, in our case, we have more information apriori in the embeddings to identify importance of a training example in terms of their relationships. Specifically, recall that the embeddings are based on symmetries in the MLN-graph which encodes relational knowledge. Thus, if two embeddings are similar, then it means that they share similar relationships. For example, if two student embeddings are similar, then it is likely that for the problems both students have solved, their strategies use similar KCs. Thus, using embedding-similarities, our model focuses the training effort on instances that encode diverse relationships.

4.3.1 Adaptive Importance Weighting

Given the instances $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{N}$, we cluster the instances using K-Means clustering. Each instance internally has two components, the student embedding as well as the problem embedding. Since we want to exploit symmetries in both, we cluster them along both dimensions. Let $\{\mathbf{C}_s^{(i)}\}_{i=1}^{n_1}$ and $\{\mathbf{C}_p^{(i)}\}_{i=1}^{n_2}$ denote the clusters found by K-Means using the student embeddings and the problem embeddings respectively, where n_1 and n_2 are the number of clusters. We now sample from each cluster to obtain a reduced set of training examples. For each cluster, we assign an importance weight to quantify how often we need to sample that cluster. Let q_i represent the importance weight of the i-th

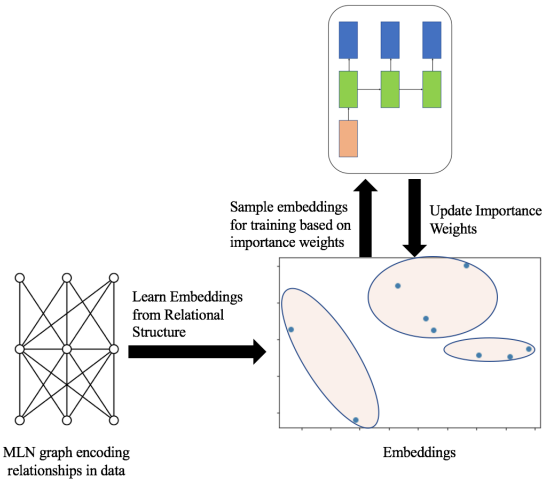

Figure 2: Schematic illustration of our proposed approach. We learn embeddings based on symmetries in the relational data. We then learn a one-to-many LSTM to map an input instance to a sequence that represents the strategy by focusing the training on a sample of the data that reflects symmetries in the data.

cluster. Ideally, we want to quantify q_i based on the symmetries encoded within the cluster. Specifically, if the cluster contains highly symmetric instances, then we require fewer training examples from the cluster. On the other hand, if the cluster contains diverse instances, we require more training samples from that cluster. One way to quantify this is using traditional clustering metrics such as within-cluster sum of squared errors (SSE) to measure cohesion within the cluster. That is, if the embedding vectors are close to each other within a cluster which implies a small SSE, then it is indicative that we may need fewer samples from that cluster. However, this approach may not necessarily yield the best results since both the embeddings and the clustering are simply approximations to true symmetries in strategies. For example, suppose the embedding vector for *Alice* is close to the vector for *Bob*, this means that considering all problems, *Alice* and *Bob* are approximately symmetrical. Similarly, if the vector for problem P_1 is close to problem P_2, this means considering all students, P_1 and P_2 are approximately similar. However, this may not always necessarily imply that the strategy followed by *Alice* for problem P_1 is guaranteed to be symmetrical to the strategy followed by *Bob* for P_2. Therefore, we use an adaptive approach to progressively learn these symmetries.

For training the model, from each cluster, we may require varying number of samples. That is, from clusters representing less symmetrical instances, we may require more samples while from other clusters that contain more symmetrical instances, we may require fewer samples. To account for this, we adapt the sampling as follows. We define the initial importance weight for the i-th cluster as $q_i^{(0)} = \frac{1}{K}$, where K is the number of clusters. Let $\theta^{(j)}$ be the parameters learned by the LSTM in iteration using samples from the clusters in iteration j. In iteration $j+1$, we update the importance

weight for the clusters as,

$$q_i^{(j+1)} = \frac{1}{m}\sum_{k=1}^{m}\mathcal{L}(\psi(\mathbf{x}_k^{(i)}, \theta^{(j)}), \mathbf{y}_k^{(i)}) \quad (2)$$

where $\mathbf{x}_k^{(i)}$ is a training example that consists of a randomly sampled instance from the i-th cluster. For example, if we are updating the i-th student cluster, $\mathbf{x}_k^{(i)}$ is a randomly sampled student s from this cluster combined with a problem p, where p is a problem that has been solved by s. Thus, if the LSTM in iteration j effectively encodes the symmetries in the i-th cluster, then the loss in Eq. (2) is likely to be small. Thus, $q_i^{(j+1)}$ is small. On the other hand, if $q_i^{(j+1)}$ is large, then we need more samples from the i-th cluster since the LSTM trained using the samples collected until iteration j does not effectively model the instances in the i-th cluster. The importance weights for the i-th cluster adaptively change from $q_i^{(0)}$ $q_i^{(1)}$ ... $q_i^{(T)}$. Note that each iteration adds training data to the LSTM and thus effectively increases training time. However, we do not begin the training from scratch in each iteration. Specifically, for iteration $j+1$, we consider the LSTM learned until iteration j as the starting point. This is similar to *pre-training* that is common in deep network training. For iteration $j+1$, the $\theta^{(j)}$ represents the pre-trained parameters of the LSTM. We stop adapting the weights after a fixed number of iterations depending based on a cutoff for the training time. Note that more advanced convergence criteria can be explored here which is a part of our future work. To summarize, Fig. 2 shows a schematic representation of our overall model.

5. EXPERIMENTS

5.1 Setup

We evaluate our approach on the publicly available KDD EDM challenge datasets, `Algebra 2008, 2009` and `Bridge to Algebra 2008, 2009` [34] which consists of data collected from the Mathia platform. Each instance consists of several discrete steps and each step is mapped to a knowledge component which is used to solve that step. The statistics for the two datasets are shown in Table 1. As shown in the table, these datasets are quite large with over 850K and 1.6M instances respectively. All our experiments were performed on a 64GB memory machine with a Nvidia GPU and an Intel Core-I9 processor. For computing accuracy, in each input instance, we compute the percentage of total steps where the true KC matches with the predicted KC. The overall accuracy is computed as the average accuracy across all instances. To measure variance of our estimates, for each of the results shown, we run the experiments 10 times and compute the mean accuracy and the standard deviation of the accuracy. Next, we describe the implementation of different approaches that we use in our experiments. The code and data for our implementations are available here[2].

5.1.1 Hidden Markov Model

We trained a Gaussian Hidden Markov Model (we refer to this as `HMM`) using the sklearn package in python. We set the number of hidden states to 100 and initialized the Gaussian emission probabilities with a full covariance matrix so that it has flexibility to generate varied sequences. We trained the model using the EM algorithm.

0.001	Adam with CCE-Loss	100	0.3	200 dimensions	300 dimensions

Table 2: Parameters for training.

5.1.2 LSTM and Neuro-symbolic Models

We implemented a one-to-many LSTM using TensorFlow and Keras. For the pure (or vanilla) LSTM, we encode inputs as one-hot-encoded vectors representing the studentID, problemHierarchy and problemName. For the Neuro-symbolic model, we vectorize each instance, using a publicly available implementation of Obj2Vec [12] using the MLN formulas as specified in the previous section. Obj2Vec internally uses Gensim [28] to compute the embeddings for each symbol in the MLN. We use the embedding vectors of studentID, problemHierarchy and problemName as input to the LSTM encoder. Special Start and End tokens are used in the decoder section of the LSTM to identify the start and end of a prediction. The decoder unit predicts the KC at each time step, until an End token is found. To train the models in a feasible manner, we used a timeout of 3 hours. Within this timeout period, it was infeasible to use the all the instances since the training for the LSTM did not converge. Therefore, we randomly sampled instances to train our model within the specified limit. We refer to the trained models using random sampling as `LSTM-Random` and `LSTM-NS-Random` for the vanilla LSTM and the Neuro-symbolic models respectively. We further implemented a stratified-sampling/group based training on students and problems. For sampling by student, we selected N students from the student pool and for each selected student, we sampled M problems solved by that student. For sampling by problems, we selected N problems from the problem pool and sampled M students who have solved those problems. By increasing values of M and N, we progressively increased the instances as we show later in the results section. We refer to this as `LSTM-NS-NaiveGroup`.

5.1.3 Adaptive Training

We implemented K-Means clustering to cluster the data based on the embeddings and sampled from these clusters. We implemented a non-adaptive training model as follows. We independently clustered the students and the problems to generate C_1 student clusters and C_2 problem clusters. We then sampled one student from each student cluster and one problem from each problem cluster nearest to the cluster centers to create a training set of at most $C_1 * C_2$ instances that effectively covers all instances in our training data. We increase the number of clusters progressively starting from 100 student clusters and 1000 problem clusters to increase the number of instances in training as we show later in our results. We refer to this approach as `LSTM-NS-Clustered`. For our proposed adaptive weighting approach, we sample each cluster according to an importance weight. In each iteration, we update the importance weight of a cluster based on predictions made on a randomly sampled set of instances that were not used in training from that cluster. Here, we used 100 student clusters and 1000 problem clusters and

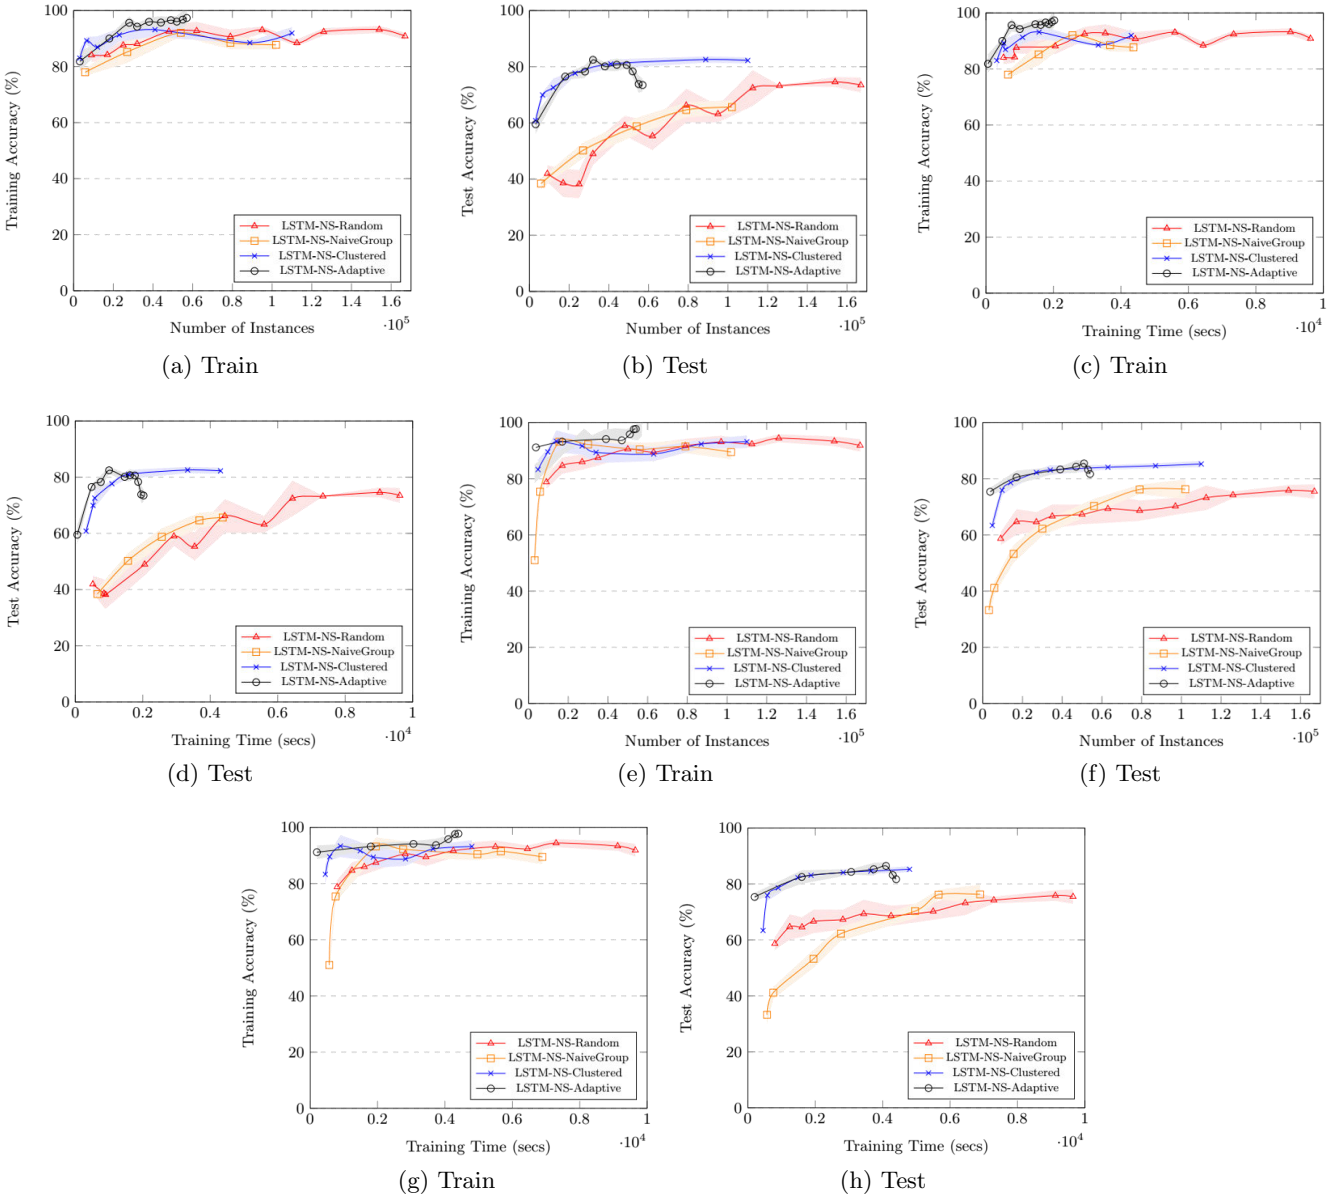

Figure 3: Accuracy results, the shaded portions show the standard deviation and the mean accuracy is plotted in the graphs. (a)-(d) corresponds to `Bridge to Algebra 2008, 2009` results and (e)-(h) corresponds to `Algebra 2008, 2009` results.

changed the importance weights of the clusters adaptively. We refer to this approach as `LSTM-NS-Adaptive`. The parameters for training our models are shown in Table 2.

5.2 Results

Fig. 3 compares the accuracy for different approaches. Fig. 3 (a), (b) shows the training and test accuracy respectively as we vary the number of instances used in training the models for the `Bridge to Algebra 2008, 2009` dataset. As we can see from these plots, `LSTM-NS-Adaptive` obtains the highest accuracy compared to the other methods. `HMM` (not shown in figures) gave us an accuracy of less than 5%. This low accuracy indicates that the strategy for diverse (or asymmetric) groups of students (or problems) cannot be represented by the same transition matrix. One possible approach that we will explore in future is to integrate our approach with HMMs, i.e., we learn an ensemble of HMMs where a HMM learns strategies for a symmetric group. A naive LSTM without embedding vectors, i.e., where inputs are a simple one-hot encoding of student and problems, also yields poor accuracy (less than 10%). This illustrates the importance of the latent features in the embedding vectors.

Note that we have only shown the results for the best performing model with latent dimension as 200 (experiments were carried out with different dimensions). As shown in Fig. 3 (a), (b), `LSTM-NS-Adaptive` and `LSTM-NS-Clustered` require a small fraction of the number of instances to obtain accuracy that is higher than `LSTM-NS-Random` and `LSTM-NS-NaiveGroup`. Further, the variance in accuracy of `LSTM-NS-Random` and `LSTM-NS-NaiveGroup` is much higher as shown by the shaded portion around the line plots compared to the variance of `LSTM-NS-Clustered` and `LSTM-NS-Adaptive`. `LSTM-NS-Adaptive` also obtains higher accuracy than `LSTM-NS-Clustered` as we adapt the weighting. However, note that the test accuracy starts to dip after the accuracy hits a peak value for `LSTM-NS-Adaptive`. This is because the adaptive cluster weights may focus too strongly on certain clusters in the training data which causes the LSTM to overfit. Therefore, in practice, we can stop the adaptation based on a validation set. Further, we can clearly see that exploiting symmetries in training leads to better generalization in Fig. 3 (b) where we see a significant difference between the accuracy for `LSTM-NS-Adaptive` and `LSTM-NS-Clustered` as compared to `LSTM-NS-NaiveGroup` and `LSTM-NS-Random` at smaller training sizes. Fig. 3 (c) and (d) also show the using relational symmetries in training results in a significant improvement in scalability since it shows that we can train `LSTM-NS-Adaptive` and `LSTM-NS-Clustered` in around half an hour to achieve an accuracy that is higher than the accuracy we obtain even after around 3 hours of training time in approaches where we do not choose training examples based on symmetries.

The results for the `Algebra 2008, 2009` dataset are similar to the ones for `Bridge to Algebra 2008, 2009`. As seen in Fig. 3 (e) and (f), the `LSTM-NS-Adaptive` model is the best performing model in terms of accuracy and it uses a small number of training instances to achieve this accuracy. Similar to the previous results, the variance for `LSTM-NS-NaiveGroup` and `LSTM-NS-Random` is much larger than that for `LSTM-NS-Adaptive` and `LSTM-NS-Clustered`. The training time shown in Fig. 3 (g) and (h) follow a similar pattern where `LSTM-NS-Adaptive` and `LSTM-NS-Clustered` can achieve high accuracy scores even with short training times since they take advantage of relational structure in the data.

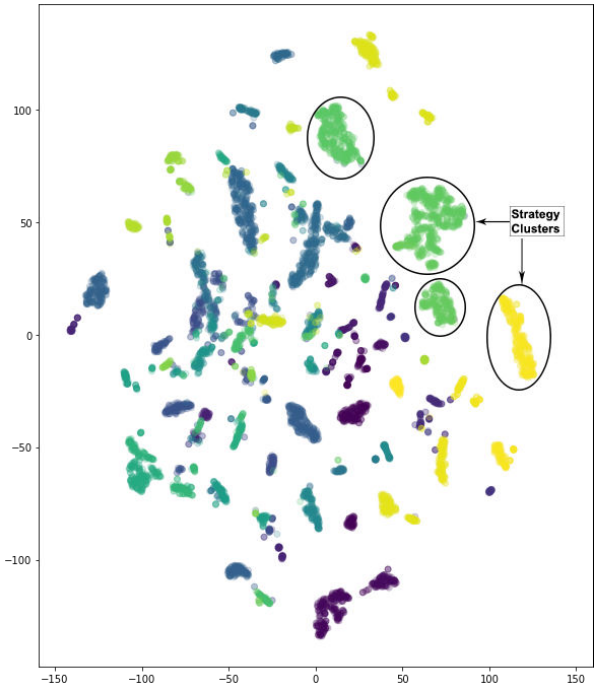

Figure 4: T-SNE visualization of strategies. The hidden layer of the final step in the LSTM is visualized for 100 test problems over all students. T-SNE reduces the latent LSTM vector to 2-D for visualization. Data points close together correspond to approximately similar strategies.

Table 3 shows the accuracy of predicting strategies for different problem units. Specifically, each problem in the dataset corresponds to a specific unit and we evaluate the models by testing the trained model on problems specific to a unit. For lack of space, we have not provided an exhaustive set of results for all units since there were around 50 units in the dataset. Instead, we provide accuracy results for the 10 units with largest number of data instances from the `Bridge to Algebra 2008, 2009` dataset. We see that on majority of the units, `LSTM-NS-Adaptive` has the best accuracy score. `LSTM-NS-Clustered` is the next best performing method. The difference in accuracy between units was significant in some cases. For instance, `LSTM-NS-Adaptive` had a very high accuracy for the unit `PERCENT CONVERSION` but a much lower accuracy for `ONE-STEP-EQUATIONS` and `TWO-STEP-EQUATIONS`. This may be due to higher complexity involved in solving equations as compared to problems involving percent conversion which may add to uncertainty in predicting strategies.

5.2.1 Structure in Strategies.

Finally, Fig. 4 shows a visualization of the strategies through a *T-SNE* plot. Specifically, we wanted to analyze if there are true patterns in the strategies. To do this, we use the `LSTM-NS-Adaptive` model to predict the strategy for 100 problems across all students. We show the results for `Bridge to Al-`

Unit	LSTM-NS-Random (%)	LSTM-NS-NaiveGroup (%)	LSTM-NS-Clustered (%)	LSTM-NS-Adaptive (%)
PROBABILITY	67.7	53.48	**77.45**	70.73
FRACTION-OPERATIONS-1	74.95	78.23	84.02	**90.49**

Table 3: Comparing accuracy on test sets corresponding to different units in `Bridge to Algebra 2008, 2009`.

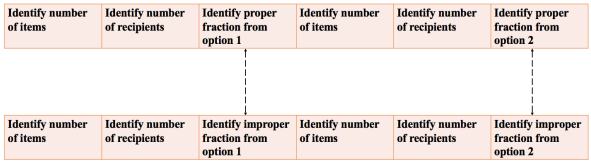

Figure 5: Strategies for different problems that have similar vector representations.

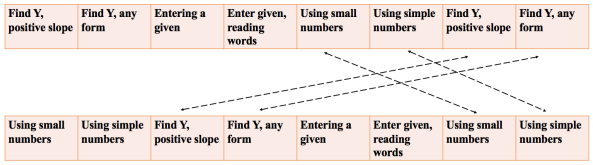

Figure 6: Strategies for the same problem that have similar vector representations.

`gebra 2008, 2009`. We use the hidden-vector from the last step of the LSTM as a representation of the strategy for a specific input instance. That is, this vector encodes information summarizing all the steps (or the full strategy) that the student performs when solving the input instance. We then plot this using the *T-SNE* plot that reduces the high-dimensional representation to a 2-D representation. Fig. 4 shows that there is a separation of different groups of strategies. The presence of such clusters of strategies indicates that there are indeed structures in student strategies and the representation learned by `LSTM-NS-Adaptive` discovers these symmetric structures.

Fig. 5 and 6 show two examples where the vectors representing the strategies are close to each other. Fig. 5 shows a case where the two strategies correspond to two different problems, one of which is related to proper fractions and the other to improper fractions. However, at a high level, these strategies are similar which is reflected in their similar vector representations. Another example shown in Fig. 6 shows a case where the two partial strategies shown correspond to the same problem are inversions of each other. That is, some of the steps in the two cases are performed in opposite orders. However, at a high-level, the strategies have symmetry which is reflected in their vector representations.

6. CONCLUSION

Predicting student strategies in problem solving can make AISs more engaging to students since the system can adapt itself to suit the student's strategy. In this paper, we described a Machine Learning approach to predict student strategies from large scale, structured student interaction data. Specifically, we adopted a Neuro-Symbolic approach, i.e., we combined LSTMs with a relational symbolic model to perform learning more efficiently. To do this, we encoded relationships in the data in the language of Markov Logic and based on relational symmetries in the data, we picked training instances are diverse. Doing this allowed us to learn our model to recognize diverse strategies at a smaller computational cost. Our evaluation on the KDD EDM challenge datasets show that our approach generalizes better and has significantly smaller training times as compared to approaches that do not exploit relational symmetries during learning. In future, we will extend our approach to datasets with finer-grained learner information and also develop joint inference models connecting mastery and strategies.

ABSTRACT

Open-ended questions in mathematics are commonly used by teachers to monitor and assess students' deeper conceptual understanding of content. Student answers to these types of questions often exhibit a combination of language, drawn diagrams and tables, and mathematical formulas and expressions that supply teachers with insight into the processes and strategies adopted by students in formulating their responses. While these student responses help to inform teachers on their students' progress and understanding, the amount of variation in these responses can make it difficult and time-consuming for teachers to manually read, assess, and provide feedback to student work. For this reason, there has been a growing body of research in developing AI-powered tools to support teachers in this task. This work seeks to build upon this prior research by introducing a model that is designed to help automate the assessment of student responses to open-ended questions in mathematics through sentence-level semantic representations. We find that this model outperforms previously-published benchmarks across three different metrics. With this model, we conduct an error analysis to examine characteristics of student responses that may be considered to further improve the method.

1. INTRODUCTION

In many K-12 mathematics classrooms, teachers have come to rely on the use of open-ended questions to assess their students' knowledge and understanding of assigned content. Unlike close-ended problems, where there is a single or finite-number of accepted answers (e.g. a multiple-choice question), open-ended questions allow students to justify and express their thinking processes through language; it is common that students may combine language, images, tables, or other mathematical expressions, equations, and terminologies to illustrate their knowledge and understanding of the material.

While the use of open-ended questions is not found only in mathematical contexts, aspects of this domain make it particularly difficult to develop teacher supports for these types of question. Within computer-based learning platforms, research across fields of study have led to the development of a multitude of teacher-augmentation tools [1] and methodologies that leverage machine learning techniques. Among these supports, automated methods have been developed and deployed to help teachers assess student essays and short answers in several domains [25, 2, 3, 15]. As was highlighted in [9], the arduous task of manually assessing and providing feedback to student open-ended work may explain the decline of open-ended questions assigned over the course of a school year (e.g. Figure 1 which shows the number of open response questions assigned within the ASSISTments learning platform, aggregated over the last 10 years). In addition to this decline, as was also reported in [9], very few student responses to open-ended questions are ever scored by the teacher, with even fewer ever receiving feedback. Figure 2 illustrates this, as well as the subsequent plot of these values from February through October of 2020, during COVID-19 induced remote learning.

There are several notable challenges in developing automated supports to help teachers assess student open-ended work. It is also the case that student responses to open-ended questions differ in the context of mathematical and non-mathematical domains. One such difference, for example, is that many non-mathematical domains such as history or language arts, student "open-ended" essays and short answers are often comprised of multiple sentences and paragraphs [21, 25, 5, 8], whereas in mathematics, responses are generally shorter (maybe one or two, often incomplete sentences) [14, 9] that combine language with mathematical symbols, expressions, or other visuals. Aside from these response-level characteristics, however, several other student-, problem-, and even teacher-level factors can make the development of

Sami Baral, Anthony F Botelho, John A Erickson, Priyanka Benachamardi and Neil T Heffernan "Improving Automated Scoring of Student Open Responses in Mathematics". 2021. Figure 1: The number of open response problems assigned over the course of a school year with the ASSISTments learning platform, aggregated from 2010-2020.

these automated supports more challenging; consider, for example, the variation in how teachers approach the assessment of student answers, using different inherent rubrics and pedagogical philosophies [15, 17, 22, 23].

While the examination of student answers to open-ended poses challenges in developing automated assessment supports for teachers, prior work has shown promise in this context [9]. In that work, the authors explore several machine-learning and natural language processing (NLP) methods to predict teacher-provided scores to open-ended problems, offering an evaluation method and benchmark of comparison for similar methods[1]

In this paper, we build upon prior research presented in [9] to develop and evaluate an automated assessment model of student open responses in mathematics. We introduce a modeling approach using a sentence-level semantic representation of the student open responses to the existing models through Sentence-BERT (SBERT;[20]), using a novel reformulation of the "score prediction" problem. We compare our method to the previously-developed scoring models from [9], and subsequently apply an exploratory error analysis to identify areas of improvement that may be addressed by future iterations of these methods. Toward this, we seek to address the following research questions:

1. How does a model utilizing Sentence-BERT compare to previously developed approaches in predicting teacher given assessment scores for student response to open-ended problems?

2. What are the characteristics of student answers that correlate with errors observed in our Sentence-BERT model?

3. Which of student-, problem-, or teacher-level characteristics most explain the variance of error observed when the model is applied in real learning environments?

[1]The data and evaluation code from [9] was used in this work with permission from the original authors and in compliance with IRB.

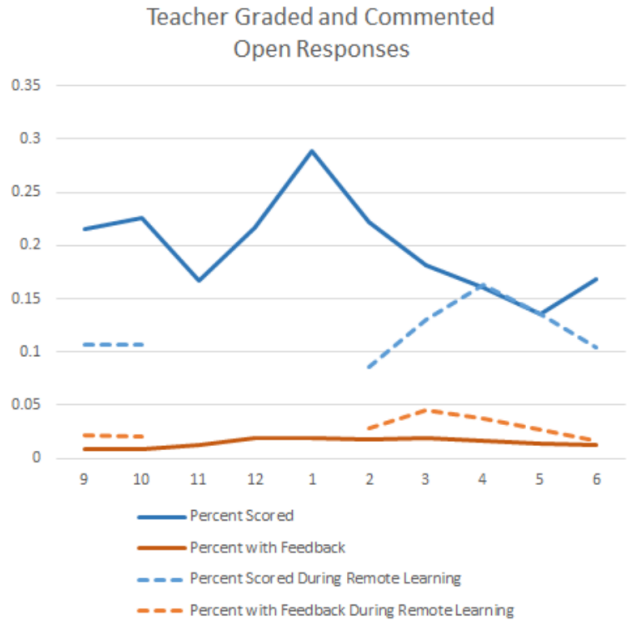

Figure 2: The percent of student open-response answers that were scored and given written feedback by a teacher before and during remote learning in response to COVID-19.

2. BACKGROUND

There have been several works related to the automated scoring of open-ended responses in the past. Most of such works utilize a combination of Natural language Processing (NLP) and machine learning techniques of ranging complexity to process open-ended responses. Much of the existing work in this area has been applied in the context of non-mathematical content. Developments such as C-rater[15] is a well-cited approach that uses such methodologies to estimate the assessed correctness of answers to short answer questions. This method uses grading rubrics and breaks down scores into multiple knowledge components to evaluate each student response. Other works [2, 3] have implemented clustering techniques to grade short textual answers to questions. More recently, studies have based their approach around deep learning methods, which have led to promising improvements over previous benchmarked results [21, 25]. While most of these works have been on non-mathematical domains, studies like [14] explore mathematical language processing using clustering techniques and the bag-of-words approaches for automated assessment of open-ended response in mathematics. However, this study only considers the mathematical content, discarding the non mathematical texts.

Many of these more-recent studies have utilized publicly-released embedding methods trained on large corpuses of data, including those of Word2Vec [18] and GloVe [19], to model the semantic meaning of words. However, word embeddings capture limited information about the semantics of a sentence, where the sequence of words may have large im-

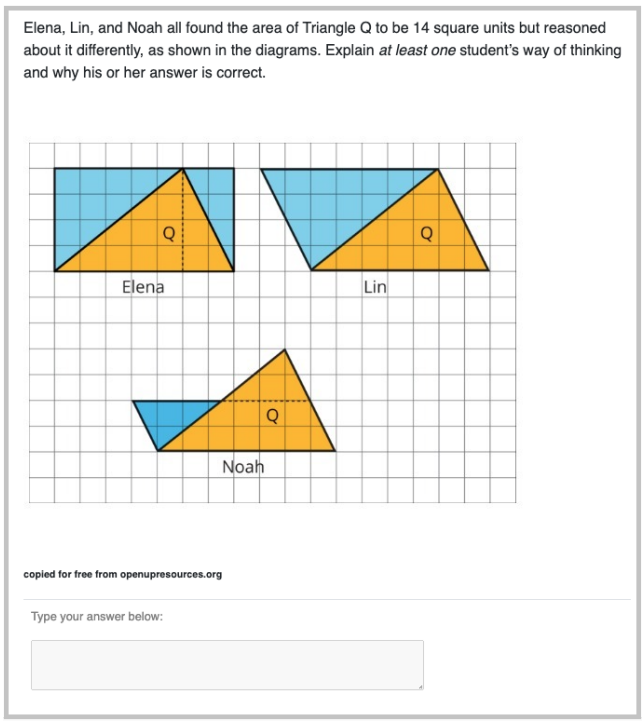

Figure 3: Example of an open ended question taken from openupresources.org

pacts on interpreted meaning. To capture the contextual information within sentences and further increase the generalization capabilities of NLP embedding methods, techniques such as Universal Sentence Encoders [4] and Sentence-BERT [20] generate a single embedding that is designed to be representative of the entire sentence while preserving the semantic and contextual information of the words within such sentences.

One of the most commonly-used NLP embedding methods in recent years has been that of Bidirectional Encoder Representations from Transformers (BERT, [7]). Building upon and distinguishing itself from other methods such as GloVe, the BERT method is designed to incorporate contextual information into generated embeddings to distinguish words that may have the same spelling but different meanings depending on usage (e.g. the word "bank" referring either a financial institution or perhaps a slope of land near a river); BERT has been shown to outperform many other approaches in a number of NLP tasks including, as is important for this work, semantic textual similarity (STS) [7]. Sentence-BERT, or SBERT [20], modifies the pre-trained BERT network to reduce the computational overhead of BERT in order to also generate a sentence-level embedding of a given series of words.

2.1 A Benchmark Comparison

In this work, we are exploring the use of this SBERT method to build upon the prior benchmark set in Erickson et al., 2020 ([9]) in assessing student answers to open-ended problems in mathematics. In that work, the authors discuss the challenges in developing models to predict teacher assigned grades for student open responses in mathematics, using a dataset of authentic student responses within the ASSISTments [11] learning platform. Erickson et al. compares 6 models utilizing machine learning (e.g. random forest and XGBoost [6]) and more complex deep learning (e.g. LSTMs [12]) techniques, combined with natural language processing algorithms to assess responses that are combinations of mathematical expressions and non-mathematical text. For the feature extraction process from the open response data, the study uses the Stanford Tokenizer [16] combined with Global Vectors for Word Representation (GloVe) [19].

3. METHODOLOGY

In this study, we build upon the work of [9] to develop and evaluate an automated scoring model based on the SBERT methodology; as will be detailed further, we refer to this model as the SBERT-Canberra model throughout the remainder of this work. Then, in a secondary analysis, we utilize real data collected from a pilot study of our model running within a computer-based tool that provides teachers with suggested scores to explore the limitations of our approach through an exploratory error analysis. Our data and approach to these analyses are described in this section.

3.1 Dataset

In this work, we utilize two datasets[2] of student answers to open-ended questions paired with teacher-provided assessment scores. An example of one of these open-ended mathematics questions is shown in Figure 3. In this example, students are not asked to find the area of the triangles, but rather explain in their own words what one of the figures is illustrating an approach to solving the problem.

For the development of our SBERT-Canberra model, we use the dataset (and evaluation code) from the Erickson et al. study [9]. This dataset is comprised of student answers to open response questions within the ASSISTments[11] online learning platform; the dataset consists of 150,477 total student responses from 27,199 unique students to 2,076 unique problems graded by 970 unique teachers. As was performed in [9], we omit any case where a student response contained no characters (e.g. an empty response or one containing only whitespace characters), or contained nothing but an image (cases where there was an image accompanied by other text or non-whitespace characters is not omitted). The removal of such empty responses resulted in the dataset dropping to 141,612 graded student responses, 25,069 unique students, 2,042 unique problems, and 891 unique teachers. Within this data, each response is accompanied by a teacher-provided assessment score that follows an integer ordinal 5-point scale from 0-4; a "4" here is synonymous with a student receiving a 100% for the response.

Table 1 lists several student answers contained within the dataset, chosen from across multiple problems for illustrative purposes. As was noted in the introduction, these responses highlight some of the challenges of this modeling

[2]The data and code used in this work cannot be publicly posted due to the potential existence of personally identifiable information contained within student open response answers. In support of open science, this may be sharable through an IRB approval process. Inqueries should be directed to the trailing author of this work.

Table 1: Sample student responses (selected from across multiple problems for illustrative purposes) and the teacher provided scores on a scale of 0 to 4 to the open ended questions in mathematics.

Sample Responses	Score
y=4x-2	4
I counted	4
I multiply -3 and 2x	2
diagram is on paper	3
Yes Because Y=mx+b	0
I got 2/9 by dividing by 4	3
I was not in class for this so I don't know.	1
I went multiplication first then division then multiplication	3
I got this by doing 45/75. I knew that 75 + 75 = 150 and 150 goes into 450 3 times and 3 x 2 = 6. So the answer is 6.	4
You would need an example and then you would need to draw a line and find out far away your shape is from the line and mark it and then do that on the rest of your lines on the shape	4
The distributive property means that a number outside a set of parentheses can be multiplied by each of the numbers within the parentheses and the answer will be the same. It works because it would be the same as multiplying each number by the number outside the parentheses and then adding them together.	1

task. First, the length of responses varies greatly between students as well as across problems. In addition to this, the interleaving of mathematics and linguistic text likely makes it difficult for pre-trained embedding models to interpret. Similarly, the variation in mathematical representation (i.e. the use of the term "dividing" rather than the "/" operator), may lead to confusion in a machine learning model trained over such data. As the mathematical variables are also represented by recognized english characters (e.g. "y"), it may be difficult to derive semantic meaning for such tokens. It is for this reason that we hypothesize that a contextual-based embedding approach, such as BERT and SBERT, may be superior to traditional embedding methods that do not account for context within the sentence. Finally, the noise in ground truth labels become evident from the table. The student who answered "I counted" but still received full credit, for example, exemplifies that some teachers may score students based on completion or other factors unrelated to their demonstration of understanding or mastery. This is not to say that any one scoring method is more correct or valid than another, but rather that there is likely large variation in these labels, making it difficult for machine learning models to effectively learn associations between student answers and these scores in some cases.

The second dataset used in this work is comprised of student responses collected during the pilot testing of a teacher-augmentation tool designed to aid in the assessment of student open response answers within ASSISTments [11]. This tool, called QUICK-Comments, used our developed model to predict the scores of student answers to open response questions in mathematics. Models were trained over the same open educational resource (OER) curricula from which the problems used in the first dataset were collected and produce estimates using the same grading scale as the first study. During the pilot study, 12 middle school mathematics teachers were given access to the tool and compensated for their time to assign, assess, and provide feedback to student open ended work during the Spring and Fall of 2020. This dataset consists of 30,371 graded student open responses to 915 unique open response problems solved by 1,628 unique students.

3.2 SBERT-Canberra Model

The model developed for this work follows a 2-stage process to generate estimates of teacher-assigned scores for a set of given student answers. In approaching this model, we propose a reframing of the initial problem. In [9], the problem was posed as a traditional supervised learning problem; in other words, given a set of student answers A, train a model $f(.)$ such that $Y = f(A)$. Instead, we propose a more unsupervised approach as depicted in Figure 4. If we have a set of historic answers $A_{0...n-1}$, and want to predict the score of a new answer A_n, a logical choice of score may be that corresponding with the historic answer that is most similar to the new answer A_n. In this way, the problem is posed as a similarity ranking problem rather than a supervised learning problem.

There are several potential advantages to this approach. First, when utilizing a pre-trained model of SBERT, described in Section 2, no actual model training is necessary (so long as a reasonable distance metric is identified). Second, as SBERT is optimized for contextual similarity tasks, the problem is better suited to utilize the embedding method's strengths. Finally, in a practical sense, as no model training is necessary (beyond utilizing the pre-trained embedding model), such a model can be more easily applied at scale, requiring just a pool of historic answers to compare against. We hypothesize that this method may also require fewer example answers than traditional machine learning methods as well, but this claim is not deeply explored in this current work.

In applying this method, the set of historic answers $A_{0...n-1}$ are fed through the pre-trained SBERT model to produce

Table 2: Features for the Linear Model of Error analysis of SBERT-Canberra model

Title	Description	Mean
Answer Length	Length of the answer	10.39
Average character per word	the average number of characters per words	3.54
Numbers count	total number of digits	3.54
Operators count	total mathematical symbols in the response	1.47
Equation percent	percentage of mathematical equations in answer	0.27
Presence of Images	Indicator of presence of images in the answer	0.15

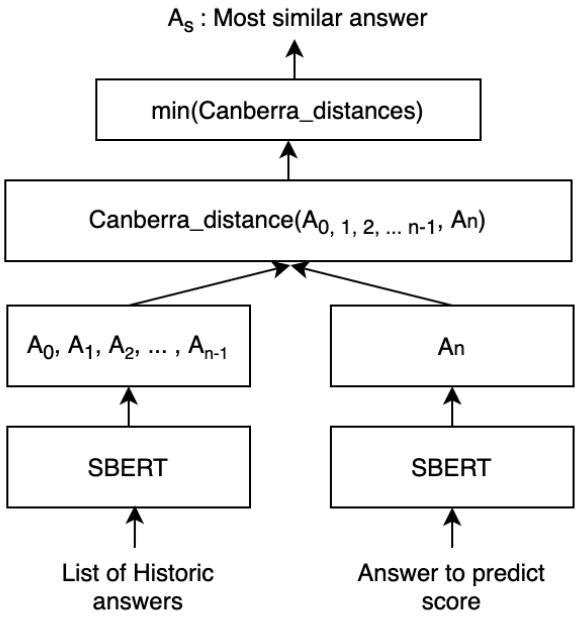

Figure 4: The design of the SBERT-Canberra method, that suggests scores based on similarity between the answers.

a 768-valued feature vector for each answer; these vectors are then stored for later access.. Given a new answer, A_n, a feature vector is similarly produced. In stage two of our method, all pairwise comparisons are then made between A_n and $A_{0...n-1}$, calculating Canberra distance [13] for each pair. Canberra distance, as opposed to other common distance metrics such as Euclidean or Cosine similarity, is a distance metric calculated over ranked lists. With this metric calculated for all pairs, the $A_{0...n-1}$ historic answers are then min-sorted to identify the most similar historic answer, A_s, to our new answer A_n. The score associated with A_s is then used as the prediction for the given answer A_n. The design to this approach is outlined in Figure 4.

As an additional component of this model, a "fallback" condition is implemented to be able to produce scoring estimates for problems where there are no historic answers on which to compare. In this case, we train a single multinomial regression model over all known answers, utilizing 1) the number of words in the answer and 2) the average length of each word in the answer; this model produces a probability distribution over 5 categorical labels (observing the 0-4 grading scale as a multinomial regression formulation). This one model is trained over all known answers and used then only in the case that no historic answers are available for the SBERT-Canberra model. This component is viewed as being part of our SBERT-Canberra approach.

3.3 Evaluation of SBERT

To evaluate our SBERT-Canberra scoring method, we utilize the same data and code presented in [9]. In that paper, the authors present the usage of a 2-parameter rasch model [24] (equivalent to a traditional item response theory, or IRT, model). The purpose of this model is to learn a separate parameter for each student and problem presented, representing student ability and problem difficulty, respectively. The intuition behind the use of this model is to evaluate an NLP automated scoring model based solely on its ability to interpret the words in each student answer. As the score of each answer is likely correlated with student ability (or knowledge) and problem difficulty (e.g. easy problems are likely to exhibit higher scores), such a model provides a reasonable minimum baseline of comparison. By adding a model's scoring estimates as covariates to the rasch model and then comparing the performance of such a model to the rasch model without covariates, we are able to observe the true value-added performance of the NLP scoring model.

Following the same procedure as conducted in [9], we are able to directly compare our Sentence-BERT method to those presented in that prior work. The models are trained and evaluated using a 10-fold student-level cross validation, and model performance is compared based on 3 performance metrics. First, treating the label as multinomial, rather than ordinal, AUC is caluclated using the method described in [10]. Second, the root mean squared error (RMSE), is calucalted over the ordinal prediction and label. Finally, a multi-class kappa is calculated, again using the multinomial label representation. The multinomial representations were argued to be appropriate due to the likely non-linear distribution of scores, while then RMSE provides insight into a more linear assumption of the data. Arguably an additional rank-based metric such as Spearman's Rho would also be a suitable metric of comparison, but is not included for more direct comparisons to the previous work.

3.4 Approach to Error Analysis of the SBERT-Canberra Method

In evaluating the SBERT-Canberra method, it is important to explore limitations of the approach in order to identify where the model does well and where it may yet improve through future iteration. As such, we also conduct an exploratory error analysis of the method using the data

Table 3: Rasch Model Performance compared to the models developed in Erickson et al.[9]

Model	AUC	RMSE	Kappa
Current Paper			
Rasch* + SBERT-Canberra	**0.856**	**0.577**	**0.476**
Erickson et al. 2020			
Baseline Rasch	0.827	0.709	0.370
Rasch + Number of Words	0.829	0.696	0.382
Rasch* + Random Forest	0.850	0.615	0.430
Rasch* + XGBoost	0.832	0.679	0.390
Rasch* + LSTM	0.841	0.637	0.415

*These rasch models also included the number of words.

collected from the QUICK-Comments pilot study. Toward this, we observe two regression models that observe absolute model error as a dependent variable. By exploring characteristics of student answers in the context of this modeling error, we can observe which aspects correlate most with higher prediction error. Similarly, we apply then a multi-level model to observe which of student-, problem-, and teacher-level identifiers most explains any observed modeling error.

3.4.1 Uni-level Linear Model

The uni-level linear model is based on student answer level characteristics. The student answer level characteristics are comprised of a set of six answer-level features extracted from the student open response data. These features are listed in Table 2. In calculating these features, the answer is first tokenized using the Stanford NLP tokenizer[16], dividing each textual answer into smaller tokens. For example, if the response to a particular problem is "I got 2/9 by dividing by 4", a simple tokenizer splits this response text by spaces which would give the list of tokens as: ("I", "got", "2/9", "by", "dividing", "by", "4"). Then from the tokenized data, we separate the tokens consisting of either digits or mathematical symbols. The number of such tokens is divided by the total number of tokens to calculate the equation percentage[3]. The average equation percentage calculated by the procedure mentioned above is 27% across the entire dataset. For calculating the length of the answer text, we count the total words in the text simply by splitting them by space. The average length of answers across the dataset is 10.39. Similarly, within each response, the number of numeric digits (i.e. Numbers count) and number of operator characters (i.e. Operators count) are counted independent of the tokens.

ASSISTments[11] allows students to upload images as part of the response to open-ended questions; this is most commonly a picture taken of work done on paper. The response text in such cases includes the URL of the uploaded image to the system. About 15% of the total responses in the dataset contains images. Some of such responses are entirely images, whereas in others, some text is provided as context. Since these scoring models are not yet designed to support images, we hypothesize that the images' presence contributes significantly to the modeling error.

A simple linear regression model is fit to the pilot study student answers, observing absolute model error as the dependent variable. This value is calculated by simply subtracting the predicted score from the teacher-provided label (as a linear label), and taking the absolute value. In this case, a value of 0 would indicate a correct estimate, while higher values (up to 4) represent greater prediction error; we do not differentiate between under- and over-predicting in this analysis.

3.4.2 Multi-level Linear Model

The uni-level linear model observes features that describe characteristics of the student responses, but as described in Section 3.1, modeling error may not be confined to just characteristics of the responses themselves. It is very likely that modeling error can be attributable to other external factors at the student-, problem-, and teacher-levels.

To explore this possibility, we apply a multi-level linear model observing the student answer characteristics as fixed effects, and student, problem, and teacher identifiers as three separate level-2 random effect variables. As it is the case that the same student may write multiple answers within our data, this structure is similar to that of a repeated-measure analysis.

$$\begin{aligned} abs(\text{model error}) = &\text{Answer Covariates} \\ &+ (1|\text{student identifier}) \\ &+ (1|\text{problem identifier}) \\ &+ (1|\text{teacher identifier}) \end{aligned} \quad (1)$$

Again observing absolute prediction error as the dependent variable, this analysis will be able to answer 1) whether the majority of explainable variance exists at the student-answer level or at a higher level, and 2) which of student-, problem-, and teacher-level identifiers most explains variance in our modeling error (e.g. which of these identifiers is most correlated with the error). The equation, expressed as its R code formulation, is reported as Equation 1.

[3]We acknowledge that this feature is a misnomer as it includes numeric terms, operators, and expressions as well as equations, but chose this feature name for sake of brevity.

Table 4: The resulting model coefficients for the uni-level linear regression model and random and fixed effects of the multi-level linear model of absolute error.

4. RESULTS

4.1 SBERT Model

The results of the SBERT model is compared directly to the results from Erickson et al.[9] as shown in Table 3. As can be seen in that table, the SBERT-Canberra method outperformed the baseline as well as all previous models across all three metrics. While the difference in AUC values between our method and the previous best approach is notably small, the difference in both RMSE and Kappa appears to be comparatively larger. To interpret these two metrics, these results suggest that we should expect teachers to agree with our method's estimates 47% of the time accounting for random chance, and is likely to be wrong by just over half a grade-point on average. This also does suggest, however, that there is still plenty of room for improvement of these models.

What is also worth noting from the results of Erickson et al. [9], is the high performance of the baseline rasch model. This emphasizes the difficulty of this NLP modeling task in that the baseline model is using nothing other than the student and problem identifiers; it is able to seemingly predict teacher-provided scores with an AUC above 0.8 without using any part of the student response; there is only a 0.03 AUC difference between that baseline model and our current proposed method. This suggests that these external factors may be explaining a large portion of the student scores, and may subsequently explain a large portion of our prediction error.

4.2 Error Analysis of SBERT

In exploring this further, the results of the error analysis of the SBERT-Canberra method are presented in Table 4. It is found that the uni-level linear model explains 38.6% of the variance of the outcome as given by r-squared. Out of the six student answer-level features, nearly all were found to be statistically reliable predictors of model error; in verifying these results, it was found that all included covariates exhibited inter-correlations less than 0.3 (suggesting a moderately low impact of multicollinearity potentially skewing the interpretation of these results). In close examination of the coefficients of these features, however, despite being statistically reliable, many are found to be close to 0, suggesting a very little meaningful correlation with the modeling error. This is not the case, however, for two of these variables, Equation Percent and Presence of Images, we see a more meaningful coefficient. This suggests, due to the direction of this value, that the presence of mathematical elements as well as the presence of images (unsurprisingly) both correlate with higher prediction error. It further follows, then, that further improvements to the SBERT-Canberra method should explore methods of better representing and accounting for these mathematical terms in student responses; similarly, though likely much more difficult, incorporating an aspect of image recognition could be another area worth exploring.

In regard to the multi-level linear model, accounting for student, problem, and teacher identifiers each as random effects, we see that the inclusion of these level-2 factors explains some of the impact of the fixed effects (also in Table 4). Here it is found that all but two of the fixed effects are statistically reliable. It is also found that the magnitude of the coefficients for the Equation Percent and Presence of Images is also reduced. This suggests that, perhaps, the student and/or problem identifiers partially explain these correlations (some problems may be more likely to have responses with images or mathematical terms in them, or some students may be more inclined to use images or such terms more than others). What is worth noting, however, is that it was found that the level-2 variables account for 55.5% of the variance of the outcome. This suggests that a majority of the modeling error can be explained by these factors that are external to the student answers.

Looking at the variance of the random effects, it can be seen that the problem level identifiers contribute most in terms of explaining the variance of the outcome. It is certainly the

case that the SBERT-Canberra method is accounting for each individual problem in producing its estimates (e.g. it only observes historic answers within each unique problem), but it would seem that there are other problem-level factors that are not being accounted for within this approach.

5. LIMITATIONS AND FUTURE WORK

In regard to our approach as well as in light of our findings, there are several limitations and opportunities for future directions. While the SBERT-Canberra approach, utilizing sentence-level embeddings, outperforms the previously-developed models in predicting scores for open responses, the difference in AUC is rather small; the fact that the method produces a classification (as opposed to a probability as is often the case with such models) likely impacts its AUC performance. The manner in which the method makes its prediction can be considered a greedy approach in that only the closest historic answer is used to predict the score. Instead, a weighted vote approach using all historic scores (or a subset of similar scores above an identified threshold) may improve the model by allowing for some degree of uncertainty. Similarly, the use of the word count model as a fallback may further be improved; while it was the case that there were very few instances of problems not having enough data within the cross validation, improving this fallback method may help to improve the model when applied in practical settings where the "cold start" problem is more prevalent; as the method currently relies heavily on having a sufficiently-sized pool of human-scored historic answers, future research can focus on utilizing unlabeled student answers or exploring other unsupervised methods that may additionally support these methods in cases where labeled data is scarce.

While the SBERT-Canberra model performed arguably well, the error analysis revealed several areas where this approach, as well as others, may focus in future works. Most notably, as highlighted, the use of mathematical expressions and terms were found to be correlated with higher error; improving the representation of such elements can certainly be addressed in future work. A limitation of this, however, is that both models left variance unexplained in the outcome. We chose to look at these factors based on hypotheses and anecdotal observations, but there may be other large factors that can explain more of the error that we are seeing. Subsequent works could conduct more thorough surveys of both answer-level and higher-level factors. Future works can also explore additional model structures and language features that may lead to improvements to performance. The analyses presented in this work, however, can act as a baseline to further evaluate if future iterations of our approach truly improve upon these identified areas.

It is also the case that this work focuses only on models that predict numeric assessment scores, while we strongly believe that it will be equally, if not more important to additionally develop methods to suggest or generate directed feedback for for these student answers; teachers use textual feedback messages to offer constructive guidance to students, but it is often a very time-consuming task to write these messages for each students' answer. We believe that the SBERT-Canberra approach can be extended to support this task as well, where such a model may be able to recommend feedback to new student answers that has been previously given to an identified similar historic answer. Future work is intended to explore these methods further for such feedback-suggestion tasks.

6. CONCLUSION

In this paper, we have presented a novel approach in addressing and formulation of the problem of automating the assessment of student open-ended work. We have illustrated that our SBERT-Canberra method outperformed a previously-established benchmark, but still exhibits areas where it may be able to improve. Through the conducted error analysis, we have identified areas where more advanced methods of image processing and natural language processing (or math language processing), may lead to further improvements. With all of this, however, it was also identified that problem-level features appear to be most impactful in explaining the variance of modeling error; this is particularly surprising as variations in teacher grading were previously hypothesized to be a larger factor in this context.

With the findings from the study, our goal next is to use them to overcome the limitations mentioned above and guide our focus on improving the methods for assessment of open-ended questions in mathematics. It is the goal of this work to act as a step toward building better teacher supports for these types of open-ended problems, as well as provide others with guidance toward the same or similar goals.

ABSTRACT

With the emergence of MOOCs, it becomes crucial to automate the process of a course design to accommodate the diverse learning demands of students. Modeling the relationships among educational topics is a fundamental first step for automating curriculum planning and course design. In this paper, we introduce *Topic Transition Map* (TTM), a general structure that models the content of MOOCs at the topic level. TTMs capture the various ways instructors organize topics in their courses by modeling the transitions between topics. We investigate and analyze four different methods that can be exploited to learn the Topic Transition Map: 1) Pairwise Constrained K-Means, 2) Mixture of Unigram Language Model, 3) Hidden Markov Mixture Model, and 4) Structural Topic Model. To evaluated the effectiveness of these methods, we qualitatively compare the topic transition maps generated by each model and investigate how the Topic Transition Map can be used in three sequencing tasks: 1) determining the correct sequence, 2) predicting the next lecture, and 3) predicting the sequence of lectures. Our evaluation revealed that PCK-Means has the highest performance in the first task, HMMULM outperforms other methods in task 2, while there is no winning in task 3.

Keywords

Topic Transition Map, Topic Transition, Word Distribution, Mixture Model, Hidden Markov Model, Clusters, Sequencing Tasks.

1. INTRODUCTION

For many decades, the process of creating courses has been a manual task that needs to be carefully managed by instructors and experts. However, with the recent advances in technologies and the emergence of Massive Open Online Courses (MOOCs), it becomes critical to automate the process of course design to accommodate the heterogeneity of online students and their diverse needs. According to [32], learning on demand is considered one factor that causes the high dropout rate in MOOCs. Learners have different learning demands depending on their motivations and goals. For instance, learners may seek knowledge about an interdisciplinary domain and hence need to learn modules from courses in several areas. This problem requires adopting a model in which MOOCs are used as modularized resources, rather than a set of pre-designed static courses. A crucial first step toward developing such a model is the automation of course plan design by sequencing lectures among different courses.

The main principle in designing the curriculum of any course is to organize course content according to some relations between topics. For instance, to help students to learn the materials, instructors carefully organize lectures as a sequence, based on the difficulty levels of topics [10, 27, 1] as well as the dependency relations between topics [11, 21, 23, 1]. The fundamental sequential structure of a course design is to place topics that are easy or prerequisite in earlier lectures while more advanced and dependent topics are taught in later lectures [1]. Consequently, modeling the relatedness among educational topics is a very crucial first step for automating curriculum planning and course design.

Modeling the content structure of MOOCs has recently attracted much research. Most of the current research has focused on modeling the prerequisite relationships between courses [29, 15], between lectures or segments of lectures [6, 7], or between concepts discussed within or across courses [3, 14, 17, 29, 15]. Using concepts to model MOOCs' content can be easily generalized to capture the relations in the concept space. However, because concepts are represented as keywords or phrases, it is hard to capture the different levels of granularity between lectures and courses. In addition, modeling prerequisite relationships between concepts cannot capture the various learning paths accommodated by different courses.

In this paper, we introduce the **Topic Transition Map**, a general structure that models the educational materials at the topic level. We model a course as a set of topics, and each topic is a set of concepts. Modeling content at the topic level is a more natural way to design custom course plans. We can think of a course as a path in the generalized Topic Transition Map. Thus, designing a new course becomes a task of identifying a path in the Topic Transition Map. Additionally, we investigate four methods that can be leveraged to construct the Topic Transition Map: *Pairwise Constrained K-Means* (PCK-Means) [2], *Mixture of Unigram Language Model* (MULM), *Hidden Markov Mixture Model* (HMMULM), and *Structural Topic*

Model (strTM) [24]. We analyze and compare the Topic Transition Maps learned by these methods by studying how to exploit the Topic Transition Map in three sequencing tasks: 1) determining the correct sequence, 2) predicting the next lecture, and 3) predicting the sequence of lectures. To the best of our knowledge, we are the first work to introduce and investigate the use of Topic Transition Maps in modeling MOOCs content and sequencing lectures.

To evaluate the effectiveness of all methods, we use real MOOCs from three different domains: Python, Structural Query Language, and Machine Learning Clustering algorithms. Our evaluation revealed that while the PCK-Means has the highest performance on the task of finding the best sequence from a list of possible sequences, the HMMULM achieves the best performance on the task that predicts the next lecture in the sequence. Additionally, all methods perform similarly in the task of predicting the whole sequence with MULM has the lowest performance as it sometimes cannot predict the whole sequence. In addition to comparing various models in sequencing tasks, we visualize the Topic Transition Maps generated by different methods to qualitatively compare the resulted topic transition maps. We found that PCK-Means has extracted more meaningful topics with the best word distributions that clearly explain each topic.

The rest of the paper is organized as follows. In section 2, we present some of the related work. Section 3, defines the topics and topic transitions and states some applications of the topic transition maps. In section 4, we formally define our problem before describing the four different methods we exploit to construct the topic transition maps in section 5. Section 6 elaborates on our approach for the evaluation and the analysis of various models. Finally, we conclude our work in section 7.

2. RELATED WORK

Most of the work that models the content of MOOCs has focused on capturing the prerequisite relationships using different levels of granularity such as courses [29, 15], lectures or segments of lectures [6, 7], or concepts discussed within or across courses [3, 14, 17, 29, 15]. Modeling the relations between courses, lectures, or seqments of lectures is restricted to these units and cannot be generalized. While modeling dependency relations between concepts is considered a general structure that captures the required concepts before learning any concept, prerequisite relations cannot model the various learning paths accommodated by different courses. ALSaad and Alawini [2] have addressed this problem by proposing the precedence graph that captures the similarities and variations of learning paths among different courses. We build on their work and introduce the **Topic Transition Map** that maps each lecture to a topic and leverages the sequences of lectures among courses to capture the topic transitions pattern and hence the likelihood of such a transition. The main difference between the Topic Transition Map and the precedence graph is that Topic Transition Map models self transitions between a topic and itself and also captures how likely each topic to be the first topic in courses. While ALSaad and Alawini [2] have investigated the use of PCK-Means in modeling the precedence graph, in this paper, we explore three more methods in addition to PCK-Mean, namely MULM, HMMULM, and strTM, for modeling Topic Transition Maps. We also examine the impact of the learned topic transition maps on three different sequencing tasks. We believe that we are the first work that examines the use of topic transitions modeled from existing MOOCs to learn how to sequence new courses.

Some research has investigated the use of prerequisite relations between concepts to construct and sequence learning units [1, 16]. Both studies [1, 16] have developed supervised approaches based on feature engineering that extracted features from some external knowledge such as Wikipedia [1] and DBpedia [16] to infer the prerequisite relations between concepts. Our work is different as instead of modeling the prerequisite relations between concepts using supervised approaches, we model the Topic Transition Map or the various paths between topics using unsupervised methods, where a topic is a set of concepts. In addition, our methods rely only on the content of MOOCs without using any external knowledge. While Agrawal et al. [1] used the concept dependency graph to organize concepts to construct learning units and then sequence the learning units, we use lectures from existing MOOCs and investigate the impact of the learned transitions between topics to sequence lectures.

The most relevant research to our study is the work by Shen et al. [22]. Shen et al. [22] have proposed a method for linking similar courses to construct a map of lectures connected by two types of relations: similar and prerequisite. The constructed map only captures the similarity and prerequisite relations between certain units (lectures) and is not generalized to other lectures and thus cannot be used to predict the sequence of new lectures. In this paper, we map lectures to topics and construct the Topic Transition Map that depicts the precedence relations between topics and hence not tied with any specific units. Having a generalized Topic Transition Map can help in finding the sequence of lectures or predict the next lecture in the sequence as we discuss in section 6.2.

Another related line of research is the work on structural topic modeling by the Natural Language Processing, NLP, Community. In NLP, topic transitions have been used to model latent topical structures inside documents by assuming each sentence is generated from a topic where topics satisfy the first order Markov property [12, 25]. While Gruber et al. [12] only modeled the transition between topics as a binary relation (either remain on the current topic or shift to a new topic with a certain probability), Wang et al. [25] have developed a Structural Topic Model called strTM to explicitly model the topic transitions as probabilities that capture how likely one transits from a topic to another. Modeling transitions have been used in many applications related to NLP such as sentence ordering [25], topic segmentation [9], and multi-documents summarization [28]. In this paper, we investigate the use of topic transitions on modeling the topical structures in MOOCs by assuming a lectures is generated by one topic and use the sequences of lectures to learn the transitions between topics. We also explore the impact of using the Topic Transition Map to sequence lectures in three different sequencing tasks.

3. TOPIC TRANSITIONS

Before defining the topic transitions, it is important to briefly explain our representation of topics used in this paper. Similar to the definition of topics in the literature of the topic modeling research [5, 13], we define a topic as a distribution of concepts where concepts with higher probabilities tend to explain or characterize the topic. Concepts can be represented as words or phrases of words [3, 18, 26]. Each lecture is a composition of concepts and hence can be mapped to some topics. Depending on the length of lectures, lectures can cover one or more topics. Longer lectures usually cover more topics than shorter lectures. For example, traditional university lectures tend to be more elaborated and have longer duration than MOOCs lectures, which are usually concise and short in length. Therefore, the number of topics per lecture discussed in MOOCs is less than that of traditional university lectures. In this paper, since our work focus on learning the topic transitions from MOOCs, we assume

that each lecture is mapped only to one topic. This assumption is reasonable as lectures in MOOCs are concise and short in length. Having this assumption is also very useful as it helps in leveraging the sequences of lectures to learn the relations between topics.

A topic transition captures the precedence relations between topics. In other words, it means how likely instructors move or transit from one topic to another in the course delivery. It models the various ways of how instructors dynamically assemble concepts from the concepts space in order to construct the study plan of their courses. For instance, some instructors decide to start their *Python* course by explaining the topics: data types, conditional statements, loops, and then reading and writing from files. Other instructors may choose a different order, such as conditional statements, loops, string, and then lists. By leveraging the sequences of lectures from multiple courses, we can infer the latent topics of each lecture and hence model the common transition patters shared by multiple courses as well as the variations of different transitions or paths. To determine the strength or how common that transition is, each transition is attached with a score or a probability. For example, given the topics in Computer Science Programming: "Conditional Statements", "Loops", and "Arrays". It is more likely that instructors will explain the topic "Conditional Statements" immediately before the topic "Loops" and thus the topic transition score between them would be higher than the transition score between the topic "Conditional Statements" and the topic "Arrays".

Learning the topic transitions can be the initial block to facilitate several useful applications that can support modern learning. For instance, we can use the Topic Transition Map to extract the most common paths of topics in the field or explain the topic space in the current MOOC offerings. Learners can use transition maps to get more insights about the structure of topics in MOOC offerings. On the other hand, instructors can use these maps to improve their course offerings by examining the topic structure of related courses.

One important application of the Topic Transition Map is to support automatic curriculum planning and course design. Since courses consist of topics, learning the relations between topics would be the initial step to understand how likely instructors transit from one topic to another. We can think of a course as a path in the generalized Topic Transition Map. Thus, designing a new course becomes a task of identifying a path in the Topic Transition Map. In this paper, we analyze how can we use the learned topic transitions to sequence new courses.

4. PROBLEM FORMULATION

In this section, we formally formulate our problem. Given a set of courses $C = \{X_1, X_2, X_3, \ldots, X_N\}$ from a particular domain, where N is the total number of courses. We assume that courses in C are similar and hence have some content overlaps between them and also have the same difficulty level (e.g. Beginner, Medium, or Advance). A course X_i is represented as an ordered list of lectures $X_i = [x_{i1}, x_{i2}, \ldots, x_{i|X_i|}]$, where $|X_i|$ is the total number of lectures in the course X_i. Each lecture is a composition of concepts represented in some narrative way. In this paper, we assume a concept as a single word and hence lectures are represented using a bag-of-word representation.

Given the number of topics M, our goal is to map each lecture to a topic and leverage the sequences of lectures to learn topic transitions and construct the Topic Transition Map. The Topic Transition Map is represented as a matrix $\mathbf{A}$, where $\mathbf{A} \in \mathbb{R}^{M \times M}$. Each entry a_{ij} of the matrix $\mathbf{A}$ represents the likelihood of the transition from topic i to topic j. It reflect how common the precedence relation from topic i to j in the dataset courses. In addition to the Topic Transition Map, we also aim to learn the probability of each topic being an initial topic in courses. We denote the initial probability of each topic as a vector π, where $\pi \in R^M$. Along with the Topic Transition Map and the initial probability of each topic, it is important to model the word distribution of each topic, which represented as a matrix $\mathbf{B} \in \mathbb{R}^{M \times V}$, where V is the vocabulary size.

5. MODELING TOPIC TRANSITIONS

In this section, we explain the four different models we exploit to capture topics and Topic Transition Maps.

5.1 Pairwise Constrained K-Means

PCK-Means clustering algorithm [4] is a variation of the standard K-Means algorithm. To cluster instances, PCK-Means incorporates distance between points as well as pairwise constraints to guide the clustering process. Since the purpose of clustering is to capture topic transition patterns across courses, using PCK-Means helps to restrict the clustering process to cluster lectures across courses instead of within courses [2]. To guide the clustering, PCK-Means uses two types of constraints: **Must-Link** and **Cannot-Link**. Must-Link constraint determines lecture pairs that need to be clustered together, while Cannot-Link constraint specifies pairs that should not be grouped into the same cluster. To find the clusters, PCK-Means uses an objective function that minimizes both: 1) the distance between points (lectures) and the cluster centroid, and 2) the penalty costs of violating the constraints. For more information about PCK-Menas, please refer to [4].

Similar to ALSaad and Alawini [2], we use PCK-Means to build the Topic Transition Map $\mathbf{A}$. We first construct the list of Must-Link and Cannot-Link constraints to clusters lectures based on their content similarity into clusters. We assume that each cluster forms a topic and hence we need to learn the word distributions of each topic along with topic transitions. We link clusters by using the precedence relations between adjacent lectures and capture the strength of the transition by accumulating the frequency of transitions. To find the word distribution of each cluster or topic in the matrix $\mathbf{B}$, we accumulate the vector representations of each lecture that belongs to the same cluster. For more information, please see [2].

In order to estimate the initial probability π for each topic, we simply count the number of times of each topic being the first topic in the set of courses C. Then we do normalization to find the probability.

5.2 Mixture of Unigram Language Models

To capture topics, we use a mixture model of M unigram language models (MULM) with a bag-of-words representation. The mixture model is a generative probabilistic model that has been used for documents clustering. Thus, it will help in clustering lectures based on their topics, where each lecture belongs only to one cluster or one topic. In the mixture model, to generate a document, first one needs to choose the topic of the document according to the probability $P(\theta_i)$, where M is the number of topics, and then generate all the words in the document using the probability $P(w|\theta_i)$. According to the model, the likelihoods of a document x and the corpus C are calculated as follows:

$$P(x|\lambda) = \sum_{i=1}^{M} P(\theta_i) \prod_{w \in V} P(w|\theta_i)^{c(w,x)} \quad (1)$$

$$P(C|\lambda) = \prod_{j=1}^{N} P(x_j|\lambda) \tag{2}$$

To estimate the model parameters $\lambda = (\{\theta_i\}, P(\theta_i))$, where θ_i is the word distribution of topic i from the matrix $\mathbf{B}$, we use Expectation-Maximization algorithm [8] to find the parameters that maximize the likelihood of the data:

$$\bar{\lambda} = \arg\max_{\lambda} P(C|\lambda) \tag{3}$$

After learning the parameters, we map each lecture to a cluster or topic by maximizing the following equation:

$$c = \arg\max_{z_i} P(x|z_i) \tag{4}$$

Using the mixture model can help in clustering lectures according to their topics, however; it will not capture the transition patterns between topics or the initial probability of each topic. Therefore, similar to the PCK-Means method, we leverage the sequences of lectures to calculate the score of topic transitions and construct the Topic Transition Map $\mathbf{A}$. Likewise, we count the number of times courses start with each topic and normalize the results to model the initial probability π.

5.3 Hidden Markov Mixture Models

Instead of separately clustering lectures and then learning the transitions between them, using a Hidden Markov Model would allow us to jointly learn the word distributions of each topic ($\mathbf{B}$), the transition probabilities between topics ($\mathbf{A}$) as well as the initial probability of each topic (π).

The Hidden Markov Model, HMM, is a probabilistic graphical model that describes the process of generating a sequence of observable events according to some hidden factors [20]. It simulates how the real world sequence data is generated from hidden states. Particularly, it consists of two stochastic processes: 1) invisible process, and 2) visible process [30]. In HMM, invisible process consists of hidden states whereas visible process is observed sequence of symbols that are drawn from the probability distributions of the hidden states. Figure 1 demonstrates the HMM model. As you can see from Figure 1, each observable event in the sequence are generated from a hidden state and observations are conditionally independent given the hidden state. You can also notice that the hidden states form a Markov chain where each hidden state depends only on the previous state such as Z_{t+1} depends on Z_t.

To control the process of generating the observed sequences from hidden states, HMM has three parameters: π, $\mathbf{A}$, and $\mathbf{B}$. The first parameter, $\pi = \pi_1, \pi_2, \ldots, \pi_M$, is the initial probability distribution of each hidden state. The parameter π determines the probability of the Markov chain to start at each state and hence controls which state can be chosen as an initial state for the observed sequence. The second parameter, $\mathbf{A} \in \mathbb{R}^{M \times M}$, is the transition probability matrix that specifies how likely the model can transit from one state to another, denoted by $P(Z_{t+1}|Z_t)$ in Figure 1. The third parameter, $\mathbf{B} \in \mathbb{R}^{M \times V}$, is the emission probability matrix, where V is the total number of distinct symbols. It determines the likelihood of each state to produce each symbol, denoted by $P(X_{t+1}|Z_{t+1})$ in Figure 1. For example, to generate a sentence, a sequence of words would be drawn from the HMM model according to the three parameters π, $\mathbf{A}$, and $\mathbf{B}$.

In MOOCs, we only observe courses, where courses are sequence of lectures, while the topics of lectures and the transition between them are invisible or latent. Therefore, HMM would be a great model to simulate the generation process of courses and hence infer the latent states that contribute in the evolution of these lectures. In HMM, each hidden state generates only one symbol or word (see Figure 1). As our goal is to capture topic transitions using sequences of lectures as observed data, we map each lecture to a topic and assume each hidden state generates a lecture instead of a word. Our revised HMM assumes that each hidden state produces one lecture where each lecture is a bag-of-words. We ignore the sequence of words in lectures since the order of the words would not contribute to capturing the topic of each lecture. Figure 2 depicts the HMMULM utilized to capture the content of MOOCs.

In order to capture both the lectures' topics and the transitions between them, we combine the mixture model (MULM) with HMM, and we call the new model Hidden Markov Mixture of Unigram Language Model (HMMULM). To do that, we assume the Markovian assumption between topics where in the generation process, the choice of the next topic depends only on the current topic. Even though, the choice of the topic in the course delivery depends on the previous topics discussed so far, this simplified assumption makes sense due to the locality of reference property [1] of course design. Based on this property, when an instructor designs a course, a dependent lecture should appear as soon as possible after the prerequisite lecture to reduce students comprehension burden. Therefore, assuming the dependency between adjacent lectures not only simplifies the model but also aids in capturing the transitions between highly related topics. By combining the HMM with mixture model the likelihood of generating a course is as follow:

$$\begin{aligned}
P(X|\lambda) &= \sum_{all\ Z} P(Z|\lambda) P(X|Z,\lambda) \\
&= \sum_{all\ Z} P(z_1) P(x_1|z_1) \prod_{t=2}^{T} P(z_t|z_{t-1}) P(x_t|z_t) \\
&= \sum_{all\ Z} P(z_1) \prod_{w \in V} P(w|z_1)^{c(w,x_1)} \\
&\prod_{t=2}^{T} P(z_t|z_{t-1}) \prod_{w \in V} P(w|z_t)^{c(w,x_t)} \\
&= \sum_{i=1}^{M} \sum_{j=1}^{M} \pi(z_1 = s_i) \prod_{w \in V} B(z_1 = s_i, w)^{c(w,x_1)} \\
&\prod_{t=2}^{T} A(z_{t-1} = s_i, z_t = s_j) \prod_{w \in V} B(z_t = s_j, w)^{c(w,x_t)}
\end{aligned} \tag{5}$$

To estimate the HMMULM parameters $\lambda = (\pi, A, B)$, we use a modified version of Baum-Welch algorithm in order to model the observation sequences as a multidimensional categorical events. Following the work [19], we derived the equations of E-step and M-step to train the model and infer the transition probability between topics. In the E-step, we use the equations:

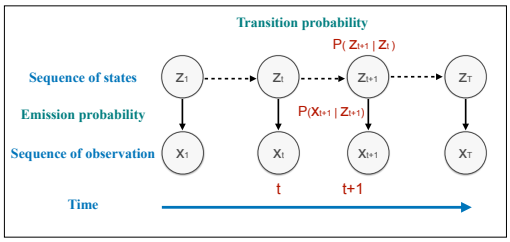

Figure 1: *The graphical model of HMM.*

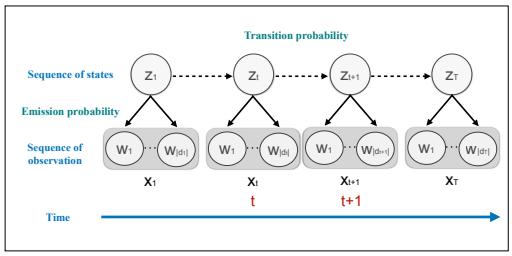

Figure 2: *The graphical model of HMMULM used to model the content of MOOCs.*

$$\gamma_t(i) = P(z_t = s_i|X, \lambda) = \frac{\alpha_t(i)\beta_t(i)}{\sum_{j=1}^{M}\alpha_t(j)\beta_t(j)} \quad (6)$$

$$\xi_t(i,j) = P(z_t = s_i, z_{t+1} = s_j|X, \lambda) = \frac{\alpha_t(i)A_{ij}\beta_{t+1}(j)\prod_{w\in V}B_j(w)^{c(w,x_{t+1})}}{\sum_{i=1}^{M}\sum_{j=1}^{M}\alpha_t(i)A_{ij}\beta_{t+1}(j)\prod_{w\in V}B_j(w)^{c(w,x_{t+1})}} \quad (7)$$

In the M-step, the following equations are used to choose the parameters that maximize the likelihood of the observed sequence of lectures:

$$\pi(i) = \gamma_1(i) \quad (8)$$

$$A_{ij} = \frac{\sum_{t=1}^{T-1}\xi_t(i,j)}{\sum_{t=1}^{T-1}\gamma_t(i)} \quad (9)$$

$$B_i(w) = \frac{\sum_{t=1}^{T}\gamma_t(i)c(w,x_t)}{\sum_{v=1}^{V}\sum_{t=1}^{T}\gamma_t(i)c(v,x_t)} \quad (10)$$

For more information about Baum-Welch algorithm, please see [20]. It is clear that the E-step and M-step equations are very similar to the standard HMM except that instead of emitting one symbol, HMMULM emits one lecture represented as a bag-of-words.

5.4 Structural Topic Model

The Structural Topic Model (StrTM) [25] is another probabilistic graphical model that functions very similar to HMMULM. It has been used to model the latent topical structures inside documents. Like HMMULM, it models topics and their transitions as hidden states that emit lectures as bags-of-words. Unlike HMMULM, strTM assumes each lecture as a mixture of content topics and functional topic. Functional topic, denoted by z_B, is used to filter out document-independent words that models the corpus background (or general terms) [31]. Each word in the lecture is either generated by one of the content topics or the functional topic:

$$w \sim \theta P(w|\beta, z_i) + (1-\theta)P(w|\beta, z_B) \quad (11)$$

where θ is the controlling parameter. According to strTM, the probability of lecture x_j being generated by some topic z_i is:

$$P(x_j|z_i) = \prod_{w\in V}[\theta P(w|\beta, z_i) + (1-\theta)P(w|\beta, z_B)]^{c(w,x_j)} \quad (12)$$

Another difference between strTM and HMMULM, is that strTM assumes the transition probabilities $\mathbf{A}$ and the emission probability $\mathbf{B}$ are drawn from Multinomial distributions and use the conjugate Dirichlet distribution to impose a prior on the Multinomial distributions:

$$\alpha_z \sim Dir(\eta) \quad (13)$$

$$\beta_z \sim Dir(\gamma) \quad (14)$$

Where η and γ are the concentration hyper parameters that control sparsity of α_z and β_z respectively.

To estimate the parameters of strTM, we use the expectation-maximization algorithm as described by [25]. For more information about strTM, please refer to [25].

Table 1: *The dataset utilized in the experiment.*

Domain	# of Courses	# of Lectures	Avg # of Lectures
Python	21	460	22
SQL	15	247	16
ML	10	99	10

6. EVALUATION

In this section, we first demonstrate our dataset and the parameters settings. Second, we compare different models by studying the impact of topic transitions learned from various models on three lecture sequencing tasks. Finally, we qualitatively evaluate the topics and their transitions.

6.1 Dataset and Parameters Settings

We collected our dataset from real online courses using various MOOC platforms and in three different domains: Python, Structural Query Language (SQL), and Machine Learning Clustering algorithms (ML). Table 1 presents the statistic of the dataset. We use 75% of the data as a training set and 25% as a test set. To choose the number of topics in each domain, we manually inspected the dataset to choose the number of topics. The number of topics for Python, SQL, and ML were set to 13, 10, and 9 respectively.

Each course in the dataset is represented as a sequence of lecture video transcripts. We preprocess lecture transcripts by eliminating stop words and some rare terms. After cleaning the data, we constructed the bag-of-word vector representations of all lectures. We only use lecture transcripts to represent lectures; therefore, we only need to set two thresholds (K_1 and K_2) of the PCK-Means method in order to select the list of Must-link and Cannot-link constraints. Since we do not have labeled data we chose the thresholds that maximize

Table 2: *The performance of **Task 1**: Finding the correct sequence using the permutation method. It is clear that PCK-Means achieves the highest performance.*

Dataset	Measures	Methods				
		Cosine	PCK-Means	MULM	HMMULM	strTM
Python	kendall's $\tau(\sigma)$	0.60	**0.73**	0.49	0.66	0.54
	Dir-P	0.37	**0.50**	0.43	0.28	0.31
	Undir-P	0.52	**0.56**	0.50	0.44	0.35
	Lev-Sim	0.60	**0.63**	0.45	0.49	0.50
SQL	kendall's $\tau(\sigma)$	0.58	**0.59**	0.58	0.55	0.41
	Dir-P	**0.46**	0.43	0.40	0.36	0.41
	Undir-P	**0.67**	0.58	0.49	0.44	0.41
	Lev-Sim	0.53	**0.57**	0.54	0.49	0.37
ML	kendall's $\tau(\sigma)$	0.68	**0.75**	0.63	0.58	0.64
	Dir-P	0.34	0.34	**0.44**	0.34	0.43
	Undir-P	0.52	0.52	**0.57**	0.41	0.53
	Lev-Sim	0.61	**0.65**	0.55	0.43	0.53

the *Silhouette Coefficient* clustering measure using the training data. We set $K_1 = 0.55$ and $K_2 = 0.004$ for Python, $K_1 = 0.8$ and $K_2 = 0.01$ for SQL, and $K_1 = 0.55$ and $K_2 = 0.01$ for ML. To set the hyper parameters of strTM method, we used a grid search and chose the values that maximize the likelihood of the training data. We set $\theta = 0.2$, $\gamma = 0.3$, and $\eta = 0.6$ for Python, $\theta = 0.1$, $\gamma = 0.3$, and $\eta = 0.1$ for SQL, and $\theta = 0.1$, $\gamma = 0.1$, and $\eta = 0.6$ for ML.

6.2 Sequencing Tasks

In this experiment, our goal is to compare the topic transitions modeled by different methods in three tasks: 1) Finding the correct sequence of lectures, 2) Predicting the next lecture given a sequence of lectures, and 3) Predicting the sequence of a list of lectures where the first lecture in the sequence is given. An example of real application for task 1 and task 3 is designing a new course plan by sequencing lectures before delivering them to students. However, task 1 and task 3 exploit two different techniques to find the sequence. In contrast, task 2 can be applied to recommend the next lecture to learners to customize their learning based on the history of lectures they already watched. In the evaluation, the purpose of each task is to compare different methods and evaluate the ability of the parameters (A, B, and π) of each model to find the correct sequence in the three different tasks.

6.2.1 Evaluation Measures

To compare different models, we use the sequences of lectures from courses in the test set as the ground truth sequences and exploit different measures to do the evaluation. First, we follow Wang et al. [25] and use kendall's $\tau(\sigma)$. Kendall's $\tau(\sigma)$ is an information retrieval measure that captures the correlation between two ranked list. It indicates how the predicted order differs from the ground truth where 1 means perfect match, -1 means total mismatch, and 0 indicates that the two orders are independent. Second, we use Levenshtein normalized similarity which is the opposite of Levenshtein normalized distance that measures the minimum number of edits (insertions, deletions or substitutions) required to transform the predicted sequence to the ground truth sequence. The goal is to find the sequence that has the Levenshtein normalized similarity close to 1 which indicates that the number of edits required is minimal. Third, we utilize the directed bigram precision (see equation 15) that captures the correctness of the order between adjacent lectures. The intuition behind using this measure is to evaluate whether the transition maps learned by different models have the ability to capture the correct direction order between topics and adjacent lectures. Finally, we use the undirected bigram precision shown in equation 16 to measure whether the transition map of each model can recognize adjacent lectures but incorrectly captured the direction between topics.

$$P_{Dir-bigram} = \frac{\#\ of\ correct(a \rightarrow b)\ in\ estimated\ sequence}{\#\ of\ correct(a \rightarrow b)\ in\ ground\ truth} \tag{15}$$

$$P_{Undir-bigram} = \frac{\#\ of\ correct\{a,b\}\ in\ estimated\ sequence}{\#\ of\ correct\{a,b\}\ in\ ground\ truth} \tag{16}$$

6.2.2 Task 1: Finding The Correct Sequence

To find the correct sequence of lectures, we follow the permutation method utilized by [25]. With courses that have large number of lectures, it is infeasible to find all the orderings of lectures. Therefore, when the number of the permutations exceeds 500, we randomly permutated 500 possible orderings of lectures as candidates. We ran the experiment 20 times for each method and recorded the average results.

In order to select the optimal sequence from the list of permutations in strTM and HMMULM, we follow Wang et al. [25] and choose the sequence that has the highest generation probability calculated as:

$$\bar{\sigma}(m) = \arg\max_{\sigma(m)} \sum_{Z} P(x_{\sigma[0]}, x_{\sigma[1]}, \ldots, x_{\sigma[m]}, Z|\lambda) \tag{17}$$

To choose the best sequence for MULM, we first find the best topic **c** that generates each lectures in the test set according to equation 4. After that, we select the sequence that has the highest likelihood

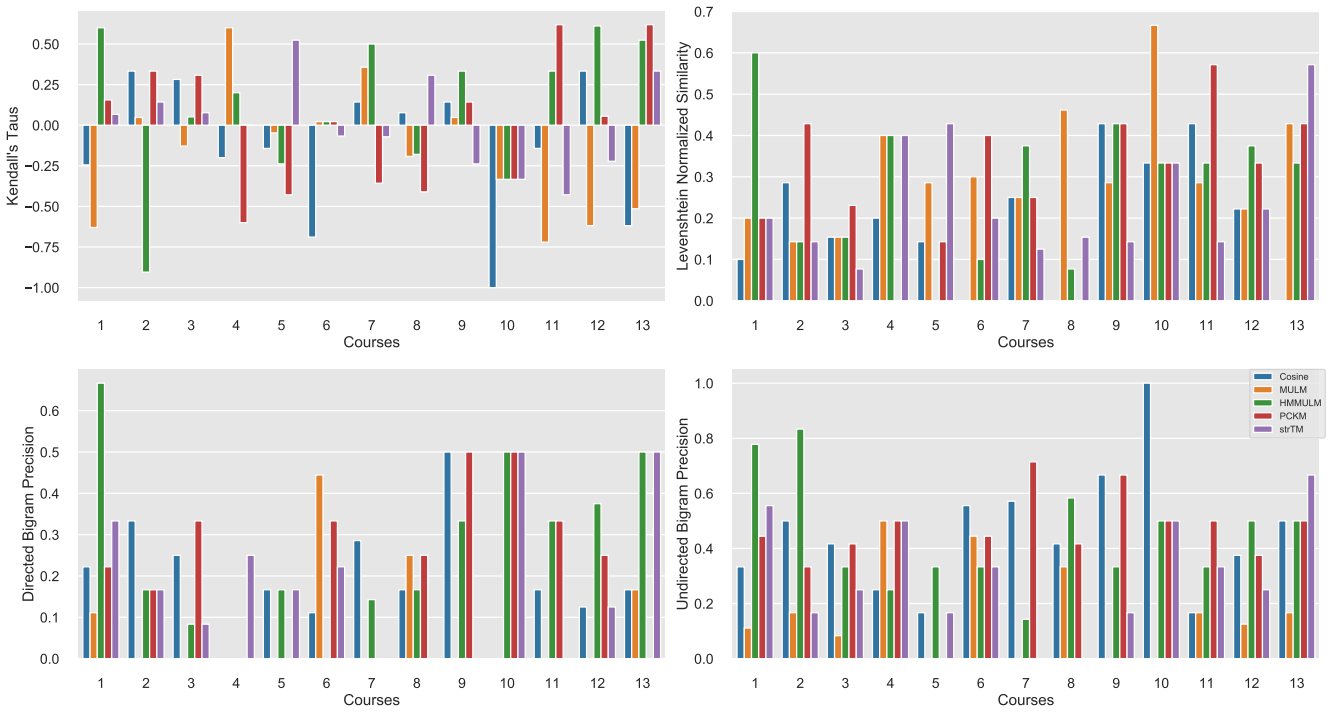

Figure 3: *The performance of different methods in **Task 3**: Predicting the whole sequence. All methods have comparable performance.*

based on the equation:

$$\begin{aligned}\bar{\sigma}(m) &= \arg\max_{\sigma(m)} P(C)P(X|C) \\ &= P(c_1)P(x_1|c_1)\sum_{i=2}^{|\sigma(m)|} P(c_i|c_{i-1})P(x_i|c_i)\end{aligned} \tag{18}$$

Since PCK-Means is a clustering method that minimizes the distance between lectures and clusters' centroids, we assign lectures x of the test set to the closest clusters z_i using Euclidean distances as shown in equation 19. Then, we select the sequence that maximizes the topic transitions between lectures in the sequence as well as minimizes the distance between adjacent lectures (see equation 20). The intuition behind that is to ensure the topic coherence between adjacent lectures and also reduces the gaps by minimizing the distance between them.

$$c(x) = \arg\min_{z_i} \|x - \mu_{z_i}\|^2 \tag{19}$$

$$\bar{\sigma}(m) = \arg\max_{\sigma(m)} \pi(c(x_1)) \sum_{i=2}^{|\sigma(m)|} A(x_{i-1}, x_i) - \|x_i - x_{i-1}\|^2 \tag{20}$$

As a baseline we accumulate the cosine similarity between adjacent lectures in the sequence and select the sequence in the permutations that has the highest similarity score to be the optimal sequence.

Table 2 summarizes the results of Task 1 for each method. We can notice that PCK-Means has the highest score in kendall's $\tau(\sigma)$ and Levenshtein normalized similarity in all datasets which indicates that PCK-Means has chosen the sequences that are very correlated to the ground truth sequences and need the minimal edits to be transformed to the ground sequences. However, PCK-Means only outperforms other models in the directed and undirected bigram precision in the Python dataset, indicating that it sometimes not able to capture the sequence between adjacent lectures.

Table 3: *The performance of **Task 2**: Predicting the next lecture. It is clear that HMMULM achienes the highest performance.*

	Accuracy		
Method	Python	SQL	ML
Cosine-Similarity	0.46	**0.56**	0.42
PCK-Means	0.45	0.49	0.47
MULM	0.41	0.34	0.37
HMMULM(Viterbi)	**0.52**	**0.56**	**0.60**
StrTM(Viterbi)	0.39	0.27	0.43

In general, it is clear that PCK-Means achieves the highest performance in most measures and almost in all the datasets. We think that combining the topic transitions with the Euclidean distance helps PCK-Means in finding the best sequence from the list of possible sequences.

6.2.3 *Task 2: Predicting The Next Lecture*

In task 2, each model predicts the next lecture given a sequence of lectures. We varied the length of the given sequence starting from one. As strTM and HMMULM are based on HMM, we utilized the Viterbi algorithm [20] to find the most probable sequence of hidden states or topics that generated the lectures in the given sequence. Then we greedily choose the next probable lecture in the sequence

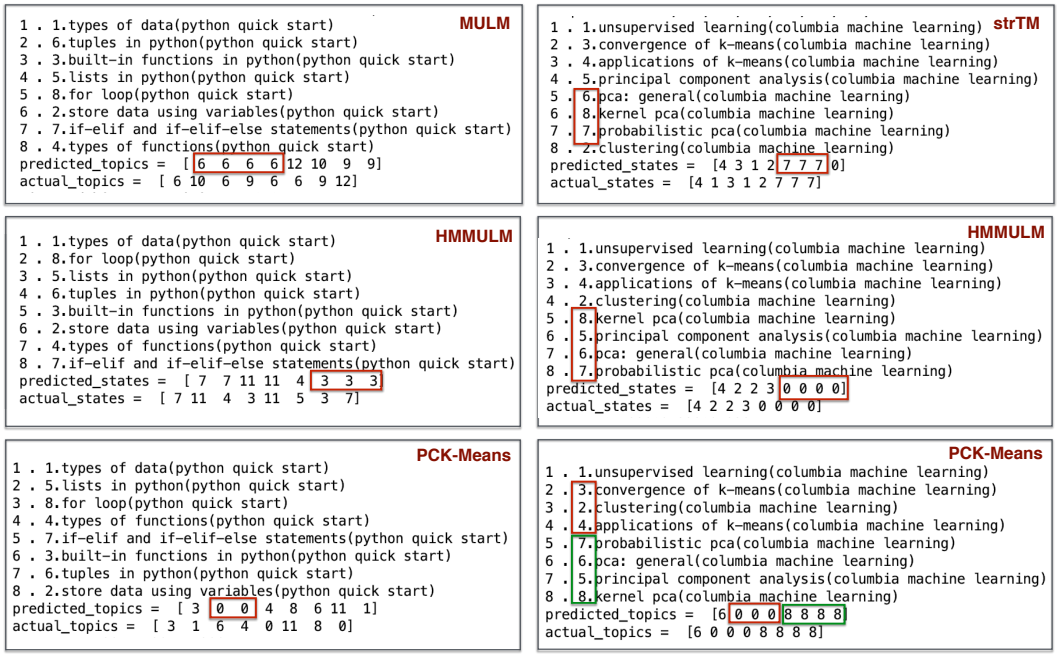

Figure 4: *Qualitative Analysis of Sequencing Task 3. (a) Examples of preferring self transition behaviour when selecting next lecture in the sequence, (b) Examples of the problem of sequencing adjacent lectures that cover the same topics.*

according to the equation:

$$\bar{x} = \arg\max_{x} P(z_i|z_{i-1})P(x|z_i) \tag{21}$$

Similar to task 1, for MULM and PCK-Means models we assign lectures to the best clusters using the equations 4 and 19 respectively. After that MULM greedily chooses the next lecture that maximizes the equation 21. On the other hand, PCK-Means model selects the next lecture that maximizes the topic transition and minimizes the distance with the last lecture in the given sequence. For the baseline, we use the cosine similarity where we choose the next lecture that has the highest similarity score with the last lecture in the given sequence.

Table 3 summarizes the results of Task 2 for each method. We can notice that HMMULM achieves the highest accuracy in all datasets. Using the Viterbi algorithm along with the learned topic transitions helps in capturing the most probable hidden states or topics that generate the given sequence of lectures. In addition, the topic transitions learned by HMMULM help in greedily pick the next lecture in the sequence. While StrTM also uses Viterbi algorithm similar to HMMULM, its accuracy scores were far less than HMMULM. We think the main reason for that due to the performance of the learned topic transitions as we explain in section 6.3.

6.2.4 Task 3: Predicting The Sequence

Task 3 is very similar to task 2 except that each method needs to find the whole sequence of given lectures where the first lecture in the sequence is given. Figure 3 depicts the results of Task 3.

As this task is considered the most challenging task, it is clear that there is no wining method. However, from the upper left graph that captures the Kendall's taus in Figure 3, we can notice that HMMULM has achieved a taus score ≥ 0.50 in four courses, PCK-Means has achieved the same score in only two courses, MULM and strTM in only one course, and Cosine method in non courses. For the Levenshtein normalized similarity, it is clear that all methods have comparable results. For the directed and undirected bigram precision, all methods have also comparable results except MULM. The reason is that MULM sometimes cannot complete the whole sequence because it only uses the greedy method which cannot complete the sequence in the case of the absence of the topic transitions required to sequence courses in the test set. In the case of other methods, they always find the whole sequence either because of the Viterbi algorithm used by HMMULM and strTM or due to the similarity or distance measures utilized by PCK-Means and Cosine methods.

In addition to quantitatively comparing the methods, we try to qualitatively evaluate the results by examining the generated sequences of each methods. In general, we found two common behaviour shared by all methods.

First, in most cases almost all the methods prefer self transition when they pick the next lecture in the sequence. For example, as shown in Figure 4 (a) , MULM, HMMULM, and PCK-Means select the next lecture that has the same topic as the current lecture.

Second, all methods cannot sequence lectures that belong to the same topic. In MOOCs, due to the short length of lectures, instructors sometimes explain the same topic using multiple lectures. As a result, it is hard to find the correct sequence of lectures that cover the same topic. For example, as shown in Figure 4 (b), the last four lectures of the course explain the "Principal Component Analysis algorithm" and hence strTM, HMMULM, and PCK-Means cannot predict the correct sequence of these lectures. In this case, we need to use other

Figure 5: *Python topics and their transitions using **PCK-Means** method. The table represents the top terms in each topic.*

techniques to predict the sequence. One naive solution is to assume that all adjacent lectures the belong to the same topic as one atomic unit and we only need to sequence lectures that have different topics. Further investigation of solving the sequencing problem of lectures that belong to the same topic is left for future work.

6.3 Topic Transitions Examples

In this section, we present examples of topics and topic transitions learned by different methods. Due to space constraint, we present examples using Python dataset. We try to analyze the words with the highest probabilities in the word distributions of topics learned by each methods and manually mapped them to topic words or phrases. For instance, if the word distribution has the words: *list, range, items, index, and append*, then it is clear that this word distribution captures the topic "List". The word distributions with topic phrases of each topic learned by PCK-Means, MULM, HMMULM, and strTM methods in Python dataset are depicted in Figure 5, 6, 7, and 8 respectively. Since we have 13 topics in the Python dataset, we only visualize the topic transitions of a subset of these topics and depicted the transitions that have scores ≥ 0.05.

It is clear from the Figures that all models extract some useful topics where the top terms of each topic clearly explain the topic. However, PCK-Means has the best word distributions that clearly explain each topic followed by HMMULM and then MULM while strTM has the lowest performance. We also notice from the Figures that PCKMeans have extracted 11 useful topics with two topics that have unclear word distributions and cannot be mapped to any useful topics. In contrast, MULM has modeled 10 meaningful topics with three topics form noise and cannot be mapped to any topics. On the other hand, HMMULM and strTM capture 9 topics with four unclear topics that cannot be mapped to any phrase. In general, this finding indicates that PCK-Means has the best performance in modeling the topics of the courses in the Python dataset as it models more useful topics with clear word distributions. The results also indicate that strTM achieves the lowest performance because even though it captures the same number of meaningful topics as HMMULM, strTM has the lowest performance in the clarity of the word distributions.

Figure 8: *Python topics and their transitions using **strTM** method. The table represents the top terms in each topic.*

As shown in the Figures 5, 6, 7, and 8, the meaningful topics extracted by all methods are very similar with some variations. For example, while PCK-Means and MULM separate "*Files*" and "*CSV Files*", HMMULM and strTM combines them into one topic. In addition, while PCK-Means and HMMULM combines "*Loops & Condition*", MULM differentiates between them. StrTM, on the other hand, has both "*Loops & Condition*" and "*Conditional Statements*."

Regarding the topic transitions, it is clear that all models capture self transitions with the topic and itself. This indicates that, in MOOCs, instructors used multiple lectures to explain the same topic. However, HMMULM gave higher probability to self transitions compared to other methods. We can notice from the Figures that there are some consensus between all methods on some transitions between topics such as: "*List*"→ "*Dictionary*" and "*String*"→ "*File*." There are also some variations of topic transitions between different models. For instance, wile PCK-Means, HMMULM, and strTM have a transition between "*String*"→ "*List*", MULM combines these two topics into one topic or cluster. Another variation is that, PCK-Means, strTM and MULM have a transition "*Loop & Condition*"→ "*String*", whereas HMMULM misses this transition.

In general, all methods captures useful topics with clear word distributions. Regarding the topic transitions, all methods capture self transitions and also have some consensus on some transitions. There are also some variations between methods and these differences due to how each method identify topics of each lecture. Improving the modeling of topics and the mapping between lectures and topics clearly would improve the quality of the topic transition maps.

7. CONCLUSION

In this paper, we introduce the Topic Transition Map which is a general structure that models the content of MOOCs as topics, where each lecture is mapped to a topic, and captures the transition between topics. It models the various ways of how instructors organize topics in order to construct the study plan of their courses. We investigate four different methods to construct the Topic Transition Map: PCK-Means, MULM, HMMULM, and strTM. PCK-Means and MULM separately cluster lectures into topics and then learn the transitions between topics, by leverage the sequences of lectures in different courses. In contrast, HMMULM and strTM assume first order Markov property among latent topics and hence jointly learn topics and their transitions. While the three model, MULM, HMMULM, and strTM are probabilistic models, PCK-Means is distance-based clustering algorithm that incorporates some constraints to guide the clustering process.

We evaluated the generated topic transitions from various methods using three different tasks: 1) determining the correct sequence, 2) predicting the next lecture, and 3) predicting the sequence of lectures. Our evaluation revealed that PCK-Means achieves the highest performance in determining the correct sequence while HMMULM outperforms other methods in the task of predicting the next lecture. Since the task of predicting the whole sequence of lectures is considered the most challenging task, there was no winning method and all methods have comparable performance with MULM has the lowest performance as it sometimes fails to predict the whole sequence. We also visualize the the Topic Transition Maps generated by different methods to qualitatively evaluate the resulted maps. We found that PCK-Means has extracted more meaningful topics with the best word distributions that clearly explain each topic.

In the future, we plan to explore incorporating Topic Transition Map with concept dependency relations and examine if this can solve the problem of sequencing lectures that belong to the same topic. Further, we aim to combine different methods such as PCK-Means and HMMULM in order to improve the accuracy of the Topic Transition Map and hence improving the performance of the sequencing tasks. Finally, we plan to apply our work on other domains such as traditional University courses or educational books. To do that, we need to investigate how to divide long lectures or book sections into segments where each segment is mapped to one topic.

ABSTRACT

Early predictors of student success are becoming a key tool in flipped and online courses to ensure that no student is left behind along course activities. However, with an increased interest in this area, it has become hard to keep track of what the state of the art in early success prediction is. Moreover, prior work on early success prediction based on clickstreams has mostly focused on implementing features and models for a specific online course (e.g., a MOOC). It remains therefore under-explored how different features and models enable early predictions, based on the domain, structure, and educational setting of a given course. In this paper, we report the results of a systematic analysis of early success predictors for both flipped and online courses. In the first part, we focus on a specific flipped course. Specifically, we investigate eight feature sets, presented at top-level educational venues over the last few years, and a novel feature set proposed in this paper and tailored to this setting. We benchmark the performance of these feature sets using a RF classifier, and we provide and discuss an ensemble feature set optimized for the target flipped course. In the second part, we extend our analysis to courses with different educational settings (i.e., MOOCs), domains, and structure. Our results show that (i) the ensemble of optimal features varies depending on the course setting and structure, and (ii) the predictive performance of the optimal ensemble feature set highly depends on the course activities.

Flipped Classroom, MOOC, Success Prediction, Early Warning, Clickstream, At-Risk Students, Learning Analytics.

1. INTRODUCTION

An increasing number of universities are now running blended courses that combine traditional lectures with online instruction, providing educational models tailored to the needs of our society [20]. A popular instructional strategy to enable blended learning is represented by *flipped classrooms*, where students complete *pre-class activities* before attending face-to-face lessons [18]. Recent studies have shown the positive impact and dependency of this strategy on student-centered variables such as self-efficacy and self-regulation [22, 17, 6, 19]. Pre-class activities usually consist in watching videos and completing quizzes part of *Massive Open Online Courses* (MOOCs) used as supplementary material [27]. Each week, students are asked to perform these pre-class activities and to then complete exercises and have discussion in class. Pre-class activities are fundamental for the success of flipped courses [12, 21, 28]. However, students often lack skills, time, and motivation to regulate their pre-class activity; as a consequence, they may experience difficulties in class and end up failing the course [10, 14]. To ensure that no learner is left behind, *Early Success Predictors* (ESPs) are becoming crucial to support instructors in identifying and timely acting upon risk factors of failing a course.

So far, there are few studies on analyzing student success in flipped courses based on pre-class activities. For instance, Jovanovic et al. [9, 8] clustered interaction sequences in pre-class clickstreams to identify learning strategies, showing how strategy-based student profiles differ in course grades. Beatty et al. [2] found that frequency counts of video usage are often correlated with course grades in flipped classrooms. In blended, but not flipped settings, Akpinar et al. [1] showed that student's strategy counts, with strategies modelled as clickstream event n-grams, are indicative of course homework grades. Wan et al. [25, 26] trained gradient boosting classifiers on an extensive set of clickstream-based features to identify at-risk students in a small private online course delivered in hybrid mode. They also analyzed the importance of the features, finding that the time spent in online activities and the stability of time distribution during weeks have the highest importance in that course. To the best of our knowledge, no prior work on flipped courses specifically focused on ESPs.

Conversely, there is a large body of research on success prediction for fully online courses (e.g., MOOCs). A multitude of feature sets have been extracted from clickstreams for this purpose. Recent work proposed video-counting (e.g., number of videos viewed per week, rewinds, fastforwards, pauses, and plays, and the fractional and total amount of time played and paused for videos) and session-based (e.g., number of sessions, mean and standard deviation of the time for all sessions and between sessions) features [4, 13]. These features were fed into different commonly used classifiers

Mirko Marras, Julien Tuan Tu Vignoud and Tanja Käser "Can Feature Predictive Power Generalize? Benchmarking Early Predictors of Student Success across Flipped and Online Courses". 2021. (e.g., Logistic Regression, Naive Bayes, Decision Tree, RF, and Neural Networks) to predict success in weekly assignments or in the entire specific MOOC. In [3], several features that measure intra-course, intra-week and intra-day regularity in video watching were proposed, and their correlation with the course grade was shown. Other researchers leveraged attendance rates, usage rates, and watching ratios [7, 15]. Specifically, they explored how the difference in these indicators affects academic performance, showing that students whose indicators are high are more likely to graduate on schedule. More fine-grained features on video usage (e.g., total video views, mean and standard deviation of the proportion of videos watched, re-watched, and interrupted per week, and the frequency and total number of all video actions and of each type of video action) were proposed in [11]. The authors clustered students according to their watching behavior and found that such a behavior is representative of course performance. Similarly, Mubarak et al. [16] extracted implicit features from video-clickstream data, and investigated the extent to which neural networks fed with those features can predict weekly students' performance. For an extensive discussion on success prediction in MOOCs, we recommend this survey [5].

The above features and classifiers, however, are designed for fully-online learning contexts, such as MOOCs. Despite clear connections, there are essential aspects which distinguish flipped courses from MOOCs. First of all, flipped course data includes relatively few students. A large part of the learning activity happens offline and cannot be tracked, leading to data only on course segments. Flipped courses generally have also an intense instructor guidance and performance on them has direct impact on the academic portfolio. As a motivating example, we consider a flipped course on Linear Algebra later described in this paper and the regularity features proposed for MOOCs in [3]. They quantify students' time regularity by considering their activities over the course (e.g., studying at the same days of the week). Boroujeni's study revealed that the final grade in the MOOC is correlated with two intra-week regularity measures and the periodicity of day hour and week hour ($.46 < c < .7$, $p < 0.001$). Conversely, the same features resulted to have no correlation with the final grade in the above flipped course ($.0 < c < .1$, $p < 0.001$). Therefore, it remains unexplored whether existing features and classifiers for MOOCs generalize to different educational settings (e.g., flipped classrooms), and to what extent the feature importance varies according to the topic, structure, and educational setting of the course.

The contribution of this paper is two-fold: we tackle the problem of ESPs in flipped classroom settings[1], and we provide an extensive analysis and benchmark of classifiers and features for early success prediction across different types of courses, namely MOOCs and flipped courses. A schematic overview of our analysis in this paper is shown in Figure 1.

In a first step, we propose a novel feature set for early success prediction in flipped courses. Our feature set measures students' alignment, anticipation, and strength in quiz and video usage. We benchmark our new feature set using a Random Forest (RF) classifier against eight feature sets presented in previous work on success prediction in online courses. We retrieved these feature sets by systematically scanning the recent papers published at major educational venues (e.g., EDM, AIED, etc.) and reproducing the features based on the relevant papers. Our results on data of 214 students enrolled in a linear algebra flipped course show that the novel feature set outperforms all previously suggested feature sets. We also show that predictive performance can be increased by selecting the optimal features from the ensemble of all feature sets.

In a second step, we extend our analysis to further courses along three dimensions: domain, structure, and educational setting. We compute the early predictive performance again using a RF classifier for three additional courses: a flipped course on functional programming (where pre-class activities include videos only), a MOOC on linear algebra (including video and quiz activities), and a MOOC on functional programming (including video activities only). For each course, we select the optimal features from the ensemble of feature sets (eight feature sets from prior work and one novel feature set from this paper) as input features for the RF classifier. Our results show that the structure of the course significantly influences performance. Predictive performance for courses including quizzes is much higher than for courses including only videos. Furthermore, we also show that while there is some overlap between the optimal features across courses, the importance of the features highly depends on the setting and structure of the course.

2. EARLY PREDICTION FORMULATION

The problem addressed in this paper can be framed into a time series classification task that relies on clickstreams to predict student success in a course. For clarity and reproducibility, we present and formalize the addressed problem.

Course. Early success predictions are provided in the context of a course (e.g., a MOOC or a course run in a flipped classroom setting). In what follows, we hence mathematically define fundamental concepts, such as the course schedule, the learning objects, and their properties. Specifically, we consider a set of students $\mathbb{U}$ who are enrolled in a course c part of the online educational offering $\mathbb{C}$. Each course $c \in \mathbb{C}$ has a pre-defined schedule $\mathbb{S}_c$ consisting of $N = |\mathbb{S}_c|$ online activities, such that $\mathbb{S}_c = \{s_1, \ldots, s_N\}$. We assume that each online activity s_j included in the course schedule is represented by a tuple (o_j, t_j), consisting of learning object $o_j \in \mathbb{O}$ and its corresponding completion deadline for students $t_j \in \mathbb{R}^+$, modelled as a timestamp. Each learning object $o \in \mathbb{O}$ is characterized by descriptive properties denoted with an M-dimensional vector $f_o = (f_1, \ldots, f_M)$ over a set of features $\mathbb{F} = \{\mathbb{F}_1, \ldots, \mathbb{F}_M\}$ that vary according to the type of the learning object (e.g., the duration for a video or the maximum grade for a quiz). Specifically, each feature $\mathbb{F}_j \in \mathbb{F}$ can be envisioned as a set of discrete or continuous values describing an attribute of a learning object o, $f_{o,j} \in \mathbb{F}_j$ for $j = 1, \ldots, M$. Our study in this paper assumes that learning objects can be either videos or quizzes, but the notation can be easily extended to other types (e.g., forum posts or readings). The type of a learning object $o \in \mathbb{O}$ is returned by a function $type : \mathbb{O} \rightarrow \{video, quiz\}$.

[1] https://github.com/d-vet-ml4ed/flipped-classroom

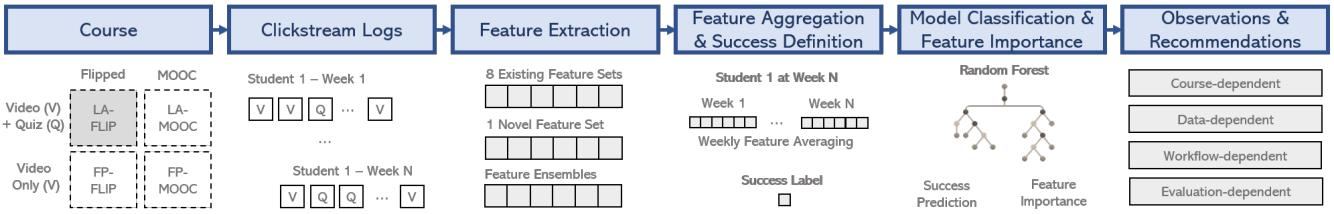

Figure 1: Our Framework. We first analyze a flipped course with videos and quizzes, then investigate differences between courses in flipped and MOOC settings and with videos only and videos plus quizzes. Eight state-of-the-art feature sets, a novel feature set, and feature ensembles are computed for each student and each week of the course. Weekly features are averaged and a success label is attached, according to the course type. Classification is performed using a Random Forest. Observations and recommendations on the predictive power of features are provided for each course setting, highlighting open challenges.

Based on common log data collected by educational platforms, we assume that learning objects of type *video*, denoted as $\mathbb{O}^{video} = \{o \in \mathbb{O} \,|\, \text{type}(o) = video\}$, are described by properties associated to the video duration in seconds as $\mathbb{F}^{video} = (\text{duration} \in \mathbb{R}^+)$. Learning objects of type *quiz*, denoted as $\mathbb{O}^{quiz} = \{o \in \mathbb{O} \,|\, \text{type}(o) = quiz\}$, are characterized by descriptive properties that model the maximum grade students can achieve in that quiz as $\mathbb{F}^{quiz} = (\text{maxgrade} \in \mathbb{R}^+)$. For convenience, we use superscripts to denote a descriptive property of a learning object. For instance, the duration of a video $o \in \mathbb{O}^{video}$ can be referred to as $o^{duration}$. The same notation applies to other descriptive properties.

Interaction. Students enrolled in an online course interact with the learning objects included in the course schedule, generating a time-wise clickstream. We denote a clickstream in a course $c \in \mathbb{C}$ for a student $u \in \mathbb{U}$ as a time series I_u, such that $I_u = \{i_1, ..., i_K\}$, with $K \in \mathbb{N}$ (e.g., a sequence of video plays and pauses, quiz submissions, and so on). We leave these definitions very general on purpose, in particular allowing the length of each time series to differ, since our models are inherently capable of handling this. Likewise, we neither enforce nor expect all time series to be synchronized, i.e. being sampled at the same time, but rather we are fully agnostic to non-synchronized observations. This configuration is common in educational time series. We assume that each interaction i_j is represented as a tuple (t_j, a_j, o_j, d_j), consisting of a timestamp $t_j \in \mathbb{R}^+$, the action $a_j \in \mathbb{A}$ performed by the student (e.g., play or pause), the learning object $o_j \in \mathbb{O}$ involved in the action a_j (e.g., a certain video or quiz), and an L-dimensional descriptive vector $d_j = (d_1, \ldots, d_L)$ over a set of features $\mathbb{D} = \{\mathbb{D}_1, \ldots, \mathbb{D}_L\}$. These descriptive vectors are used to append relevant information to an action a_j performed at time t_j, such as the current video time when the action occurred or the grade received by the student on a quiz. Based on the type of the learning object $o \in \mathbb{O}$, the student can perform different actions $\mathbb{A}$. We assume that video interactions, denoted by $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, \text{type}(o_j) = video\}$, are limited to actions $a_j \in \mathbb{A}^{video} = \{Load, Play, Pause, Stop, SpeedChange, Seek\}$. These actions are derived from those commonly allowed to students in online educational platforms. Conversely, quiz interactions, denoted by $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, \text{type}(o_j) = quiz\}$, include actions $a \in \mathbb{A}^{quiz} = \{\text{Submit}\}$.

In online educational platforms, clickstream interactions include a payload with additional information beyond the timestamp, the action, and the involved learning object. For instance, if a student submits a quiz, the resulting interaction includes also the grade assigned by the system to the student's quiz. Our notation models each dimension $\mathbb{D}_l \in \mathbb{D}$ of a clickstream interaction as a set of discrete or continuous values describing the interaction $i_j \in \mathbb{I}_u$, $d_{j,l} \in \mathbb{D}_l$ for $l = 1, \ldots, L$. Specifically, we assume that interactions involving base video actions $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, a_j \in \{Load, Play, Pause, Stop\}\}$ include descriptive properties associated to the current video time the interaction occurred, i.e. $\mathbb{D}^{Base} = (\text{current-time} \in \mathbb{R}^+)$. Interactions involving a speed change in a video, denoted as $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, a_j \in \{SpeedChange\}\}$, are characterized by descriptive properties associated to both the old and the new speed the video has been and will be watched, i.e. $\mathbb{D}^{SpeedChange} = (\text{oldspeed} \in \mathbb{R}^+, \text{newspeed} \in \mathbb{R}^+)$. Interactions generated by students while seeking the video backward or forward, denoted as $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, a_j \in \{Seek\}\}$, are modelled by descriptive properties related to the previous and current video time the student moved on, i.e. $\mathbb{D}^{Seek} = (\text{oldtime} \in \mathbb{R}^+, \text{newtime} \in \mathbb{R}^+)$. Finally, submit interactions generated in quiz activities, denoted as $\{i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \,|\, a_j \in \{Submit\}\}$, include descriptive properties on the grade assigned to the quiz answer and the progressive number of the attempt made on that quiz, i.e. $\mathbb{D}^{Submit} = (\text{grade} \in \mathbb{R}^+, \text{subnum} \in \mathbb{R}^+)$, with $\text{grade} \in [0, 1]$.

For convenience, we denote as $\mathbb{I}_u^t$ the clickstream including interactions $i_j \in \mathbb{I}_u$, such that $t_j < t \; \forall t_j \in \mathbb{I}_u^t$, namely those occurred before time t. Similarly, since online activities in MOOCs and flipped courses are organized on a weekly basis, t_w identifies the time t where the course week w ends. For instance, the clickstream of user u generated till the end of the second week can be denoted as $\mathbb{I}_u^{t_2}$.

Success Label. Once interactions are modelled, we need to associate a success label according to the final grade the corresponding student has received for that course. We consider a dataset $\mathbb{G}$ to consist of tuples, i.e. $\mathbb{G} = \{(I_{u_j}, y_{u_j})\}$, where I_{u_j} denotes the interactions of student u_j and $y_{u_j} \in \{0, 1\}$ the pass-fail label or the above-below average grade label.

Feature Extraction. Machine-learning models rarely receive raw interaction sequences, as so we abstract such interactions through a feature extraction step. Given the interactions $\mathbb{I}_u^{t_w} \subset \mathbb{I}_u \in \mathbb{I}$, generated by student u till the course week $w \in \mathbb{N}$, we produce fixed-length representations in

$\mathbb{H} \subset \mathbb{R}^{w \times H}$, where $H \in \mathbb{N}$ is the dimensionality of the feature set. Therefore, we assume that H-dimensional vectors are extracted for each week. For instance, if the feature set includes "number of sessions" and "number of clicks", feature vectors of size $H = 2$ are extracted each week. Formally, the extraction process is denoted as $\mathcal{H} : \mathbb{I} \rightarrow \mathbb{H}$, from interactions to features.

Model. Given the dataset $\mathbb{G}$ with interactions - success label pairs, an early success predictor $\mathcal{E}$ aims to predict the success label y_{u_j} associated to the interactions $\mathbb{I}_{u_j}$. Formally, this operation can be abstracted as a function $\widetilde{y}_{u_j} = \mathcal{E}(\mathbb{I}_{u_j}|\theta)$, where $\widetilde{y}_{u_j}$ denotes the predicted label, θ denotes the model parameters, and $\mathcal{E}$ denotes the predictive function that maps interactions $\mathbb{I}_{u_j}$ to the predicted label $\widetilde{y}_{u_j}$ according to θ.

Objective Function. Hence, training an early success predictor $\mathcal{E}$ with interactions - success label pairs till course week w becomes an optimization problem, aimed to find model parameters θ that maximize the expectation on the following objective function (i.e., predicting the correct success label, given the interactions) on a dataset $\mathbb{G}$:

$$\tilde{\theta} = \underset{\theta}{\operatorname{argmax}} \underset{(\mathbb{I}_u, y_u) \in \mathbb{G}}{\mathbb{E}} y_u = \mathcal{E}(\mathcal{H}(\mathbb{I}_u^{t_w}) \mid \theta) \tag{1}$$

In this paper, we focus on *feature extraction*, which formally results in the operationalization of the function $\mathcal{H}$.

3. REPRESENTATIVE FEATURE SETS

To make sure that our work is not only based on individual examples of published research, we systematically scanned the proceedings of conferences and journals for relevant papers in a manual process. In our analysis, we considered papers that appeared in the last years in the top educational technology conferences (e.g., LAK, EC-TEL, AIED, and EDM) and journals (e.g., IEEE TLT, Springer EIT, Journal of Learning Analytics). We considered a paper to be relevant if it (a) proposed a novel feature set for course success analysis, and (b) focused on the context of online courses or courses with online activities. Papers on other tasks, e.g., prediction of affective state or conceptual understanding, or other educational contexts, e.g., interactive simulations or games, were not considered. Moreover, papers with highly overlapping feature sets were filtered, and the paper with the most extensive set was used as representative. Finally, eight papers were included in our study.

In a next step, we reproduced the feature sets described in the above papers. Our approach was to rely as much as possible on the artifacts provided by the authors themselves, i.e., their source code and the descriptions included into the papers. In theory, it should be possible to reproduce published results using only the technical descriptions in the papers. In reality, there are many tiny implementation details with an impact on experiments. Overall, we could reproduce with reasonable assumptions all eight feature sets based on the relevant papers. In what follows, we give a description of each feature set included in our study.

AkpinarEtAl. This feature set consists of consecutive subsequences of n clicks extracted from the session clickstreams of a blended course [1]. In addition to sub-sequences, the authors considered four features related to the number of clicks, the number of session clickstreams, and attendance information. Note that in comparison to the original paper, we extract sequences from a different set a raw events, namely only videos and quizzes (e.g., no events on forums). Hence, in our case the feature set has a size of $|\mathbb{A}^{video} \cup \mathbb{A}^{quiz}|^n$ features per student. Since we expect short patterns to be un-interpretable and particularly long patterns to be rare, we choose $n = 3$ for our analyses.

BoroujeniEtAl. This feature set was originally used to measure to what extent MOOC students are regular in their study patterns [3]. Specifically, it is considered whether students study on certain hours of the day, day(s) of the week or similar weekdays. Other features monitor whether students have the same distribution of study time among weekdays over weeks, particular amount of study time on each weekday, and finally to what extent a student follows the schedule of the course. This set includes 9 features per student. Other papers proposed similar regularity features [23, 24, 8, 9, 2]. We limit our analysis to the feature set listed in [3], as in our first experiments it exhibited the best predictive power (among papers focusing on regularity features).

ChenCui. The feature set presented in this paper [4] includes click countings from a mandatory undergraduate course run through Moodle. Features include the number of total clicks and of clicks on campus, the ratio of on-campus to off-campus clicks, the number of online sessions (with average and standard deviation), standard deviation of time between online sessions, number of clicks during weekdays or weekends, ratio of weekend to weekday clicks, and the number of clicks for each type of module (e.g., assignment, forum, and quiz). To accomodate the scenario presented in Section 2, our study does not cover the features not easily generalizable to different types of online courses: the number of clicks on campus, the ratio of on-campus to off-campus clicks, the number of clicks for modules file, forum, report system. We therefore obtain a feature set of size 13 for each student.

LalleConati. This paper [11] focuses again on MOOCs. The presented feature set is composed by video interaction features at two levels of granularity. Features on video views include the total number of videos views (both watches and rewatches), in addition to the average and standard deviation of the proportion of videos watched, re-watched, and interrupted per week. On the other hand, features on actions performed within the videos include the frequency and total number of all performed video actions, frequency of video actions for each type of video action, and the average and standard deviation duration of video pauses, seek lengths, and so on. This feature set has a size of 22 per student.

LemayDoleck. The next paper [13] is also focused on MOOCs. Presented features include the number of videos watched per week, the average time fraction paused, played or spent watching, the average and standard deviation of the playback rate, and the total number of rewinds, pauses, and fast-forwards. Note that this feature set includes only video-related measures, resulting in vectors of size 10 per student.

MbouzaoEtAl. In this MOOC paper [15], the authors introduce three novel features, namely attendance rate, uti-

lization rate, and watching ratio. The attendance rate of a student on a given week is the number of videos the student played over to the total number of videos in that week. The utilization rate is the proportion of video play time activity of the student over the sum of video lengths for all videos on that week. Finally, the watching ratio is defined as the product between the two former features. This 3-sized feature set has been tested in MOOCs, extending an already-existing feature set [7].

MubarakEtAl. This paper [16] is primarily focused on implicit features about video-usage behavior in MOOCs. Composed by 13 features, this set covers fine-grained characteristics, such as the percentage of the video the learner watched not counting repeated segments, the amount of real time the learner spent watching the video (i.e. when playing or pausing) compared to the video duration, and the sum of times a learner viewed a video in its entirety.

WanEtAl. This set was designed for a small private online course [26]. Features measure the online learning time, the strength of the learner's engagement in forums and weekly assignments, the extent to which students attempt to do the homework soon, as examples. Table 1 and 2 in the cited paper provide further details. Given that we do not cover forum interactions, our study does not consider forum features. Finally, this set includes 14 features per student.

4. EARLY PREDICTORS IN FLIPPED COURSE SETTINGS

In this section, we first present a novel feature set for flipped courses, based on alignment, anticipation, and strength in content usage. We then describe the experimental setup and results aimed to assess to what extent the feature sets (including ours) are predictive of student success.

4.1 Our Feature Set

The feature sets presented so far mainly tackle video-related features and/or consider only low-level features, with only a few of them including features related to quizzes or assignments. Considering that predicting the success of a student based on clickstream data only is a challenging task per sé, we believe that limiting features to those extracted from videos may result in inferior predictive performance. We therefore suggest a number of additional features assessing students' knowledge and alignment with the course schedule.

Competency Strength is defined as the average of the inverse number of submissions for a quiz, weighted by the highest grade achieved by the student on that quiz. Given the inverse term, the value of this feature decreases when the student attempts the quiz multiple times and if the grade achieved by the student on the last attempt is not the highest-possible one. Hence, good-performing students may use few attempts and reach the maximum quiz grade fast (value close to 1). Students struggling with the material may attempt the quiz many times and not reach the maximum grade (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{1}{|Q_u|}\sum_{q\in Q_u}\frac{1}{Q_u^q}\,max(G_u^q) \tag{2}$$

where:

- $Q_u = \{o_j | i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \cap \text{type}(o_j) = quiz \cap t_j \leq t_w\}$ are the quizzes taken by student u till week w.
- $Q_u^q = |\{i_j | i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \cap o_j = q \cap t_j \leq t_w\}|$ is the number of attempts a student had on quiz q.
- $G_u^q = \{d_j^{\text{grade}} | i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \cap o_j = q \cap t_j \leq t_w\}$ is the set of grades a student got on quiz q.

Competency Alignment is defined as the number of quizzes the student received the maximum grade until week w, divided by the total number of quizzes scheduled for the period of consideration. Good-performing students may receive the maximum grade in all quizzes for the period of consideration (value close to 1); low-performing students may be behind the schedule and pass fewer quizzes than those proposed (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{|Q_u^{\text{pass}} \cap S^{leq(t_w)}|}{|S^{leq(t_w)}|} \tag{3}$$

where:

- $Q_u^{\text{pass}} = \{o_j | i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \cap \text{type}(o_j) = quiz \cap d_j^{\text{grade}} = o_j^{\text{maxgrade}}\}$ is the set of quizzes the student u received the maximum grade until week w.
- $S^{leq(t_w)} = \{o_j \in \mathbb{O} | (o_j, t_j) \in \mathbb{S}_c \cap type(o_j) = \text{quiz} \cap t_j \leq t_w\}$ is the set of quizzes to complete by week w.

Competency Anticipation is defined as the number of quizzes attempted by the student among those in subsequent weeks of the current week of study. This feature can be seen as a proxy of the learning propensity of a student. For instance, if a quiz is scheduled to be solved in subsequent weeks, we expect that good-performing students try them earlier, anticipating the deadline stated in the platform (value close to 1). Low-performing students may delay the consumption of quizzes across weeks or even towards the end of the course (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{|Q_u \cap S^{gt(t_w)}|}{|S^{gt(t_w)}|} \tag{4}$$

where Q_u is the set of quizzes taken by student u until week w as defined in Eq. 2, and:

- $S^{gt(t_w)} = \{o_j \in \mathbb{O} | (o_j, t_j) \in \mathbb{S}_c \cap type(o_j) = \text{quiz} \cap t_j > t_w\}$ is the set of quizzes to complete after week w.

Content Alignment is defined as the number of videos watched by the student until week w, divided by the total number of videos scheduled for the period of consideration. Good-performing students are expected to complete all videos for the period of consideration (value close to 1), while low-performing students may complete less videos than those proposed (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{|V_u \cap S^{leq(t_w)}|}{|S^{leq(t_w)}|} \tag{5}$$

where:

- $V_u = \{o_j | i_j = (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \cap \text{type}(o_j) = video\}$ is the set of videos watched by student u until week w.

- $S^{leq(t_w)} = \{o_j \in \mathbb{O} | (o_j, t_j) \in \mathbb{S}_c \cap type(o_j) = \text{video} \cap t_j \leq t_w\}$ is the set of videos to watch by week w.

Content Anticipation is defined as the number of videos completed by the student among those in subsequent weeks of the current week of study. For instance, if a video is due the next week, we expect that good-performing students might watch them earlier, anticipating the deadline stated in the platform (value close to 1). On the other hand, low-performing students may tend to delay the completion of videos (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{|V_u \cap S^{gt(t_w)}|}{|S^{gt(t_w)}|} \tag{6}$$

where V_u is the set of videos watched by student u until week w as defined in Eq. 5, and:

- $S^{gt(t_w)} = \{o_j \in \mathbb{O} | (o_j, t_j) \in \mathbb{S}_c \cap type(o_j) = \text{video} \cap t_j > t_w\}$ is the set of videos to watch after week w.

Student Shape is defined as the student's tendency of receiving the maximum grade in a quiz at the first attempt in a row. Good-performing students are expected to consecutively receive the maximum grade in quizzes at the first attempt (value close to 1); students experiencing difficulties may require multiple attempts on each quiz, before getting the maximum grade (value close to 0). Given a student u and the week w of the course, this feature is computed as:

$$\frac{1}{\sum_{(p_i,l_i)\in\mathbb{P}} p_i} \sum_{(p_i,l_i)\in\mathbb{P}} \frac{p_i \cdot l_i}{|\{p_i | (p_i, l_i) \in \mathbb{P} \ \cap \ l_i = 1\}| + \epsilon} \tag{7}$$

where $\mathbb{P} = \{(p_0, l_0), \ldots, (p_n, l_n)\}$ represents a series counting how many quizzes the student consecutively receives the maximum grade ($l_i = 1$) or failed ($l_i = 0$) at the first attempt in a row. For instance, if a student gets the maximum grade for the first five quizzes at the first attempt in a row, then is wrong in two quizzes at the first attempt, and then receives the maximum grade for ten quizzes at the first attempt in a row, $\mathbb{P}$ would be equal to $\{(5, 1), (2, 0), (10, 1)\}$.

Student Speed is defined as the average time passed between two consecutive attempts for the same quiz, among those taken by the student. This feature captures intrinsic behavior of students who take the quiz, spending less time or more time to attempt it, on average. Given a student u and the week w of the course, this feature is computed as:

$$\frac{1}{|Q_u|} \sum_{q \in Q_u} \sum_{i=1}^{|t_q|} \frac{|t_q^i - t_q^{i-1}|}{|t_q|} \tag{8}$$

where Q_u is the set of quizzes taken by student u until week w as defined in Eq. 2, and:

- $t_q = [t_j | (t_j, a_j, o_j, d_j) \in \mathbb{I}_u \ \cap \ o_j = q \ \cap \ t_j > t_{j-1})]$ are timings between trials for u on q, chronologically.

In the rest of the paper, we will refer to our set by *Ours*.

4.2 Experimental Evaluation

In this section, we benchmark our new feature set against the eight feature sets presented in prior work (see Section 3), on early success prediction in flipped courses. For convenience, we will use author-based labels to identify feature sets throughout the paper, but we will be more interested in contrasting the impact of features in those papers based on what they implicitly measure (not based on the authors).

4.2.1 Experimental Setup

Protocol. For each dataset, we applied a train-test evaluation, i.e. parameters were fit on the training data set and the performance of the models was evaluated on the test data set. We performed all experiments using Random Forest (RF) classifiers, known to achieve a good trade-off between prediction accuracy and interpretability. Performance of all models was computed using a **nested** student-stratified (i.e. dividing the folds by students) 10-fold cross validation. The same folds were used for all experiments, across feature sets. We optimized the hyper-parameters of RFs via Grid Search in Scikit-Learn. Specifically, we tuned the following hyper-parameters: number of estimators $(25, 50, 100, 200, 300, 500)$, the maximum number of features $(sqrt, None, log2)$, and the splitting criterion $(gini, entropy)$. More extensive grids were run, but they did not show any substantial improvement. To be precise, we determined the set of optimal hyper-parameters as follows: within each iteration, we ran an inner student-stratified 10-fold cross-validation on the training set in that iteration, and selected the combination of hyper-parameter values yielding the highest accuracy on the inner cross-validation. Note that we trained RFs by weeks: the RF for week w of a given course was trained on data collected up to week w. To obtain the input features for RF for week w, we computed the weekly features for the selected feature set and averaged them.

Data Set: LA-Flip. We consider a Linear Algebra course for undergraduate students taught in a flipped format for 10 weeks at EPFL. Typical pre-class work included a list of video lectures and online quizzes from a Linear Algebra MOOC. The final exam grade, lying between 0 and 6, with 4 as passing threshold, is considered as a measure for students' performance. The repeating students were filtered out, given that their repeated exposure to the material might add a bias to our findings. The final dataset consists of clickstream data from 214 students, with 41% of them failing the course. The study was approved by the university's ethics committee (HREC No. 058-2020/10.09.2020).

4.2.2 Observations

We evaluated the predictive accuracy of RF classifiers trained on the different feature sets extracted from LA-Flip under a binary classification that aims to identify passing and failing students early, as described in Section 2. We further also trained RF classifiers only on the most important features selected from all features (denoted as *EnsembleAll*) and from all features except ours (denoted as *EnsembleButOurs*). Figure 2 reports the balanced accuracy, the area under the ROC curve (AUC), and the individual percentage of passing and failing students correctly identified (recall) for each feature set over all weeks and folds.

The lowest-performing feature sets appear those monitoring students' regularity (orange) and attendance and utilization rates (blue). Hence, a first conclusion we can draw is:

Highlight #1. *Regularity and attendance/utilization features, powerful in MOOCs, do not allow to distinguish passing from failing students in the considered flipped course.*

The feature sets mostly related to video-clicking behavior, such as those from Lemay & Doleck, do not lead to substan-

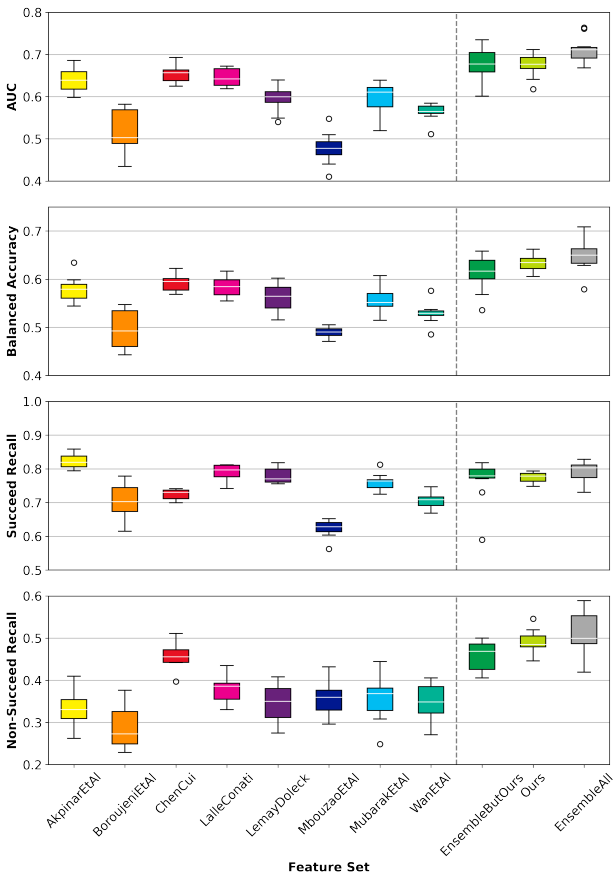

Figure 2: [LA-Flip]. Effectiveness of a RF classifier trained on separate feature sets and on ensembles. Our feature set is essential to increase the effectiveness of the classifier, especially in terms of Non-Succeed (failing students) Recall.

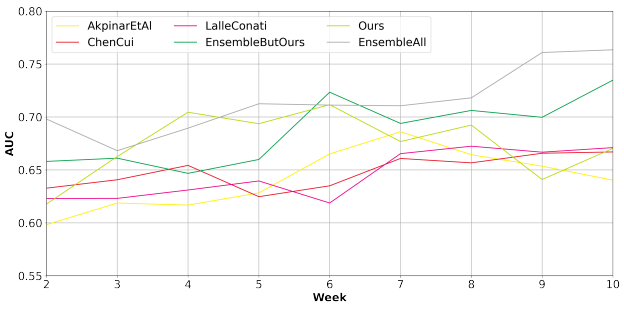

Figure 3: [LA-Flip]. AUC for the best six feature sets. The ensemble of all features (grey) leads to an increase in effectiveness, with respect to considering feature sets separately.

tial differences from each other and all achieved a balanced accuracy between 55% and 59% (similarly for AUC). This finding might reveal an intrinsic limit for video features in predicting student success from pre-class activities. Our results also raise the question on how and why a certain type of video features should be preferred compared to others.

Highlight #2. *In this flipped course, there are minimal differences in performance among video-usage features; an intrinsic predictive limit for video-usage features exists.*

This motivates investigation on the impact of features targeting quiz usage. In this direction, the features proposed by Wan et al. cover a range of raw counting and timing measures that target quizzes. Figure 2 shows that this feature set is even worse that just using video features. Conversely, by measuring more complex patterns in quiz consumption, our feature set led to a balanced accuracy of 67% (similarly for AUC). To identify the aspect our features make the difference at, we considered the percentage of passing and failing students correctly classified, as shown in the two bottom plots in Figure 2. While there are no substantial differences among our feature set and the other ones in identifying passing students (Succeed Recall), a clear improvement is obtained in the detection of failing students (Non-Succeed Recall), fundamental to ensure fewer students are left behind. The impact of our features can be also appreciated across weeks in Figure 3. Our features allowed the ensemble to be effective in the first weeks, while both ours and other features jointly led to an improvement in the second part of the course. Given our results and the characteristics of our features, we can observe that:

Highlight #3. *Extracting fine-grained features that model alignment, anticipation and strength of video/quiz usage results in higher predictive power on failing students.*

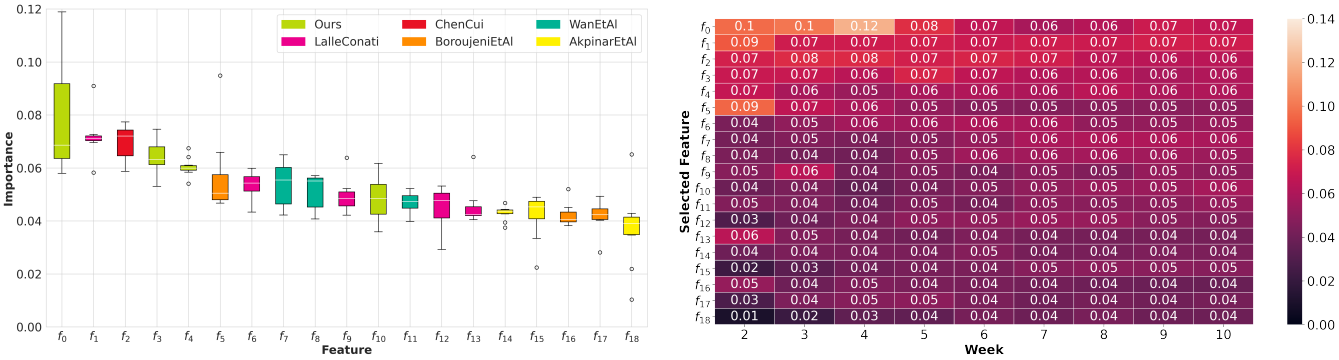
Though considering the feature sets separately allowed us to perform a fine-grained assessment and have an estimation of their predictive power, it remains unclear how the effectiveness of early predictors can be improved by training models with an ensemble of all features and to what extent the importance of the considered features varies. Hence, on the right side of the plots in Figure 2, we present the results achieved by a RF classifier only with the most important features selected from all features and from all features except ours. It can be observed that the optimal ensemble of features without ours results in lower performance, compared to the optimal ensemble that uses also our features. The optimal ensemble of all feature has an AUC score consistently higher than 0.70. To inspect what drives success prediction, we computed the feature importance over weeks and folds, and reported in Figure 4 the importance of features (short description in Table 1) selected by RF. Looking at importance scores in Figure 4(a), we observe that:

Highlight #4. *The extent to which students anticipate content consumption, the tendency of learning during weekends, the proportion of watched videos, and the strength of their performance in quizzes, had the highest importance.*

Figure 4(b) shows that the difference in importance across features is more evident in the first weeks. This finding emphasizes the fact that selecting appropriate features is more crucial when interested in very early predictions.

5. EARLY PREDICTORS OVER COURSES

Our exploratory analysis revealed interesting patterns on the predictive power and importance of a range of features. However, it remains under-explored the extent to which the patterns identified in that flipped course hold also in courses with other structures and educational settings. To this end,



(a) Average feature importance across weeks.

(b) Feature importance over weeks.

Figure 4: [LA-Flip]. Importance of the best nineteen features selected by a RF classifier from the ensemble of all feature sets. Four features of our set have been selected as important. Table 1 lists the Feature IDs and the short description of each feature.

Table 1: [LA-Flip]. Description of the most important nineteen features selected by a RF classifier from the ensemble of all feature sets, showed in decreasing order of importance. Four features of our set have been selected among the top eleven.

ID	Set	Name	Short Description
f_0	Ours	CompetencyAnticipation	The extent to which the student approaches soon a quiz provided in subsequent weeks.
f_1	LalleConati	WeeklyPropWatched-Avg	The proportion of videos the student watched, counting repeating segments.
f_2	ChenCui	RatioClicksWeekendDay	The ratio between clicks happened during weekend and weekdays.
f_3	Ours	ContentAnticipation	The extent to which the student approaches soon a video provided in subsequent weeks.
f_4	Ours	CompetencyStrength	The extent to which a student passes a quiz getting the maximum grade with a low number of trials.
f_5	BoroujeniEtAl	RegWeeklySim-M2	The extent to which the student has a similar distribution of workload among weekdays across weeks.
f_6	LalleConati	WeeklyPropInter-Std	The standard deviation of the time the student spent while interrupting a video, across videos.
f_7	WanEtAl	NumSubmissionCor	The average number of quizzes attempted and correct.
f_8	WanEtAl	NumSubmissions-Avg	The number of submissions required to pass a quiz, on average.
f_9	LalleConati	WeeklyPropInter-Avg	The average time the student spent while interrupting a video, across videos.
f_{10}	Ours	StudentShape	The extent to which the student receives the maximum grade in quizzes at the first attempt in a row.
f_{11}	WanEtAl	NumSubmissionPerCorrect	Percentage of the correct quiz submissions with respect to the total submissions.
f_{12}	LalleConati	WeeklyPropReplayed-Avg	The proportion of videos the student re-watched, not counting repeating segments.
f_{13}	LalleConati	FrequencyEvent-VideoPlay	The frequency of the video play action in the students' online sessions.
f_{14}	AkpinarEtAl	QCheck-QCheck-VLoad	The amount of times the student checks twice a given quiz and then go to load a video.
f_{15}	AkpinarEtAl	VPlay-VPause-VLoad	The amount of times the student plays a video, pause and then load the next one.
f_{16}	BoroujeniEtAl	RegPeriodicity-M3	The extent to which the daily study pattern is repeating over weeks (e.g., same days of the week).
f_{17}	BoroujeniEtAl	RegWeeklySim-M1	The extent to which the student works on the same weekdays.
f_{18}	AkpinarEtAl	VStop-PCheck-VLoad	The amount of times the student stops a video, attempts a quiz and then load the next video.

we extended our analysis to a flipped course in a different domain (Functional Programming, only video data in pre-class activities), a MOOC in the same domain (Linear Algebra, both videos and quizzes), and a MOOC from a different domain (Functional Programming, only video interactions).

5.1 Experimental Setup

Protocol. In this experiment, we followed the steps described in Section 4.2.1, with few exceptions. Specifically, for each data set, we considered only classifiers trained with the optimal ensemble of all features proposed in prior work plus the ones proposed in this paper. To obtain the input features for the RF classifier on week w, we computed the weekly features for all feature sets; then averaged features of the same week, and finally averaged across weeks till week w. For each course, we computed the most important features from the ensemble (eight existing sets and ours) based on the average importance of the features across folds and weeks. The study was approved by the university's ethics committee (HREC No. 096-2020/09.04.2020).

Data Set: FP-Flip. We consider one stream of a Functional Programming course taught to EPFL Master's students in a flipped manner for 10 weeks. The preparatory work included a list of videos from a Functional Programming MOOC. Repeating students were filtered out. Being a Master's course with a failing percentage of only 5%, we considered whether a student's final course grade (lying between 0 and 6) was above the average grade over all students as a success label. The dataset consists of clickstreams from 218 students, with 38% of them being below average.

Data Set: LA-MOOC. The content used in pre-class activities within LA-Flip was also provided by EPFL instructors on an external MOOC platform in form of three separate MOOCs, with the first MOOC being equivalent to the first 4 weeks of the flipped course, the second MOOC equivalent to week 5 to week 8, and the third MOOC equivalent to the last 3 weeks. Given that the first 4 weeks of LA-Flip were delivered in a traditional manner, we excluded the first MOOC from our study. We also excluded the third MOOC, given that the number of enrolled students was barely small. To sum up, our study in this paper considers only the second MOOC that covers the second part (weeks 5 to 8) of the flipped course. To pass the course, it is mostly necessary to obtain at least 60% of the total points for each assignment. Hence, we used this rule as a way to measure success in our study. The final data set consists of clickstream data from 170 students, with 33% of them failing the course.

Table 2: Features selected as important by RF classifiers for the ensemble of features for each course.

Set	Name	Short Description	LA-Flip	FP-Flip	LA-MOOC	FP-MOOC
AkpinarEtAl	QCheck-QCheck-QCheck	The amount of times the student checks three times the same quiz.		✓		
	QCheck-QCheck-VLoad	The amount of times the student checks twice the quiz and then go to load a video.	✓			
	VPlay-VPlay-VPlay	The amount of times the student clicks for three consecutive times on play for three different videos.			✓	
	VPlay-VPause-VLoad	The amount of times the student plays a video, pause and then load another one.	✓			
	VPlay-QCheck-QCheck	The amount of times the student plays a video, then checks twice a quiz.				✓
	VPlay-VStop-VPlay	The amount of times the student plays a video, stops, and plays another one.		✓		
	VPause-VSpeedChange-VPlay	The amount of times the student pauses a video, changes the speed, and re-plays it.		✓		
	VStop-VPlay-VSeek	The amount of times the student stops a video, then re-play it and seek to a given part.		✓		
	VStop-VCheck-VLoad	The amount of times the student stops a video, checks a quiz and then load another video.	✓			
BoroujeniEtAl	DelayLecture	The average delay in viewing video lectures, as soon as they are released.		✓	✓	✓
	RegWeeklySim-M1	The extent to which the student works on the same weekdays across weeks.	✓	✓		
	RegWeeklySim-M2	The extent to which a student has a similar distribution of workload among weekdays across weeks.	✓		✓	✓
	RegWeeklySim-M3	The extent to which the time spent on each day of the week is similar for different weeks of the course.		✓		
	RegPeriodicity-M1	The extent to which the hourly pattern of student's activities is repeating over days.				✓
	RegPeriodicity-M3	If the daily study pattern is repeating over weeks (e.g. is active on Monday and Tuesday in every week).	✓			✓
	RegPeakTime-M1	The extent to which students' activities are centered around a particular hour of the day.				✓
	RegPeakTime-M2	The extent to which students' activities are centered around a particular day of the week.				✓
ChenCui	RatioClicksWeekendWeekdays	The ratio between clicks in weekdays and weekends.	✓	✓	✓	✓
	TimeSession-Avg	The average amount of time spent from a login to the end of the session.			✓	
	TimeSession-Std	The standard deviation of time spent from a login to the end of the session.				✓
	TimeBetweenSessions	The average amount of time passed between two sessions for a student.				✓
	TotalClicks-Weekdays	The number of clicks performed by a student over weekdays.			✓	
LalleConati	PauseDuration-Avg	The average amount of time spent in pause while interacting with a video.		✓		
	SeekLength-Std	The extent to which the seek length varies across videos.		✓		
	PauseDuration-Std	The extent to which the pause duration varies across videos.		✓		
	TimeSpeedingUp-Avg	The average amount of time spent with higher than 1x speed while playing a video.		✓		
	TimeSpeedingUp-Std	The extent to which the time spent speeding up higher than 1x the videos varies.		✓		
	WeeklyPropWatched-Avg	The proportion of videos the student watched, counting repeating segments.	✓			
	WeeklyPropInter-Avg	The average time the student spent in interrupting a video.	✓			
	WeeklyPropInter-Std	The deviation of the time the student spent in interrupting a video.	✓			
	WeeklyPropReplayed-Avg	The proportion of videos the student re-watched, counting repeating segments.	✓			
	WeeklyPropReplayed-Std	The deviation of the proportion of videos the student re-watched, counting repeating segments.			✓	
	FrequencyEvent-VideoPlay	The frequency of the play event in the students' sessions.	✓			✓
MubarakEtAl	SpeedPlayBack-mean	The average speed the student used to play back a video.			✓	✓
WanEtAl	NumSubmissionsCor	The number of quizzes attempted and correct.	✓			
	NumSubmissions-Avg	The number of submissions performed for a quiz, on average.	✓			✓
	NumSubmissionPerCorrect	The percentage of the correct quiz submissions with respect to the total submissions.	✓		✓	
	NumSubmissionDistinct	The total number of distinct problems attempted by the student.			✓	
Ours	CompetencyAnticipation	The extent to which the student approaches soon a quiz provided in subsequent weeks.	✓			
	ContentAnticipation	The extent to which the student approaches soon a video provided in subsequent weeks.	✓			
	CompetencyStrength	The extent to which a student passes a quiz getting the maximum grade with a low number of trials.	✓		✓	
	StudentShape	The extent to which the student receives the maximum grade in quizzes at the first attempt in a row.	✓		✓	
	Student Speed	The average amount of time passed between two submissions for the attempted quizzes.			✓	

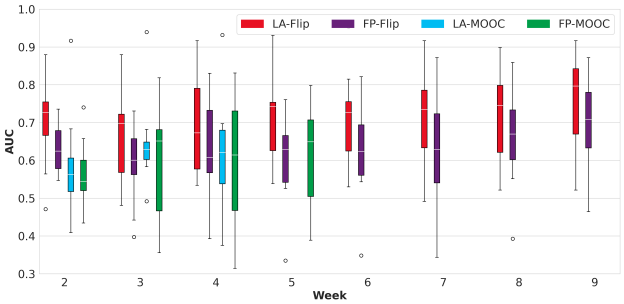


Figure 5: AUC scores per week for RF classifiers trained on feature ensembles. Flipped courses (*-Flip) last 10 weeks; LA-MOOC (FP-MOOC) last 4 (6) weeks.

Data Set: FP-MOOC. The content delivered in pre-class activities in FP-Flip was also provided by EPFL instructors on an external MOOC platform in form of two separate MOOCs, with the first MOOC being equivalent to the first 6 weeks of the flipped course and the second MOOC to the subsequent weeks. No data was available on the second MOOC, so we limited our study to only the first MOOC (week 1 to 6 of the flipped period of FP-Flip). To pass this MOOC, 80% of the total points for each of the five graded assignments are mostly needed. Hence, we used this rule to measure success in our study. The dataset consists of clickstreams from 3,565 students, with 52% failing the course.

5.2 Observations

We evaluated the predictive performance of a RF classifier across weeks for each course for the best ensemble feature set for that course. Figure 5 illustrates the predictive performance across weeks for all four courses. Considering the same course across different settings (flipped or MOOC), it can be observed that RFs trained on flipped course data achieved higher AUC scores than their MOOC counterpart. This difference can be due to multiple reasons, for example the different educational setting or the way the passing rule for the course is set up. Considering courses in the same setting (LA-Flip VS FP-Flip or LA-MOOC VS FP-MOOC), the results show that including quizzes in the LA-Flip course allows to increase the predictive power of the considered classifiers, compared to FP-Flip, that has no quizzes. This can be associated to the fact that quizzes are a good source of information for grasping the students' performance. The same observation is, however, less strong on the MOOC counterpart of the same two courses, highlighting again the high dependency from the educational setting.

In a second part of this experiment, we analyzed the average importance across weeks of the features selected by RFs across courses. Table 2 shows for each feature set and course, whether a given feature has been selected by the corresponding RF classifier. It should be noted that this table includes only features picked at least by a RF classifier across courses. In general, we show that while there is some overlap between the optimal features across courses, the importance of the features highly depends on the setting and structure of the course. The ratio of clicks between weekends and weekdays (ChenCui - RatioClicksWeekendWeekdays) is selected by all classifiers in all settings. Other features with a good level of generalizability are represented by those measuring regularity (BoroujeniEtAl). The other features were picked according to the setting or the structure of the course. In particular, RFs trained on LA-Flip and LA-MOOC assigned a higher importance to features that measure behavior in quizzes (e.g., Ours or WanEtAl). Hence, we can conclude that when available, features on quizzes are frequently selected, regardless of the setting. For courses with no quizzes, namely FP-Flip and FP-MOOC, the predictive power of RFs

is mainly based on regularity and fine-grained video usage (e.g., features on time spent in a video, e.g., LalleConati).

Highlight #5. *When quizzes are included in the schedule, quiz-related features are frequently selected as important. This is stronger in flipped than MOOC settings. When only videos are available, the predictive power mainly derives from regularity and fine-grained video-related features.*

For the same course in different settings, namely LA-Flip VS LA-MOOC and FP-Flip VS FP-MOOC, the optimal feature set heavily changed. In LA courses, quiz-related features were more important in the flipped context, while session-based features were more important in MOOCs (e.g., those from ChenCui). The latter finding holds for FP courses as well. Specifically, RFs trained on the MOOC version consistently selected features related to the students' session. Another observation for FP is that in the flipped version, tri-grams (ApkinarEtAl) and fine-grained video usage features (LalleConati) were picked; in the MOOC, regularity and session-based features were more important. To sum up, according to Table 2:

Highlight #6. *Predictors in flipped settings often rely on features based on tri-grams and fine-grained video consumption. Conversely, predictors in MOOCs consider regularity and session-based features as important. Quiz-related feature are picked in both settings, when quizzes are available.*

6. DISCUSSION

In this section, we connect the main findings coming from the individual experiments and present the implications and limitations of our study in the early success prediction task.

Course-Related Observations. A challenge, as our work shows, lies on the generalizability of feature predictive power across courses. The variability of the results when repeating the exact same experiment with data from different courses (or slightly different settings) is very high. It is therefore challenging to understand when, why, and how a feature tested on a given course could be re-used for other courses.

Highlight #7. *The predictive power of features does not often generalize across courses with different structures and educational settings. This observation is stronger with respect to the courses structure than between flipped and MOOC settings.*

This observation affects the scalability of early predictors. Being so course-dependent, identifying and enabling features predictive of student success for a given course can take hours or days, given that the intellectual and experimental work needs to be replicated on courses, case by case.

Highlight #8. *The lack of feature predictive power generalizability questions the extent to which a feature can be scaled across courses with the same structure/setting.*

Our experiments also showed that including quizzes in pre-class activities leads to substantial improvements in effectiveness. Hence, success prediction is driven by complex relationships between students' characteristics and the course domain, structure, and educational setting.

Data-Related Observations. Research in the area of early success prediction is often conducted on data extracted from online activities only. Even in our case study (for LA-flip), we could not rely on data collected in class, missing an important segment of learning. Moreover, clickstreams in this study do not cover other relevant interactions such as those in forums. In flipped courses, most (non-digitalized) discussions happen in class, and the forum is mainly used by teachers for announcements.

Highlight #9. *Early success prediction in flipped courses would benefit from including data coming from offline activities (e.g., in class).*

Workflow-Related Observations. To establish reproducibility, the description of the proposed features should go beyond plain-text only. Our formulation in this paper can be re-used to define features as formulas, making it easier to replicate them, especially when no source code is provided.

Highlight #10. *Feature descriptions can be accompanied by their mathematical formulation to ease reproducibility. When possible, sharing the code can facilitate their re-use.*

Though we validated the current features on RFs, other classifiers were not presented. However, RFs often provide the best trade-off between effectiveness and interpretability (the latter was fundamental for our study) and our framework makes it easy to run this analysis on other classifiers. Given that other classifiers (e.g., Support Vector Machines) gave worse (or comparable) results in the preliminary experiments we ran, our results depict a valid picture of feature predictive power.

7. CONCLUSIONS AND FUTURE WORK

In this paper, we analyzed recent features for early success prediction in flipped and online courses. First, we investigated the predictive power of eight existing feature sets and a novel feature set proposed in this paper on a flipped course. We benchmarked the predictive power of features using a RF classifier, and discussed the ensemble feature set optimal for that course. We then extended our analysis to courses with other settings (MOOCs), domains, and structures, showing that the optimal ensemble and its predictive power vary. Our work calls for generalizable early predictors across courses with different characteristics. To promote research in this field, we also publicly release the source code developed during our study (see the footnote in Section 1).

In future work, we plan to extend our analysis to other features (e.g., based on in-class data), and types of student success tasks (e.g., grade prediction). We also plan to analyze more advanced classifiers and to devise robust classifiers across courses before testing them in the real world.

Acknowledgments We thank Himanshu Verma (TU Delft, formerly at EPFL) and Patrick Jermann and Francisco Pinto (EPFL Center for Digital Education) for the valuable input and support on the data sharing and manipulation.

ABSTRACT

Interactive simulations allow students to independently explore scientific phenomena and ideally infer the underlying principles through their exploration. Effectively using such environments is challenging for many students and therefore, adaptive guidance has the potential to improve student learning. Providing effective support is, however, also a challenge because it is not clear how effective inquiry in such environments looks like. Previous research in this area has mostly focused on grouping students with similar strategies or identifying learning strategies through sequence mining. In this paper, we investigate features and models for an early prediction of conceptual understanding based on clickstream data of students using an interactive Physics simulation. To this end, we measure students' conceptual understanding through a task they need to solve through their exploration. Then, we propose a novel pipeline to transform clickstream data into predictive features, using latent feature representations and interaction frequency vectors for different components of the environment. Our results on interaction data from 192 undergraduate students show that the proposed approach is able to detect struggling students early on.

skip-grams, early classification, interactive simulations, conceptual understanding

1. INTRODUCTION

Over the last years, interactive simulations have been increasingly used for science education (e.g, the PhET simulations alone are used over $45M$ times a year [1]). Interactive simulations allow students to engage in inquiry-based learning: they can design experiments, take measurements, and test their hypotheses. Ideally, students discover the principles and models of the underlying domain through their own exploration [2], but students often struggle to effectively learn in such environments [3, 4, 5]. A possible reason for this is that interactive simulations are usually complex and unstructured environments allowing students to choose their own action path [6]. Providing adaptive guidance to students has therefore the potential to improve learning outcomes.

Implementing effective support in interactive learning environments is a challenge in itself: the complexity of the environment makes it difficult to define a priori how successful student behaviour looks like. Previous research has focused on leveraging sequence mining and clustering techniques to identify the key features of successful interactions. For example, [7] have used an information theoretic sequence mining approach to detect differences in the interaction sequences of students with high and low prior knowledge, while [8] investigated the effects of prior knowledge activation. Other work [9] focused on detecting behaviours leading to the design of a correct causal explanation. [10] identified key factors for successful inquiry: focusing on an unknown component and building contrastive cases. Similarly, [11] found that the identification of the dependent variable and its isolated manipulations lead to a better quantitative understanding of the phenomena at hand. Another technique is to manually categorise students' log data and use the tags as ground truth for a classifier of successful inquiry behaviour [12]. [13] developed a dashboard displaying information about the mined sequences to guide teachers in building their lessons.

More work has focused on analysing and predicting students' strategies in different types of open ended learning environments (OELEs), such as educational games. Prior research in that domain has, for example, investigated students' problem solving behaviour [14], analysed the effect of scaffolding on students' motivation [15], extracted strategic moves from video learning games [16], detected different types of confusion [17], or identified students' exploration strategies [18].

Most of the previous work on OELEs has performed *a posteriori* analyses. However, in order to provide students with support in real-time, we need to be able to detect struggling students early on. Due to the lack of clearly defined student trajectories and underlying skills, building a model of students' learning in OELEs is challenging. A promising approach for early prediction in OELEs is the use of a clustering-classification framework [19]: in the (first) offline step, students are clustered based on their interaction data and the clustering solution is interpreted. The second step is online: students are assigned to clusters in real-time. This

framework has been successfully applied to analyse and predict students' trajectories in mathematics learning [20], to differentiate between 'high' and 'low' learners [21], to build student models for interactive simulations [22], or to predict students' exploration strategies in an educational game [23].

In this paper, we aim at early predicting conceptual understanding based on students' log data from an interactive Physics simulation. All our analyses are based on data collected from 192 undergraduate Physics students interacting with a PhET simulation. We propose a novel pipeline for transforming clickstream data into predictive features using latent feature representations and frequency vectors. Then, we extensively evaluate and compare various combinations of predictive algorithms and features on different classification tasks. In contrast to previous work using unsupervised clustering to obtain student profiles [21, 20, 23, 22], our learning activity with the simulation includes a task specifically designed to assess students' conceptual understanding. With our analyses, we address three research questions: 1) Can students' interaction with the data be associated with the gained conceptual understanding? 2) Can conceptual understanding be inferred through sequence mining methods with embeddings? 3) Can the proposed methods be used for early predicting students' conceptual understanding based on partial sequences of interaction data?

Our results show that all tested models are able to predict students' conceptual knowledge with a high AUC when observing students' full sequences (offline). The best models are also able to detect struggling students early on and to provide a more fine-grained prediction of students' conceptual knowledge later during interaction.

2. CONTEXT AND DATA

All experiments and evaluations of this paper were conducted using data from students exploring an interactive simulation. In the following, we describe the learning activity, the data collection, and the categorisation of students' conceptual understanding at the end of the learning activity.

Learning Activity. The data for this work was collected in a user study where participants were asked to engage in an inquiry-based learning activity with the PhET Capacitor Lab simulation[1]. The Capacitor Lab is an interactive simulation with a simple and intuitive interface allowing users to explore the principles behind a plate capacitor (Fig. 1A and B). Specifically, students can load the capacitor by adjusting the battery and observe how the capacitance and the stored energy of the capacitor change when adjusting the voltage, the area of the capacitor plates or the distance between them. After loading the capacitor, the circuit can be opened through a switch, and students can again observe how manipulation of the different components influences capacitance and stored energy. Moreover, the simulation provides a voltmeter, while check boxes in the interface allow users to enable or disable visualisations of specific measures.

Based on this simulation, a learning activity was designed in which participants had to explore the relationships between the different components of the circuit and rank four different capacitor configurations by the amount of stored energy. The configurations were generated based on two initial setups (I and II, respectively) representing capacitors in a *closed circuit* with different settings for battery voltage,

[1]https://phet.colorado.edu/en/simulation/capacitor-lab-basics

plate area and separation (Fig. 1C). For each initial setup, two *open circuit* configurations were generated (i.e. configurations 1 & 2 from setup I and 3 & 4 from setup II) by opening the switch and then changing the values for plate area and separation. To complete this ranking task, participants were allowed to use the simulation for as much time as they needed. It should be noted that the values in the ranking task were chosen outside the ranges of the adjustable values in the simulation such that students could not simply reproduce the four configurations in the simulation, but had to solve the task by figuring out the relationships between the different components and the stored energy.

Data Collection. Data was collected from 214 first-year undergraduate Physics students who completed the capacitor ranking task as part of a homework assignment. While working with the simulation, students' interaction traces (i.e. clicks on check boxes, dragging of components, moving of sliders) were automatically logged by the environment. Moreover, it recorded students' final answers in the ranking task (i.e. the ranking of the four configurations). All data was collected in a completely anonymous way and the study was approved by the responsible institutional review board prior to the data collection (HREC number: 050-2020/05.08.2020). After a first screening of the data, several log files (9) were excluded because of inconsistencies in the data, and another 13 because they had barely any interaction (less than 10 clicks) with the environment. Removing these data points resulted in a data set of 192 students used for our analyses.

Categorisation of conceptual understanding. The design of the ranking task allows to relate students' responses to their conceptual understanding of a capacitor. For this purpose, we analysed the 16 (out of 24 possible) rankings submitted by the students with regards to conceptual understanding and grouped them accordingly. To this end, three concepts of understanding associated with the functioning of capacitors were evaluated in a top-down approach: answers were first separated by those representing an understanding of both the open and closed circuit (label *both*), and those only representing an understanding of the closed circuit (label *closed*). For those answers representing an understanding of both the open and closed circuit, two cases were distinguished. It was assumed that students who chose the only correct ranking of the configurations ("4213") gained an exhaustive understanding of the underlying concepts (label *correct*). Students who instead chose one of the other rankings were assumed to know how plate area and separation influence the stored energy in both the open and closed circuits, but failed to discover the influence of voltage on stored energy (label *areasep*). Within those answers that only represented an understanding of the capacitor's functioning in the closed circuit, we also distinguished between two cases. The first case represents the answer that would be considered correct if the task was to order the four configurations by capacitance instead of energy ("1324", label *capacitance*). Interestingly, 47 students (i.e. 24% of all students) submitted this ranking as an answer. The second case represents all other possible answers (label *other*) that could be submitted if (a part of) the closed circuit was understood.

Based on these three underlying concepts, we generated a decision tree with four leaves (each representing a group with similar conceptual understanding) and mapped all 16 rankings submitted by the students to the leaves (Fig. 2). These generated class labels will serve as ground truth labels for the classification task presented in the following sections.

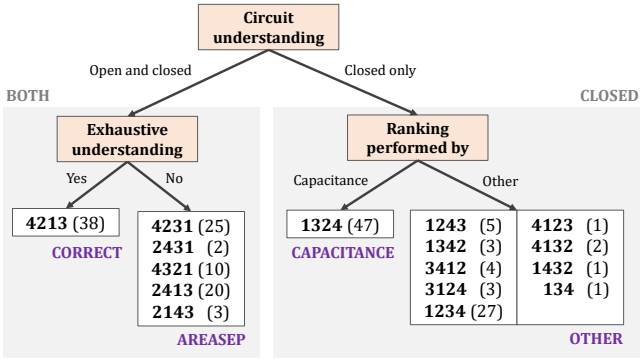

Figure 2: Tree used to map the 16 different rankings submitted by the students to class labels associated with conceptual understanding of a capacitor. The different class labels are indicated in capitalised letters. The numbers in parentheses indicate the number of submissions for each ranking.

3. METHOD

Using our proposed approach, we are interested in predicting the conceptual understanding students gain from interacting with the simulation. Therefore, we are solving a supervised classification problem, i.e. we aim at predicting the class labels (representing students' conceptual understanding) based on the observed student interactions. Our model building process to solve this classification problem consists of four steps (Fig. 3). We first extract the raw clickstream events from the logs and process them into action sequences. We then compute three different types of features for each action sequence and feed them into our classifiers.

Event Logs. From the simulation logs, we extract the clickstream data of each student s as follows: anything between a mouse click/press and a mouse release qualifies as an *event*, while anything between a mouse release and mouse click/press is called *break*. Each *event* is then labelled by the component the user was interacting with at the mouse click, and chronologically arranged with the *breaks* into a sequence.

Action Processing. We distinguish three main components on the platform, whose values can be changed: 1) *the voltage*, 2) *the separation between the plates*, and 3) *the area of the plates*. An action on these components can be conducted in a) *an opened circuit* or b) *a closed circuit*, with the stored energy information display i) *on* or ii) *off*. We categorise each event involving these main actions by the combination of: the action on the component {1), 2), 3)}, the circuit state {a), b)}, and the stored energy display {i), ii)}. Any other event is categorised as 4) *other*.

The sequence of each student s is now composed of chronologically ordered events (divided into the 13 different categories listed above) separated by breaks. The breaks may be caused by the student being inactive due to observing

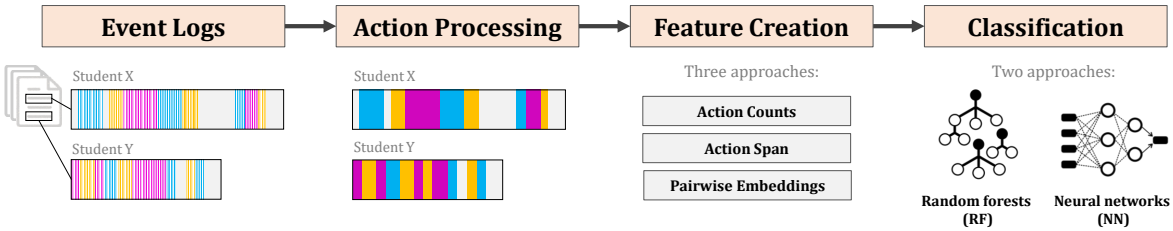

Figure 3: Schematic overview of the classification pipeline. Raw clickstream events are extracted from log data and processed into an action sequence per user. Three types of features are computed for each action sequence. Classification is performed using Random Forests (RF) and Neural Networks (NN).

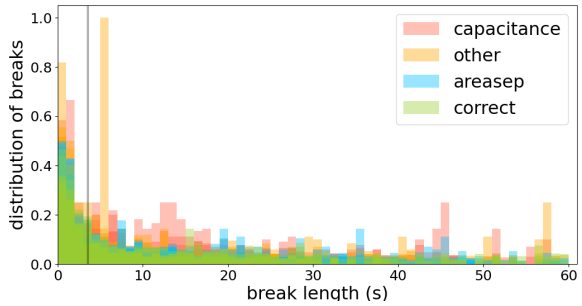

Figure 4: Distribution of break lengths in seconds, across all students. The bold gray line denotes the 60% threshold.

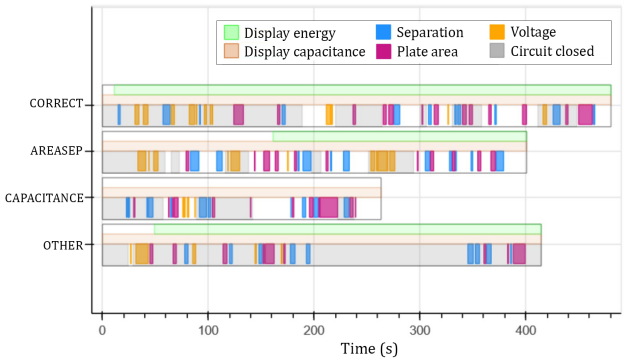

Figure 5: Timeline of an exemplary student for each class label displaying the chronological sequence of interactions with the three main components of the simulation. The green and orange bars indicate whether the student displayed the capacitance and stored energy. The background indicates whether the interactions were conducted in a closed (grey) or open (white) circuit.

the progression of a value, reflecting about an observation, or taking notes. Due to its definition as the period between a mouse release and a mouse click/press, a break may also appear due to logistic reasons, such as moving the mouse from one component in the simulation to another component. Indeed, the students' event sequences consist of many short breaks (Fig. 4). Like stop words in natural texts, our assumption is that these very short breaks, though very frequent in our sequences, do not contain much information. In fact, our classification over students' understanding may be impaired if those noisy states are not removed, like it is the case for sentiment analysis when stop words are not deleted [24]. To determine the threshold at which the breaks are removed, we plot the distribution of inactivity periods, and cut at the elbow of the curve for each student, which corresponds to a delimitation at 60%, i.e. for each student we keep the top 40% of breaks. We then categorise each of our remaining breaks similarly to our main action events: by component 5) *break*, circuit state {a), b)}, and stored energy display {i), ii)}, resulting in four different break categories.

The resulting sequence $\mathbf{r_s}$ for student s is the chronological timeline of the student's events and breaks, divided into 17 categories. We refer to this timeline $\mathbf{r_s}$ as the *raw sequence* of *interactions* for the rest of the paper. We denote the length (corresponding to the total number of interactions of student s) of $\mathbf{r_s}$ with N_s, i.e. $|\mathbf{r_s}| = N_s$. On average, these sequences have a length of $N_s = 67.86 \pm 42.56$. In terms of seconds, the sequences $\mathbf{r_s}$ lasted on average 512.18 ± 435.57 seconds. We also introduce the notion of *time*, which we define related to a student's interactions: at time t the length of the raw sequence of interactions for student s is t, i.e. $|\mathbf{r_{s,t}}| = t$. We denote the maximum time of student s with T_s, corresponding to the full sequence $\mathbf{r_s}$. Figure 5 visualises the timelines for an exemplary student of each class label. It can be observed that for these examples, certain aspects of conceptual understanding could be inferred by visual inspection (e.g. the *capacitance* student never activated the check box to visualise the stored energy). However, other differences in conceptual understanding are more difficult to detect by humans (e.g. the differences between the *correct* and *areasep* students).

Feature Creation. Next, we transform the interactions in each sequence to obtain three different types of features: *Action Counts*, *Action Span*, and *Pairwise Embeddings*.

To obtain the *Action Counts* features $F_{AC,s}$ for a student s, we first transform each interaction within the raw sequence $\mathbf{r_s}$ in a one-hot encoded vector, resulting in a 17-dimensional vector $\mathbf{h_{s,i}}$ for each interaction i and hence, a sequence of

vectors $H_s = \{\mathbf{h_{s,i}}\}$ with $i = 1, ..., N_s$. To compute $\mathbf{f_{AC,s,t}}$ for student s at time step t, we compute the average over $\mathbf{h_{s,i}}$ with $i = 1, ..., t$: $\mathbf{f_{AC,s,t}} = \frac{1}{t}\sum_{i=1}^{t} \mathbf{h_{s,i}}$. By using this aggregating technique, our features are translated to the (averaged) number of times each student has interacted in each of our categories. Therefore, for each student s, we end up with a feature set $F_{AC,s} = \{\mathbf{f_{AC,s,t}}\}$ with $t = 1, ..., T_s$.

The computation of the *Action Span* features $F_{AS,s}$ for a student s is very similar. Rather than looking into the number of times a student s has interacted with each of our components in a particular state, we look into the amount of time (in seconds) s has spent in each of the categories. We first transform every interaction i within $\mathbf{r_s}$ into a 17-dimensional vector $\mathbf{h_{s,i}}$: This vector is 0 for all dimensions but the dimension d corresponding to the category the i_h interaction belongs to. This representation is similar to a one-hot encoded vector, but instead of filling in a 1 at dimension d, we fill in the duration (in seconds) of interaction i. This results in a sequence of vectors $H_s = \{\mathbf{h_{s,i}}\}$ with $i = 1, ..., N_s$. We then compute the feature vector $\mathbf{f_{AS,s,t}}$ for student s at time t in two steps. In a first step, we again average over all vectors $\mathbf{h_{s,i}}$ up to time t, leading to $\tilde{\mathbf{f}}_{\mathbf{AS,s,t}} = \frac{1}{t}\sum_{i=1}^{t} \mathbf{h_{s,i}}$. We then normalise $\tilde{\mathbf{f}}_{\mathbf{AS,s,t}}$ to obtain $\mathbf{f_{AS,s,t}}$. By using this aggregation technique, our feature vector $\mathbf{f_{AS,s,t}}$ represents the relative amount of time student s has spent in each category up to time t. For each student s, we end up with with a feature set $F_{AS,s} = \{\mathbf{f_{AS,s,t}}\}$ with $t = 1, ..., T_s$.

The third feature, *Pairwise Embeddings*, is fundamentally different from the the two other features: we replace each interaction in the raw sequence by an embedding vector which we obtain by training a pairwise skip-gram [25]. The architecture of such a network consists of two dense layers: an embedding layer followed by a classification layer. Usually applied to natural language applications (NLP), its primary goal is to predict the context of a word. Here, our pairwise skip-gram attempts to predict the behavior of a student in the simulation before and after performing a specific interaction. The skip-gram model can be formulated as:

$$\mathbf{p} = \text{softmax}(W_2 \cdot (W_1 \cdot a)) \tag{1}$$

It takes a, an interaction we wish to predict the context of as an input, and outputs $\mathbf{p}$, a probability vector which contains the likelihood of a being surrounded by each possible *interaction*. W_1 and W_2 represent the weight matrices (embeddings). For each interaction a, we feed $2 \cdot w$ pairs into the network, where w is the so-called window size of the model (context). The first element of each pair is a. The second element of each pair, the ground truth label, is one of the w interactions preceding or following a. For example, a window size of $w = 2$ would yield the following pairs for action a: $(a, a_{-2}), (a, a_{-1}), (a, a_{+1}), (a, a_{+2})$.

In our case, to obtain the set of pairs I_s for a student s, we first again transform each interaction within the raw sequence $\mathbf{r_s}$ in a one-hot encoded vector, resulting in a 17-dimensional vector $\mathbf{h_{s,i}}$ for each interaction i and, hence, a sequence of vectors $H_s = \{\mathbf{h_{s,i}}\}$ with $i = 1, ..., N_s$. We then build the input pairs for each interaction i, i.e. $I_{i,s} = \{(\mathbf{h_{s,i}}, \mathbf{h_{s,j}})\}$ with $j \in \{-w, ..., w\} \setminus 0$. We obtain the set of pairs for all students as $I = \{I_s\}$ with $s = 1, .., S$, where S is the total number of students.

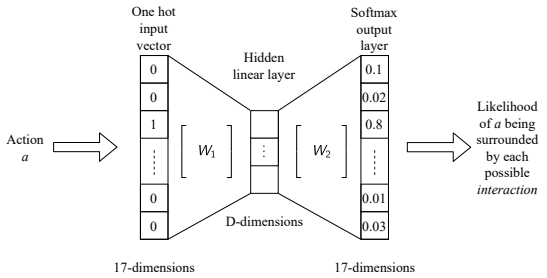

Figure 6: Skip-gram architecture. After training of the skip-gram, the corresponding row of the weight matrix W_1 represents a structure preserving embedding of action a.

After training the skip-gram model on I, we build the features $F_{PW,s}$ for each student s. The weighs W_1 of the hidden layer represent a structure preserving embedding of the interactions. In our case, W_1 has dimensions $17 \times D$ (D is the embedding dimension). For each interaction i of student s, we get the corresponding row r in W_1, i.e. $\mathbf{r_{s,i}} = W_1 \cdot \mathbf{h_{s,i}}$. This again results in a sequence of vectors $R_s = \{\mathbf{r_{s,i}}\}$ with $i = 1, ..., N_s$. To compute $\mathbf{f_{PW,s,t}}$ for student s at time step t, we compute the average over $\mathbf{r_{s,i}}$ with $i = 1, ..., t$: $\mathbf{f_{PW,s,t}} = \frac{1}{t}\sum_{i=1}^{t} \mathbf{r_{s,i}}$. Therefore, for each student s, we end up with a feature set $F_{PW,s} = \{\mathbf{f_{PW,s,t}}\}$ with $t = 1, ..., T_s$.

Classification. To perform the classification task, we explore two different approaches: *Random Forests* and *Fully Connected Deep Neural Networks*.

Random Forests (RFs) are simple, yet powerful machine learning algorithms. They consist of an ensemble of decision trees, each trained on a different subset of samples and a different subset of features. The decisions of each tree are then aggregated to determine the final prediction of a sample. The strength of this method is that overfitting is prevented through the randomisation of training samples and features during the training of each tree and that the strengths of several good classifiers are exploited. While RF classifiers are well tested and efficient to train, they require the input features to have the same dimension for every sample. We therefore train separate RF models for each time step t. The input features for the RF model for time step t are $\{\mathbf{f_{M,s,t}}\}$, with $M \in AC, AS, PW$ and $s = 1, ..., S$, where S denotes the number of students. The output of the RF is a vector $\mathbf{p_{RF,M,s,t}}$ of dimension C (with C denoting the number of classes) for each student s, which represents the probability of each class.

Neural Networks (NNs) were built with the idea of emulating neurons firing in our brain: their nodes are to the neurons what their edges are to their axons. The advantage of those deep networks is that they are able to model non-linear decision boundaries. However, the back propagation calculations make them relatively slow to train. In this work, we use a *Fully Connected Deep Neural Network* consisting of d hidden dense layers and one classification layer with a softmax activation. Similar to RFs, our NN model requires features to have the same dimension for all the samples. We therefore also train the NN models for fixed points in time. The input features for the NN model for time step t are

$\{\mathbf{f_{M,s,t}}\}$, with $M \in AC, AS, PW$ and $s = 1, ..., S$, where S denotes the number of students. Due to the softmax activation, the output of the NN is a vector $\mathbf{p_{NN,M,s,t}}$ of dimension C (with C denoting the number of classes) for each student s, which represents the probability of each class.

4. EXPERIMENTAL EVALUATION

We evaluated the predictive performance of our classification pipeline on the collected data set (see Section 2). We conducted experiments to compare the performance of different model and feature combinations for the students' full data sequences as well as for early classification using partial sequences of the data, to answer our research questions.

Experimental Setup. We applied a train-test setting for all the experiments, i.e. parameters were fitted on a training data set and performance of the methods was evaluated on a test data set. Predictive performance was evaluated using the macro-averaged area under the ROC curve (AUC). We used the AUC as a performance measure as it is robust to class imbalance.

We performed all our experiments using different levels of detail for the classification task. As ground truth, we used the class labels presented in Fig. 2. Given the hierarchical nature of the decision tree separating the students in classes based on their conceptual knowledge, we performed the classification task focusing on three different levels of detail:

- *2-class case*: starting at the root of the decision tree (see Fig. 2), we divide students into two classes based on their understanding of the circuits: *both* (98 students) and *closed* (94 students).
- *3-class case*: going one step down in the hierarchy of the tree, we further divide the left branch of the tree (see Fig. 2) based on whether the students have completely understood all concepts (leading to a correct answer in our ranking task) or not. We therefore obtain three different classes: *correct* (38 students), *areasep* (60 students), and *closed* (94 students).
- *4-class case*: here, we also split the right branch of the tree (see Fig. 2) and divide the students into two groups based on whether they ranked the configurations in the task based on capacitance, resulting in four classes: *correct* (38 students), *areasep* (60 students), *capacitance* (47 students), and *other* (47 students).

For each of those three cases, we trained two types of classifiers (RF and NN) on our three different feature types (Action Counts - AC, Action Span - AS, Pairwise Embeddings - PW), using a stratified 10-fold **nested** cross validation. We kept the folds invariant across all experiments and stratified over the classes (according to the class labels of the 4-class case). Because of class imbalance, we used random oversampling for the training sets. We used a **nested** cross validation to avoid potential bias introduced by estimating model performance during hyperparameter tuning. This allowed us to tune the hyperparameters within the training folds (by further splitting them) and hold out the test sets for performance evaluation alone.

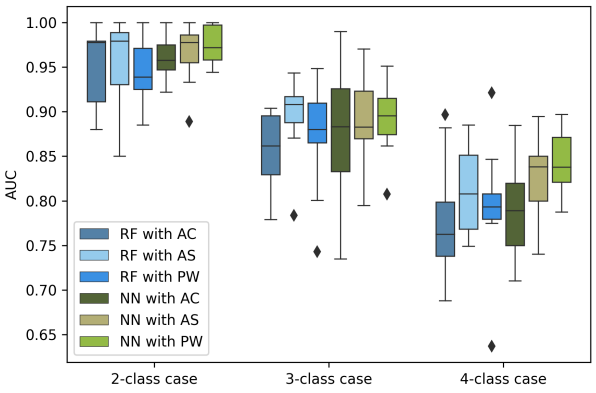

Figure 7: AUC for 4-class, 3-class and 2-class cases using different model and feature combinations. Predictions are made at the end of the interaction with the simulation, i.e. based on the complete sequential interaction data of the students.

For RF models, we tuned the following hyperparameters using a grid search: number of trees [5, 7, 9], number of features used at each decision level ['auto', 'all'], number of samples [bootstrap resampling of *training size* samples and balanced subsamples]. NN models were implemented using the *scikit-learn* library, trained for 300 epochs, and optimised for the log-loss function with the following hyperparameters: learning rate ['adaptive', 'invscaling'], initial learning rate [0.01, 0.001], solver ['adam', 'sgd'], hidden layer sizes and number [(32, 16), (64, 32), (64, 32, 16), (128, 64, 32, 16)], and activation function ['relu', 'tanh', 'identity'].

The skip-gram model providing our pairwise embedding features was implemented using the *TensorFlow* package. We trained the model for 150 epochs, with a window size of $w = 2$, a batch size of 16, and an embedding dimension of 15. We used categorical cross-entropy as the training loss. Because of its unsupervised nature, we trained the model on our whole dataset.

Offline Classification. In a first experiment, we were interested in assessing whether it is possible to associate students' behaviour in the simulation with their conceptual understanding achieved through the learning activity. This will be referred to as an offline classification task, since we are using students' complete interaction sequences r_s. The predictive performance in terms of AUC for the three classification problems (4-class case, 3-class case, and 2-class case) with a distinction between different model and feature combinations is illustrated in Fig. 7.

The results of this first experiment showed that for the 2-class case, all combinations of models and features reached very high average performances as quantified by their AUC scores (value range: $0.95 - 0.97$). The best mean score was achieved by the combination of NN with PW features ($AUC_{NN,PW} = 0.97$). However, it should be noted that the performance differences between the combinations were comparatively small. Using a one-way ANOVA, no statistically significant differences were found between the different groups ($F(5, 54) = 0.839, p = 0.528$). It seems that for this rather rough classification into groups of students who

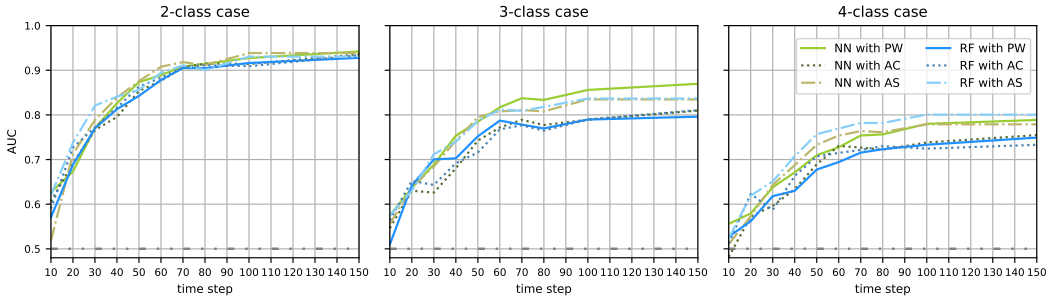

Figure 8: AUC for 4 classes, 3 classes, and 2 classes using different model and feature combinations. Predictions are made over time, stopping at time step $t = 150$ as only very few students have longer interaction sequences.

only understood the closed circuit and those who understood both the open and closed circuits, the different combinations of models and features perform equally well and with a high predictive accuracy.

By extending the classification task to the 3-class case, the AUC scores dropped in comparison to the 2-class case (value range: $0.86 - 0.90$). The lowest score was observed for RF with AC ($AUC_{RF,AC} = 0.86$), while best performances were observed for RF with AS ($AUC_{RF,AS} = 0.90$), NN with AS ($AUC_{NN,AS} = 0.89$), and NN with PW ($AUC_{NN,PW} = 0.89$). Similar to the 2-class case, no statistically significant differences were found between the different groups using a one-way ANOVA ($F(5, 54) = 0.740, p = 0.597$). This result illustrates that further dividing those who understood the functioning of the capacitor in both the open and closed circuit had a similar impact on the predictive performance of all model and feature combinations.

Finally, when evaluating the 4-class case, the most complex classification task, the mean AUC scores further dropped for all combinations (value range: $0.78 - 0.84$). The lowest performance was again observed for RF with AC ($AUC_{RF,AC} = 0.78$). Introducing the fourth class to the classification problem seemed to have a smaller negative impact on the AUC scores for NN with AS ($AUC_{NN,AS} = 0.83$) and NN with PW ($AUC_{NN,PW} = 0.84$), which obtain the best performances for the 4-class case. This observation was partially confirmed by a one-way ANOVA that showed a trend to statistical significance for differences between the combinations ($F(5, 54) = 1.989, p = 0.095$): as we increase the amount of classes, the p-value decreases.

The results of this first experiment show that it is possible to perform an offline prediction of students' conceptual understanding in the capacitor ranking task (see Section 2) based on the different combinations of models (NN or RF) and feature generation methods (AC, AS or PW) proposed in this work. From the entire data sequences of students' interactions with the simulation, we observed that predictive performance generally decreased when the complexity of the classification task was increased. While all combinations showed very good performances for the coarse classification of the 2-class case, AUC scores started to diverge more among combinations for the 3- and 4-class cases. Especially for the 4-class case, where differences became more visible with certain combinations showing a trend of better predictive performance (i.e. NN with PW and NN with AS) as compared to others (e.g., RF with AC).

Predicting over Time. In a second experiment, we were interested in assessing, whether we could predict students' conceptual knowledge for shorter interaction sequences, i.e. when not using students' full sequences, but only the first t interactions. For all three classification cases (2-class, 3-class, and 4-class), we trained all model (RF, NN) and feature (AC, AS, PW) combinations for $t = 10, 20, ..., 150$ time steps. As described in Section 3, to compute the features $\mathbf{f_{AC,s,t}}$, $\mathbf{f_{AS,s,t}}$, and $\mathbf{f_{PW,s,t}}$ for a student s at time step t, we only use the student's interactions i up to that point in time, i.e. $i = 1, ..., t$. Similarly, at each time step t, the models are exclusively used to predict students whose interactions sequences contain a minimum of t elements (i.e. $N_s \geq t$). For students with shorter interaction sequences (i.e. $N_s < t$), the last available prediction will be used. For example, for a student with 30 interactions ($N_s = 30$), we would make the first three predictions using the models for $t = 10$, $t = 20$, and $t = 30$ time steps. For the remaining time steps, the predictions from $t = 30$ will be carried over. We chose this approach for predicting because we assume that the student will leave the simulation after N_s interactions and it therefore does not make sense to update the prediction afterwards. Figure 8 illustrates the predictive performance in terms of AUC for the different model and feature combinations and all classification cases.

As expected, for the 2-class case, all models achieve a high performance for long interaction sequences. The AUC of all NN models is larger than 0.9, starting at time step $t = 70$. Generally, the difference between the models and feature combinations for $t \geq 70$ is small. We also observe some model differences for earlier time steps, where the RF model with the action span features performs better than the other models. It achieves an AUC larger than 0.8 already at time step $t = 30$ ($AUC_{RF,AS} = 0.82$). Moreover, the NN model with action span is close to that performance at time step $t = 30$ ($AUC_{NN,AS} = 0.79$). Naturally, predicting at even earlier time steps is more difficult, but some of the models achieve a decent AUC of 0.7 already after observing 20 interactions with the simulation ($AUC_{RF,AS} = 0.74$, $AUC_{RF,AC} = 0.73$, $AUC_{NN,AS} = 0.71$).

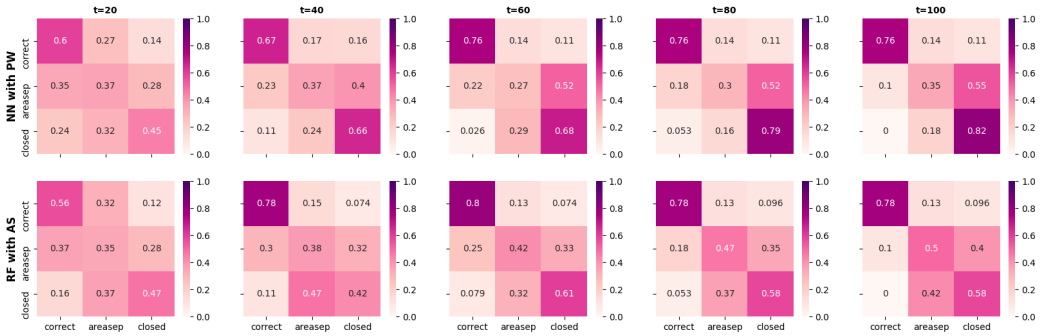

Figure 9: Evolution of confusion matrices over time steps for the 3-class case: NN with PW (top) and RF with AS (bottom).

For the 3-class case, the performances of all algorithms have decreased from time step $t = 10$ compared to the above problem. This is not surprising, as differentiating the correct students from the *areasep* students is not as straightforward as separating students who did not interact in the open circuit from the rest. Though, in the 2-class cases, all performances were close to one another, we notice that for the 3-class problem at time step $t = 40$, three model-features combinations take the lead ($AUC_{NN,PW} = 0.75$, $AUC_{RF,AS} = 0.74$, $AUC_{NN,AS} = 0.74$), while three fall behind ($AUC_{RF,PW} = 0.7$, $AUC_{RF,AC} = 0.69$ and $AUC_{NN,AC} = 0.68$) until $t = 70$, where the NN with PW outperforms all other model and feature combinations with an AUC of 0.87.

The variance across model-feature performances is larger in the 4-class case. From time step $t = 20$ already, RF with AS outperforms all other combinations, reaching an AUC of 0.8 at time step $t = 100$. Similarly to the 3-class problem, the same three models take the lead, while the others fall behind from time step $t = 70$ ($AUC_{NN,PW} = 0.75$, $AUC_{RF,AS} = 0.78$, $AUC_{NN,AS} = 0.76$ and $AUC_{RF,PW} = 0.72$, $AUC_{RF,AC} = 0.72$ and $AUC_{NN,AC} = 0.73$).

Given the fact the predictive performance in terms of AUC seems to be similar for the best performing models, we performed a more detailed analysis to assess how different the predictions of the several model and feature combinations were. In a real-world application (intervention setting), we would probably use a 2-class classifier to identify a coarse split (between classes *both* and *closed*) already at a relatively low number of time steps and use a 3-class method to provide a more detailed prediction later on. With the current model performance for the 4-class case, usage of a more detailed classifier seems not practicable. We therefore investigate the predictions of the two best models for the 3-class case: NN with PW and RF with AS. Figure 9 shows the confusion matrices for these two models for an increasing number of time steps. We do not show results for $t > 100$, as the predictive performance of the models does not improve much anymore for longer sequences (see also Fig. 8). While both models have a very similar predictive performance in terms of AUC up to time step 60, we can already see that the models evolve differently in terms of prediction. At time step $t = 40$, the RF model is already very accurate in detecting students from class *correct* ($\hat{p}(correct|c_{true} = correct) = 0.78$), while the NN model is less confident ($\hat{p}(correct|c_{true} = correct) = 0.67$). On the other hand, the NN model is already more accurate in identifying students from class *closed* ($\hat{p}(closed|c_{true} = closed) = 0.66$), while the RF model cannot identify students from this class well ($\hat{p}(closed|c_{true} = closed) = 0.42$). At time step $t = 60$, both models are almost equally accurate in identifiying students from class *correct* (NN: $\hat{p}(correct|c_{true} = correct) = 0.76$, RF: $\hat{p}(correct|c_{true} = correct) = 0.80$). The NN model is still better at classifying students from the class *closed*. Both models have trouble with correctly identifying students from class *areasep*. While the NN model tends to assign these students to class *closed* ($\hat{p}(areasep|c_{true} = closed) = 0.52$), the RF model is becoming better at correctly assigning them ($\hat{p}(closed|c_{true} = closed) = 0.42$). These observed trends continue to get stronger with an increasing number of time steps. At $t = 100$, the NN model is very accurate when it comes to classifying students from classes *correct* and *closed*. Students from class *areasep* have only a 35% chance of being correctly classified and a 55% chance of getting assigned to class *closed*. In practice, this would mean that 55% of the students would get more intervention (hints) than necessary. The RF classifier is also very accurate in detecting students from class *correct*, but is, however, not able to distinguish between students from class *closed* and class *areasep*. In practice, this would mean misclassified students from class *closed* would get less help than necessary and misclassified students from class *areasep* would get more help than necessary.

This experiment shows that we can (coarsely) classify students after observing a relatively low number of interactions. For the 2-class case, the AUC of the best model (RF with AS) is larger than 0.8 after $t = 30$ time steps. Naturally, the classification task is more complex for the 3-class and the 4-class cases. The best model on the 3-class case (NN with PW) achieves an AUC close to 0.8 at time step 50. The second analysis demonstrates that achieving a similar predictive performance in terms of AUC does not imply the same classification behaviour, i.e.the best models on the 3-class case (NN with PW and RF with AS) have different strengths. It has, however, one important limitation: students spend different amount of times on the simulation and therefore, the length of their interaction sequences varies. There are for example students with 80 interactions and other students with only 50 interactions. Performing the classification task at time step 40 is early for a student with

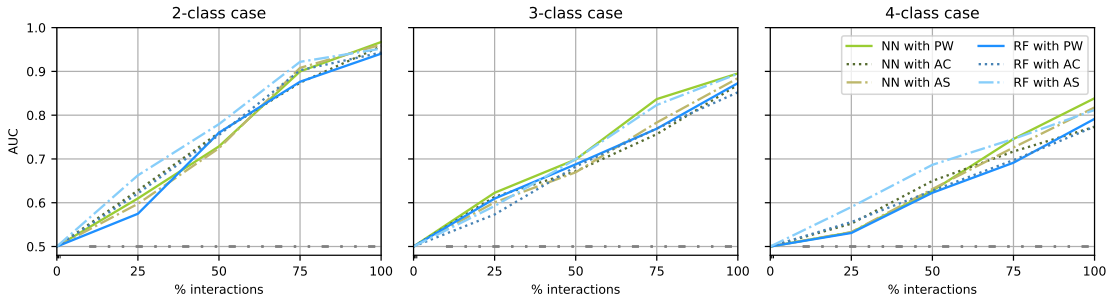

Figure 10: AUC on the 2-class, 3-class and 4-class cases for different model and feature combinations. Predictions were made for 25%, 50%, 75% and 100% of the total number of interactions for each student.

a total of 80 interactions. For a student with only 50 interactions in total, the prediction at time step 40 comes almost at the end of the interaction time with the simulation.

Online (Early) Classification. The third and last experiment addresses the limitations of the previous experiment. In this experiment, we were interested in assessing the "early" predictive performances of the different models using only a part of a student's sequence. Given the fact that the length of interaction sequences varies over the students, we did not align the sequences by absolute time steps, but by percentages of interactions. Specifically, we aimed at making the prediction for a student after having seen 25%, 50%, 75%, and 100% of the interaction sequence of this student. Note that this experiment does not require a re-training of our models. We just retrieve the predictions of the models for the corresponding time step t. For our example student with a total of 80 interactions, we retrieve the predictions of the models for time steps $t = 20$, $t = 40$, $t = 60$, and $t = 80$. Figure 10 shows the AUC of the models for all classification cases, with an increasing number of interactions (in %).

As expected, all model and feature combinations perform well for the 2-class case. To achieve a high classification accuracy, we do not need to observe the full sequence of a student. For all NN models, obtaining 75% of students' interactions is enough to achieve an AUC of around 0.9. With RF, the model using the action span features also obtains an AUC of more than 0.9 at 75% of the interactions ($AUC_{RF,AS} = 0.92$). The performance of the two other feature types is slightly lower ($AUC_{RF,AC} = 0.9$, $AUC_{RF,PW} = 0.88$). Naturally, predictive performance of all the models is lower when observing smaller parts of students' interaction sequences. If obtaining only the first 25% of students' interactions, there is more variation in the achieved AUC between models, with the best model (RF with AS) achieving an AUC of 0.66 and the worst model achieving an AUC of 0.57 (RF with PW). It is promising that the best model at 50% of the interactions exhibits an AUC of almost 0.8 ($AUC_{RF,AS} = 0.78$), which makes it a valuable candidate for a coarse early prediction and intervention, i.e. differentiating between students with a high conceptual understanding (class *both*) and students with a low conceptual understanding (class *closed*), early on.

Naturally, performance of the models for the 3-class case is overall lower as we are now differentiating the different levels of conceptual knowledge in a more fine-grained way. As we have seen in Fig. 9), it is difficult to differentiate between students from the left branch of the tree (i.e. *correct* vs. *areasep* in Fig. 2). Performance across models varies more for the 3-class case. When observing 75% of students interactions, the AUC of the worst model (NN with AS) amounts to 0.78, while the best model (NN with PW) has an AUC of 0.84. We also observe that the NN with PW features is consistently the best model, regardless of the amount of observed interactions, with an increasing gap to the other models. At 50% of interactions, the gap in performance among the three best models is still small ($AUC_{NN,PW} = 0.699$, $AUC_{RF,AS} = 0.7$, $AUC_{RF,PW} = 0.69$). It gets larger at 75% ($AUC_{NN,PW} = 0.84$, $AUC_{RF,AS} = 0.82$, $AUC_{NN,AS} = 0.78$). When observing the complete sequences of the students (i.e. 100% of the interactions), all models reach an AUC of 0.85 or higher (see also Fig.7).

Again, the performance decreases when moving to four classes, due to the increasing complexity (in terms of level of detail) of the classification task. The AUC of the best model (NN with PW) amounts to 0.83, while for the worst two models $AUC = 0.77$ (RF with AC, NN with AC). While all the models' AUC is lower than 0.7 when observing only 25% or 50% of students' interactions, interestingly there is a large gap between the best model (RF with AS) and all the other models (i.e. at 25%: $AUC_{RF,AS} = 0.59$, $AUC_{RF,AC} = 0.56$).

With this last experiment, we assessed the capabilities of our models to make predictions as early as possible during interaction with the simulation as a basis for intervention. By evaluating the models at different percentages of total interactions, we took into account the fact that the definition of 'early' depends on the student. Our results show that after observing the first 50% of interactions, we are able to reliably distinguish between students with a high and low conceptual understanding gained by the end of the learning activity (*both* and *closed*). At 75% of interactions, the best models are also able to provide a more fine-grained prediction (*correct*, *areasep*, and *closed*).

5. DISCUSSION

Over the last decade, interactive simulations of scientific phenomena have become increasingly popular. They allow students to learn the principles underlying a domain through

their own explorations. However, only few students possess the degree of inquiry skills and self-regulation necessary for effective learning in these environments. In this paper, we therefore explored approaches for an early identification of struggling students as a basis for adaptive guidance: we aimed at predicting students' conceptual knowledge while interacting with a Physics simulation. Specifically, we were interested in answering the following three research questions: 1) Can students' interaction with the data be associated with the gained conceptual understanding? 2) Can conceptual understanding be inferred through sequence mining methods with embeddings? 3) Can the proposed methods be used for early predicting students' conceptual understanding based on partial sequences of interaction data?

To answer the first research question, we analysed data from 192 first-year undergraduate Physics students who used an interactive capacitor simulation to solve a task in which they had to rank four capacitor configurations by their stored energy. Previous research has emphasised the importance of aligning instructional and assessment activities to implement pedagogically meaningful learning activities with educational technology [26, 27]. Since one objective of automatically detecting student learning behavior is to provide some kind of assessment (either formative or summative), the learning task presented in this work was designed to facilitate the application of sequence mining. The design of this learning task allowed us to relate all of the students answers to a certain level of conceptual understanding. Using a decision tree, we were able to map each ranking to one of the four labels representing groups of similar conceptual understanding. Our results show that all evaluated models were able to correctly associate students' sequential interaction data in the simulation with the generated labels, achieving high predictive performance when fed with full sequences (2-class case: $AUC > 0.9$, 3-class case: $AUC > 0.85$, 4-class case: $AUC > 0.75$). This high predictive power was also observed in [22], where they reached an accuracy of 85% when separating 'high' learners from 'low' learners based of full interaction sequences. However, despite their findings of a potential third cluster, they did not investigate the ternary classification task. In this paper, we increase the granularity of the labels in order to target more specific shortcomings in the knowledge of the students in order to provide them with more detailed feedback. We therefore conclude that we can answer research question 1) with yes.

The second research question investigates the benefits of latent features generated by skip-grams for offline classification tasks in the context of education. Usually applied to NLP problems, skip-grams have the ability to learn the context of a word in an unsupervised fashion. In our case, we use it to find the OELE behaviour of the students surrounding their interaction, and retrieve the embedding matrix of the neural network to create our latent representations. This approach has already been proven efficient to analyse student strategies in blended courses [28], but not for the identification of conceptual understanding. To evaluate the predictive power of latent feature representations, we trained two classifiers (NN and RF) on three types of feature (*Action Counts*, *Action Span* and *Pairwise Embeddings*) on the full sequences of students. At first, we notice that all model and feature combinations achieve a high AUC for all classification tasks (2-class case, 3-class case, and 4-class case). Though the ANOVA revealed no significant differences between the predictive performance of models with different types of features, we can observe that the NN with PW achieves a higher performance on average than all other combinations but the NN with AS. What is more, the performances in its first quartile dominate those from the third quartile of three model and feature combinations. Additionally, its performance variance is smaller than that of the NN with AS. This shows that pairwise embeddings generated by a skip-gram approach can be a valuable asset for finer-grained classification, even if no statistical difference was found with respect to the other model-feature combinations. We can therefore answer research question 2) with a partial yes.

To address the third research question, we assessed predictive performance of the proposed approach when only partial sequences of the students' interaction data were observed. We analysed the performances of our proposed approaches based on varying proportions of the available data and for classification tasks with different levels of complexity. The results of our experiments show that the proposed combinations of models and generated features allowed us to predict the correct class labels early on. The best models were able to reliably predict students' conceptual understanding for the 2-class case ($AUC \approx 0.8$) after having seen 50% of the students' interaction data. To reach a similar predictive performance for the more fine-grained 3-class and 4-class cases, the best models needed about 75% of the data. The findings from these experiments therefore represent a promising step towards early prediction of students' conceptual understanding in OELEs. We can therefore answer research question 3) with yes.

One of the limitations of this work is the unfeasibility to track whether students used external resources (other than the simulation) in order to rank the four capacitor configurations. This may bias the inference from the simulation usage to the extrapolated understanding level. Furthermore, due to our small sample size, we were able to only train shallow NN classifiers and skip-grams. Finally, the external validity of these experiments remains to be evaluated on other interactive simulations and different types of tasks.

To conclude, the proposed approach represents a promising step towards early prediction of students' learning strategies in interactive simulations, that moreover, can be associated with their level of conceptual understanding. The proposed learning activity seems to represent an interesting example for the design of learning tasks in OELEs that facilitates the association of detected student strategies with conceptual understanding through sequence mining. Future work could explore whether such designs could also be used to identify conceptual understanding at a more fine-grained level.

6. ACKNOWLEDGMENTS

We thank Kathy Perkins (PhET Interactive Simulations, University of Colorado Boulder) and Daniel Schwartz (Stanford University) for the valuable input on the study design and setup and for supporting data collection.

ABSTRACT

As students learn how to program, both their programming code and their understanding of it evolves over time. In this work, we present a general data-driven approach, named *Temporal-ASTNN* for modeling student learning progression in open-ended programming domains. Temporal-ASTNN combines a novel neural network model based on abstract syntactic trees (AST), named ASTNN, and Long-Short Term Memory (LSTM) model. ASTNN handles the *linguistic* nature of student programming code, while LSTM handles the *temporal* nature of student learning progression. The effectiveness of ASTNN is first compared against other models including a state-of-the-art algorithm, Code2Vec across two programming domains: iSnap and Java on the task of program classification (*correct* or *incorrect*). Then the proposed temporal-ASTNN is compared against the original ASTNN and other temporal models on a challenging task of student success early prediction. Our results show that Temporal-ASTNN can achieve the best performance with only the first 4-minute temporal data and it continues to outperform all other models with longer trajectories.

Keywords

Student Modeling in Programming, LSTM, ASTNN

1. INTRODUCTION

Learning how to program is like learning how to write in a second language. As students learn to author code, both their programming code and their understanding of it evolves over time. Prior research has either focused *exclusively* on developing accurate *linguistic* models of their artifacts [30, 24, 1, 42], or developing *temporal* models of students comprehension of programming [11, 21, 23]. In this work, we propose a general data-driven approach named *Temporal-ASTNN*, which combines a state-of-the-art neural network model based on abstract syntax trees (AST) named ASTNN – addressing the *linguistic structure* of the students' artifacts – along with Long-Short Term Memory (LSTM), which handles their *learning progression*. In this way we effectively marry *both* aspects of the process in a single system.

Much as *language* is how people communicate, *programming languages* are how we communicate with machines, and various natural language processing (NLP) techniques can be applied to modeling programming languages [15]. Traditional approaches for code representation often treat code fragments as natural language texts and model them based on their tokens [7, 9]. Despite their simplicity, token-based methods omit the rich and explicit *structural* information [25] in student codes. Until recently, deep learning models have achieved state-of-the-art results on source code analysis, including code functionality classification [24], method name prediction [1], code clone detection [42] and so on. These successful models usually combine Abstract Syntax Tree (AST) representations with various neural networks to capture the structural information from the programming language. Their impressive performance shows that by addressing the *linguistic structural* nature of code, syntactic knowledge is indeed important to learn meaningful code representation.

On the other hand, modeling student learning progression in open-ended programming environments is also a type of student modeling. Generally speaking, student modeling has been widely applied to predict the student's future performance based on historical data. For well-defined learning environments, student models usually monitor students' learning progress (*correct* or *incorrect*) over time to infer their knowledge states, such as Bayesian Knowledge Tracing (BKT) [8] and Deep Knowledge Tracing (DKT) [29]. When it comes to open-ended programming environments, student modeling becomes much more challenging because 1) the correctness evaluation concerning each step taken by students will not be available, and 2) it is extremely hard to represent student states. As a result, prior research either has focused on utilizing other features such as hint usage, interface interactions to evaluate student learning outcomes [11], or creating meaningful states by transforming student click-like log files into fixed feature sets for various student

modeling tasks [21]. While such prior work is able to capture the *temporal* information from historical data, it ignores the *linguistic, structural* property of student code. As an accurate student model is a building block for any educational system that provides adaptivity and personalization, it is especially important to model student learning progression in open-ended programming tasks by addressing both *linguistic* and *temporal* characteristics in student code sequences.

In this work, we present a data-driven approach named *Temporal-ASTNN* to model student learning progression in open-ended programming domains. Temporal-ASTNN consists of two main modules: 1) ASTNN [42] for code representation learning, which can handle the *linguistic* structure of student code, and 2) LSTM [16] for temporal learning, which handles the *temporal* nature of student learning progression. In order to explore the effectiveness of our model, we focus on two types of student modeling tasks. One is *the task of program classification (correct or incorrect)*, in which the effectiveness of ASTNN is compared against other models including a state-of-the-art algorithm, Code2Vec [1] across two programming domains: an open-ended block-based programming environment named iSnap and a textual programming environment for the Java programming language. The other is the task of *student success early prediction* in which the effectiveness of temporal-ASTNN is compared against the original ASTNN and other models integrating with different feature embeddings on iSnap only because it has trajectories of student codes.

Our main contributions are: 1) To the best of our knowledge, Temporal-ASTNN is the first model to address both *linguistic* and *temporal* properties of student learning progression in programming tasks; 2) We explored the robustness and the effectiveness of our model on student success early prediction task and compared it with state-of-the-art temporal models; and 3) We evaluated the effectiveness of ASTNN against Code2Vec and various baseline models on student program classification tasks across two domains, while most prior research mainly focused on classic tasks of *professional* source code analysis instead of novice programming.

The remainder of this paper is structured as follows. Section 2 presents the methods. Section 3 and 4 describe the two types of programming tasks together with experimental settings and results. Section 5 presents the related work. Finally, we discuss and conclude our work in Section 6.

2. METHODS

Problem Definition: For the task of student program classification, our dataset can be represented $\langle \boldsymbol{X}, \boldsymbol{Y} \rangle = \{\langle \boldsymbol{x}^1, y^1 \rangle, \langle \boldsymbol{x}^2, y^2 \rangle, ..., \langle \boldsymbol{x}^N, y^N \rangle\}$ where N is the total number of codes in the dataset where $\boldsymbol{x}^i$ represents a code snippet of student i and binary y^i indicates whether the code is correct or not.

For the task of student success early prediction, our dataset can be represented as $\boldsymbol{X} = \{\boldsymbol{x}^1, \boldsymbol{x}^2, ..., \boldsymbol{x}^M\}$, where M is the number of students. For a given student k, $\boldsymbol{x}^k = \{\boldsymbol{x}^k_1, ..., \boldsymbol{x}^k_{T_k}\}$, where $\boldsymbol{x}^k_t$ represents student k's code at time step t in $\boldsymbol{x}^k$ and T_k is the total number of codes in the student k's learning trajectories which varies with different students. For each $\boldsymbol{x}^k$, we are provided with the outcome label y^k for the outcome of the sequence of codes. $y^k = 0$ indicates the student

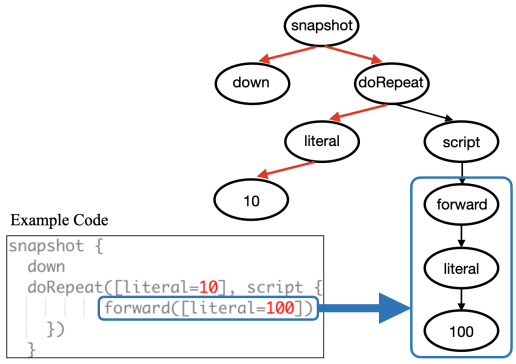

Figure 1: An examaple of iSnap code and the AST representing its syntactic structure. Red highlights a sample path, and blue highlights a sample ST-tree.

k succeeded, otherwise $y^k = 1$. The goal of student success early prediction is to predict the y^k using the student's codes from the beginning up to the certain minutes: $\boldsymbol{x}^k_1, \boldsymbol{x}^k_2, ..., \boldsymbol{x}^k_t$. For simplicity, we omit index k hereinafter when it does not cause ambiguity.

2.1 Temporal-ASTNN

Figure 2 shows the detailed structure of Temporal-ASTNN. Fundamentally, it contains a ASTNN which learns the embedding for student code and a LSTM layer which handles the temporal aspect. It is important to note that in Temporal-ASTNN, the two modules interact with each other to control how information flows.

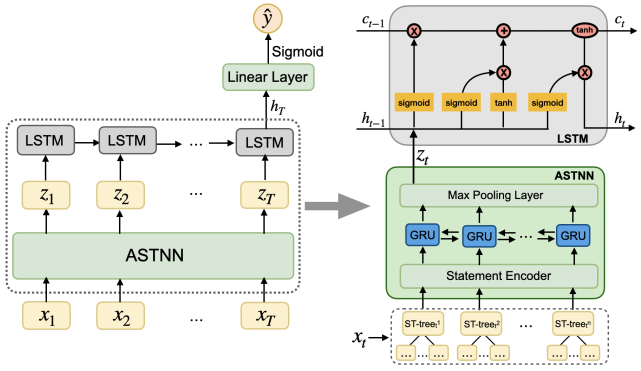

Figure 2: Temporal-ASTNN model structure: the output of ASTNN connects to the input of LSTM.

2.1.1 ASTNN

ASTNN is one of the state-of-the-art methods in source code analysis, and it's main idea is to learn a vector for the code through statement-level ASTs. Specifically, we split the large AST of a code fragment by the granularity of statement and extract a sequence of statement trees (ST-trees) via pre-order traversal. As shown in Figure 1 (highlighted in blue), we can get a ST-tree rooted at `forward`, whose child is `literal` and grandchild is `100`. In this way, we will get a sequence of ST-trees from the original AST, and feed them as the raw input of ASTNN. As shown in Figure 2, ST-trees

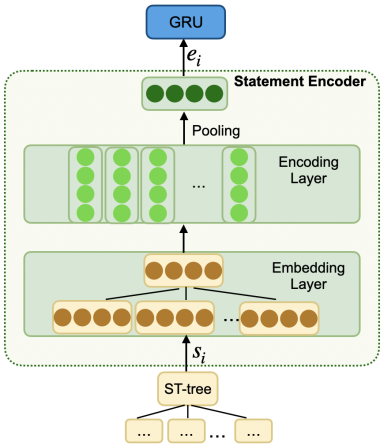

Figure 3: Statement Encoder of ASTNN, composing by an Embedding layer, an Encoding layer and a max-pooling layer.

will first pass Statement Encoder, then go through Bidirectional GRU (Bi-GRU) [2], finally pass max-pooling layer to get the vector for code representation.

Statement Encoder: Figure 3 shows the detailed structure of statement encoder. Assuming that there are J total nodes in a ST-tree s_i, for each node $n_i^j \in s_i$, $j \in [1, J]$, it will first go through the embedding layer to get initial embeddings $v_i^j = \mathbf{W_{embed}}^\top n_i^j$, where $\mathbf{W_{embed}} \in \mathbb{R}^{V \times d}$ is the pre-trained embedding matrix, V is the vocabulary size and d is the embedding dimension. Then the vector will be updated through a Recursive Neural Network [35] based encoder layer: $h_i^j = \sigma(\mathbf{W_{encode}}^\top v_i^j + \sum h_{\text{child}} + b_i^j)$. Here $\mathbf{W_{encode}} \in \mathbb{R}^{d \times k}$ is the encoding matrix and k is the encoding dimension. b is the biased term and σ is the activation function, in this work we followed the original paper to set σ as identify function. After recursive optimization of the vectors of all node in the ST-tree, we sample the final representation e_i via a max-pooing layer:

$$e_i = [max(h_i^{j_1}), max(h_i^{j_2}), ..., max(h_i^{j_k})], j \in [1, J] \quad (1)$$

Code Representation: For a set of ST-trees $(s_1, s_2, ..., s_L)$, where L is the number of ST-trees in the AST, our goal is to get a code vector z as final representation. After generating a sequence of vectors $(e_1, e_2, ..., e_L)$ from Statement Encoder, we will apply Bi-GRU to track the naturalness of statements sequence:

$$h_i = [\overrightarrow{GRU}(e_i), \overleftarrow{GRU}(e_i)], i \in [1, L] \quad (2)$$

The statement representation $h_i \in \mathbb{R}^{L \times 2m}$, where m is the embedding dim of Bi-GRU. Finally, similar to Statement Encoder, a max-pooling layer is used to sample the most important features on each of the embedding dimension. Thus we get $z \in \mathbb{R}^{2m}$, which is treated as the final vector representation of the original code fragment.

In original ASTNN, we can add another linear layer to directly fit z to the following prediction tasks. While in Temporal-ASTNN, z will be used as the input for LSTM memory cell.

2.1.2 LSTM

As shown in Figure 2, at each time step t, the output of ASTNN z_t will be used as the input for LSTM cell. Once ASTNN generates the code representation by learning the *linguistic* nature from code x_t:

$$z_t = \text{ASTNN}(x_t) \quad (3)$$

LSTM is trained utilizing input vector z_t to handle the temporal information. There are three major components: a forget gate, an input gate, and an output gate in a LSTM memory cell.

Forget Gate: In the first step, a function of the previous hidden state h_{t-1} and the new code input z_t passes through the forget gate, indicating what is probably irrelevant and can be taken out of the cell state. The forget component will calculate a weight f_t between 0 to 1 for each element in hidden state vector C_{t-1}. Here W_f and b_f are the weights and bias for the forget component.

$$f_t = \text{sigmoid}(\mathbf{W_f} \cdot [h_{t-1}, z_t] + b_f) \quad (4)$$

Input Gate: There are two steps involved in input component's calculation. In the first step, a *tanh* layer calculates a candidate vector $\tilde{C}_t$ that could be added to the current hidden state. In the second step, the input components calculate a weight vector i_t (ranging from 0 to 1) to determine to what extent $\tilde{C}_t$ should update the current memory state.

$$\begin{aligned} \tilde{C}_t &= \tanh(\mathbf{W_c} \cdot [h_{t-1}, z_t] + b_c) \\ i_t &= \text{sigmoid}(\mathbf{W_i} \cdot [h_{t-1}, z_t] + b_i) \end{aligned} \quad (5)$$

Output Gate: The output component is simply an activation function that filters elements in memory cell state C_t, where $C_t = C_{t-1} \cdot f_t + \tilde{C}_t \cdot i_t$. It calculates a weight vector to determine how much information is allowed to be revealed:

$$o_t = \text{sigmoid}(\mathbf{W_o} \cdot [h_{t-1}, z_t] + b_o) \quad (6)$$

Finally we get the output of time t: $h_t = o_t * \tanh(C_t)$. In this work, we used the last-step output from LSTM as the temporal representation of student code sequence.

2.1.3 Temporal-ASTNN: Truncated vs. Entire

As shown in Figure 2, by combining ASTNN and LSTM, the final Temporal-ASTNN can be described as:

$$\begin{aligned} z_1, ..., z_T &= \text{ASTNN}(x_1, ..., x_T) \\ h_T &= \text{LSTM}(z_1, ..., z_T) \\ \hat{y} &= \text{sigmoid}(\mathbf{W_l} h_T + b_l) \end{aligned} \quad (7)$$

where $\hat{y}$ is the output from Temporal-ASTNN, $\mathbf{W_l}$ is the weight matrix b_l is the bias term for the liner layer. The entire Temporal-ASTNN framework is learned by optimizing ASTNN and LSTM parameters spontaneously. They are optimized by minimizing the binary cross-entropy:

$$\mathcal{L}(\hat{y}, y; \Theta) = -(y \log(\hat{y}) + (1 - y) \log(1 - \hat{y})) \quad (8)$$

Prior research on applying ASTNN for source code analysis only used one snippet of code fragment to extract meaningful representation for following machine learning tasks. However, when combining ASTNN with LSTM on student

programming sequences such as iSnap for early prediction, we have the choices of either using the truncated training sequences or using the entire sequences. The advantage of using truncated sequences is that the training data would be more similar to the testing data and thus, the learned representations are more likely to emerge and be representative for the early success task. On the other hand, the advantage of using *entire* sequences is that the longer the sequences, the more meaningful AST patterns can be considered and discovered. Thus, we explored Temporal-ASTNN using both the *entire* and the *truncated* sequences for representation learning and referred as Temporal-ASTNN$_{\text{Trunc}}$ and Temporal-ASTNN$_{\text{Entire}}$ respectively.

2.2 Code2Vec

Code2Vec [1] leverages different features and model structures, and focuses on the dependency of distant components in code structures to achieve code classification tasks. As with ASTNN, Code2Vec is designed to address the *linguistic* structure of programming languages. Fundamentally, there are two main differences between these two models: 1) ASTNN takes a set of statement-level ASTs as inputs, while Code2Vec utilizes the syntactic paths of ASTs to learn the representation (an example path is shown in Figure 1 in red). And 2) After encoding the vector representations of ST-trees, ASTNN uses Bi-GRU to handle the sequence of vectors; while Code2Vec utilizes an attention mechanism to learn a weighted average of path vectors and thus to produce the final code representation. With the vector representing code, Code2Vec can also be used for various prediction tasks.

3. STUDENT PROGRAM CLASSIFICATION

In the task of student program classification, we aimed to predict the correctness (correct or incorrect) of student submitted code. The effectiveness of ASTNN is compared against Code2Vec and other token-based models across two programming domains: iSnap and Java.

3.1 Datasets

3.1.1 iSnap

iSnap is an extension to Snap*!* [13], a block-based programming environment, used in an introductory computing course for non-majors in a public university in the United States [32]. iSnap extends Snap*!* by providing students with data-driven hints derived from historical correct student solutions [31]. In addition, iSnap logs all students actions while programming (e.g. adding or deleting a block), as a *trace*, allowing us to detect the sequences of all student steps, as well as the *time* taken for each step. In this work, we focused on one homework exercise named Squiral, derived from the BJC curriculum [13]. In Squiral, students are asked to write a procedure that draws a square-like spiral. As shown in Figure 4, correct solutions require procedures, loops, and variables using at least 7 lines of code. We collected students' data for Squiral from Spring 2016, Fall 2016, Spring 2017, and Fall 2017. We excluded students who requested hints from iSnap to eliminate factors that might affect students' problem-solving progress, leaving a total of 65, 38, 29, and 39 student code traces from each semester, respectively.

The data collected from iSnap consists of a code trace for each student's attempt. This code trace represents a sequence of timestamped snapshots of student code. In prior research, an expert feature detector has been proposed to automatically detect 7 expert features of a student snapshot [43]. Those expert features are binary and indicate whether the corresponding feature presents or not. We ran the expert-feature detector to tag each snapshot in all 171 code traces, making a total of 31,064 tagged snapshots. With the temporal sequences, iSnap data is evaluated not only on this classification task, but also on the temporal early prediction task as described in Section 4.

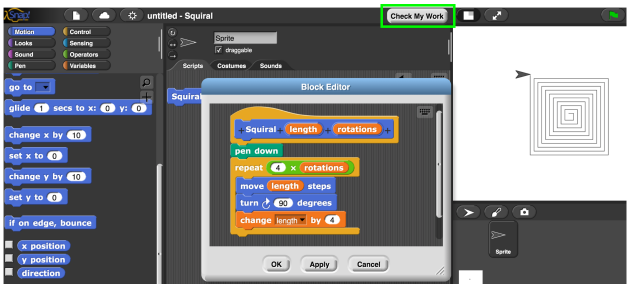

Figure 4: The iSnap interface, with the blocks palette on the left, the output stage on the right, the scripting area in the middle, and the hints button on top.

3.1.2 CodeWorkout

CodeWorkout[1] is an online and open system for programming in Java. It provides a web-based platform on which students from various backgrounds can practice programming and instructors can offer courses [10]. Different from iSnap, CodeWorkout *doesn't* log students' traces during programming but only their submissions. In this work, we focused on one programming exercise named isEverywhere, where the knowledge of loops and array will be mainly evaluated. In isEverywhere, students are asked to write a Java function to check if a value is "everywhere", that is in the given array if the value exists for every pair of adjacent elements. As shown in Figure 5, the system will show detailed feedback regarding the student's submission, indicating how it failed/succeed on the corresponding test cases.

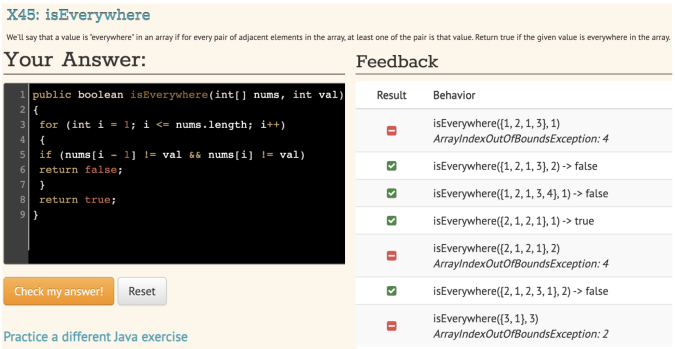

Figure 5: The CodeWorkout interface, with the problem description on the top, the coding area in the middle, and the feedback on the right.

The data collected from CodeWorkout is in Progsnap2 [33] format, and consists of two semesters: Spring 2019 and Fall

[1]https://codeworkout.cs.vt.edu/

2019. Similar to iSnap, we processed the data to eliminate factors that might affect students' problem-solving progress, and only kept the first compliable program from each student. In total, we have 448 and 307 student submissions from each semester, respectively. Please note that in CodeWorkout, only submissions from students are recorded and sequences of student edits are not available, thus it is only evaluated on the task of student program classification.

3.2 Task Description

For the task of student program classification, the ground truth labels are generated as follows: in iSnap, a student's submission is correct only if it satisfies all rubrics requirements, which are based on the expert-designed features and verified by humans; in CodeWorkout, a submission is correct if it passes all testing cases. Table 1 shows the number of correct and incorrect submissions across the semesters in each dataset. Note that here we include one submission per student to ensure that all data points are independent in both datasets. More specifically, for each student, we include the student's "own" submission before receiving any detailed feedback, which means the student's final submission for iSnap and the first submission for CodeWorkout.

Table 1: Data overview on Student Program Classification

Semester	iSnap	
	correct	incorrect
S16	24	41
F16	16	22
S17	12	17
F17	11	28
Total	63	108

Semester	CodeWorkout	
	correct	incorrect
S19	156	151
F19	223	265
Total	379	416

3.3 Experiments

3.3.1 Models Configuration

We conducted a series of experiments across both domains by comparing ASTNN against the state-of-the-art model *Code2Vec* and three *token-based* classic ML models.

Three Token-based ML Models: Three classic ML models, K-Nearest Neighbors (KNN), Logistic Regression (LG), and Support-Vector Machine (SVM) are explored. Following prior token-based approach, we applied TF-IDF to extract textual features [42, 34]. The input sentence for TF-IDF is the sequence of AST-tokens, which is generated by the pre-order traversal of original ASTs. For each of the three models, we explored different parameters to obtain the best results. For KNN, we had $k = 10$, for LG we used $L1$ regularization, and for SVM we used *linear* kernel. Those parameters are tuned from 10-fold cross-validation with grid search, and all three models are implemented through the sklearn library.

Two AST-based Deep Learning Models: Code2Vec takes a set of AST-based paths as input, where the number of paths may vary from different student submissions. Thus we manually padded the number of paths to 100 over all code submissions. During the training, we set the maximum training epochs as 200, with the *patience* of early stopping set to 100, tuned learning rate to 0.0002. Linear layer and embedding dimensions are kept default to 100. To ensure a highest efficiency of the model, we set the batch size as the full batch. For ASTNN, the inputs are a set of ST-trees, and we padded the statement sequences to the maximum length to accommodate the longest sequence before feeding to Bi-GRU. During the training, we leverage 32 as batch size, 0.001 as learning rate, and keep the max training epoch as 50. The encoding dim for the statement encoder is set to 128, and the number of hidden neurons for Bi-GRU is set to 100. We implemented both ASTNN and Code2Vec in Pytorch. Same as the classic models, 10-fold cross-validation was applied for hyperparameter tuning.

For the task of student program classification, we did not compare ASTNN and Code2Vec against any models that used expert-designed features for two reasons: one is that the expert-designed features are only available for iSnap but not CodeWorkout; and the other reason is that these expert-designed features are used to determine the ground truth label of the student's final submission in iSnap.

3.3.2 Evaluation Metrics

Our models were evaluated using Accuracy, Precision, Recall, F1 Score, and AUC (Area Under ROC curve). Accuracy represents the proportion of students whose labels were correctly identified. Precision is the proportion of students who were predicted to be *incorrect* by each model were actually in the *incorrect* group. Recall tells us what proportion of students, who will actually be *incorrect*, were correctly recognized by the model. F1 Score is the harmonic mean of Precision and Recall that sets their trade-off. AUC measures the ability of models to discriminate groups with different labels. Given the nature of the task, in the following, we consider Accuracy and AUC as the most important metrics because the former is most commonly accepted while AUC is believed to be generally more robust.

Finally, it is important to emphasize that all models were evaluated using semester-based temporal cross-validation for both domains in this task, which only applied data from previous semesters for training and is a much stricter approach than the standard cross-validation.

3.4 Results

Table 2 and 3 compare the performing of the five models in iSnap and CodeWorkout respectively. In iSnap, among the three token-based models, LG and SVM have very similar performance as both have an accuracy score of 0.6604; moreover the best AUC and Precision are from LG and the best Recall and F1 are from SVM. Both LG and SVM outperform KNN on all metrics. While in CodeWorkout, Table 3 shows that the best accuracy, AUC, and Precision are from SVM and the best Recall and F1 are from KNN. Between the two AST-based models, ASTNN outperforms Code2Vec in both domains. It suggests that across the two different student programming environments, ASTNN is more effective than Code2Vec on the task of student program classification.

The comparisons between AST-based models with token-based models show the former significantly out-perform the latter in both domains; the only exception is that SVM with token has the highest precision in Java (Table 3). Note that here the difference between the SVM and ASTNN on

Precision is rather small while the former has a much worse accuracy, F1-score, and AUC than ASTNN.

To summarize, our results show that in both domains, ASTNN achieves the best performance. These results show that by capturing the meaningful *linguistic* structure in student code, ASTNN is indeed more robust on the task of student program classification. Given its effectiveness, we further explored the effectiveness of Temporal-ASTNN which combines ASTNN with powerful temporal model LSTM on the task of student success early prediction.

4. STUDENT SUCCESS EARLY PREDICTION

For student success early prediction task, Temporal-ASTNN is compared against the original ASTNN and other temporal models. As mentioned in Section 3.1.2, here we only explored the early prediction task in iSnap.

4.1 Task Description

In iSnap, we have a total of 171 students and 31,064 temporal snapshots. Following the definitions used in prior research [23], the *successful* students are those who completed the programming assignment within one hour *and* got full credit while the rest are counted as *unsuccessful*. We have 59 *successful* and 112 *unsuccessful* ones. The detailed statistics for iSnap dataset are shown in Table 4. Note that for the purpose of learning, unsuccessful students are of interest for this classification task.

To predict student early success, we are given the first *up to n minutes* of a student's sequence data and our goal is to predict whether the student will successfully complete the programming assignment at any given point in the remainder of the sequence. To conduct this task, we left-aligned all the students' trajectories by their starting times and our *observation window* (the part of data used to train and test different machine learning models) includes the sequences from the very beginning to the first n minutes. If a student's trajectory is less than n minutes, our observation window will include their entire sequence *except* the last one.

It is worth noting that student success early prediction is a much more challenging task compared to program classification: 1) besides the *linguistic* nature in student code, it also involves temporal information, and 2) the observation window is very early and thus student final submissions are not available for training or testing.

4.2 Experiments

4.2.1 Models Configuration

To further explore the power of ASTNN, we did extensive experiments and compared it with the start-of-the-art expert-designed features [43] and token-based features on the student success early prediction task. For each of the feature embedding (expert, token, AST), we explored two categories of models: the *last value*-based Logistic Regression (LG) models, and the *temporal* LSTM models. Note that LG is selected because, among the three classic ML methods explored on the task of student program classification in iSnap, LG has achieved the highest accuracy and AUC.

Last-Value Models: Motivated by prior work, we used a "Last Value" approach [4, 37, 23] to treat the last measurements within the given observation window as the input to train models. For early prediction settings, we truncated all the sequences in the training dataset in the same way as the testing dataset. For example, when our observation window is the first 4 minutes, we will only apply the last values in

Table 4: Detailed data statistics for iSnap, including total steps, total time spent in minutes, and the success labels distribution for each of the four semesters.

Semester	Total Steps				Total Time (minutes)				Success Labels	
	min	max	median	mean(std)	min	max	median	mean(std)	successful	unsuccessful

the sequence within the first-4-minute observation window and use them as inputs for each model. More specifically, we used the expert features of the last submission within the observation window to train and test expert-LG; similarly, the tokens from the last snapshot within the observation window to train and test token-LG; and the ASTs of the last submission within the observation window for both training and testing the original ASTNN.

Temporal Models: We applied LSTM to handle the temporal sequences of student code. Here we used the *temporal* sequences in the observation window for early predictions. Specifically for a given first-n-minute observation window: we used the sequences of expert features to train and test expert-LSTM; the sequences of token features to train and test token-LSTM. For Temporal-ASTNN, we explored Temporal-ASTNN$_{\text{Trunc}}$ and Temporal-ASTNN$_{\text{Entire}}$. Both models would first convert student code sequences in the observation window into sequences of AST vectors and then feed them into LSTM. They only differ on how their AST vectors are trained: the former uses truncated sequences while the latter uses entire sequences (see Section 2.1.3).

To summarize, we analyze two main model settings: *last-value* and *temporal*, together with three different feature embeddings: *expert*, *tokens*, and *ASTs*. Thus in total we explored the effectiveness of six models.

4.2.2 Evaluation Metrics

For student success early prediction, all the models are evaluated using Accuracy, Precision, Recall, F1 Score, and AUC. Similarly to the first task, we consider Accuracy and AUC as the most important metrics, and the more stringent semester-based temporal cross-validation was carried out.

4.3 Results

We present our results of student success early prediction by first comparing the effectiveness of all six models on first-4-minute early prediction and then by exploring their average performance across different observation windows up to the first-10-minute data.

4.3.1 Results at First-4-minute Only

Table 5 shows different performance measures of all the six models at first-4-minute. In the group of *Last-Value* models, ASTNN has the best accuracy, Recall and F1 scores while the best AUC and Precision are from Expert-LG, and both of them have better performance than Token-LG. Actually, in terms of accuracy, Expert-LG and Token-LG perform worse than the simple majority baseline. This is probably either because only relying on the first-4-minute is too early or because the last snapshot of the first-4-minute does not provide enough information for these models to make effective early predictions. The fact that across the five evaluation metrics, the best performance either comes from Expert feature or comes ASTNN suggests that ASTNN is comparable to expert-designed features because of its ability of handling the *linguistic* structure of student syntactic code.

In the *Temporal* group, Temporal-ASTNN based models are the best. More specifically, both Temporal-ASTNN$_{\text{Trunc}}$ and Temporal-ASTNN$_{\text{Entire}}$ outperform Expert-LSTM and Token-LSTM on accuracy, AUC, precision and F1 scores, except that the best recall is from Token-LSTM. Between the two Temporal-ASTNN models, Temporal-ASTNN$_{\text{Trunc}}$ is generally better than Temporal-ASTNN$_{\text{Entire}}$ as it achieves higher accuracy, Recall, F1-score, and AUC. This is probably because by using the truncated training data for representation learning, Temporal-ASTNN$_{\text{Trunc}}$ is more likely to capture the temporal information that are not only predictive of student success but also more likely to be observed in the testing with only the first-4-minute data.

When further comparing temporal models with last-value models, we can see that all *temporal* models achieve better accuracy than their corresponding *last-value* models. It is reasonable since *temporal* models are able to capture the temporal information related to student success from the

Table 6: iSnap Student Success Early Predictions in First-10-minute Overall

Data	Feature	Model	Accuracy	Precision	Recall	F1_score	AUC
Majority Baseline			0.6604	-	-	-	0.5
Last-Value	Expert	Expert-LG	0.6566 (0.05)	**0.8209** (0.06)**	0.6229 (0.11)	0.7017 (0.06)	**0.6725 (0.05)**
	Tokens	Token-LG	0.5528 (0.02)	0.7072 (0.03)	0.5571 (0.07)	0.6203 (0.04)	0.5508 (0.03)
	ASTs	ASTNN	**0.6642 (0.01)**	0.7635 (0.03)	**0.7200 (0.07)**	**0.7379 (0.02)**	0.6378 (0.03)
Temporal	Expert	Expert-LSTM	0.7189 (0.03)	0.7305 (0.05)	0.9343 (0.04)	0.8145 (0.01)	0.6255 (0.07)
	Tokens	Token-LSTM	0.6887 (0.02)	0.6966 (0.03)	**0.9429** (0.04)**	0.8001 (0.01)	0.5687 (0.05)
	ASTs	Temporal-ASTNN$_{\text{Trunc}}$	0.7396 (0.02)	0.7597 (0.03)	0.8914 (0.03)	**0.8190** (0.01)**	0.6679 (0.04)
		Temporal-ASTNN$_{\text{Entire}}$	**0.7472** (0.02)**	**0.7932 (0.04)**	0.8316 (0.04)	0.8110 (0.02)	**0.6943** (0.03)**

Note: best models in each group are in **bold**, and the overall best labeled with **

temporal sequences, but such information is not available to *last-value* models.

Generally speaking, Temporal-ASTNN achieves the best performance at the first-4-minute observation window, which indicates that by combining ASTNN with LSTM, the temporal-ASTNN is able to learn the *temporal* and *linguistic* knowledge from student code sequences.

4.3.2 Results in First-10-minute Overall

Figure 6 (a) and (b) report Accuracy and AUC performance respectively for four models predicting student success: three *temporal* models and the best *last-value* model, ASTNN. For each graph, x-axis is the observation window of early prediction, here we vary the observation window from the first 2 minutes up to 10 minutes; and y-axis is the Accuracy/AUC score. As shown in Table 1, students generally take 10 to 60 minutes to complete the task and thus we took a measurement every 2 minutes for the first 10 minutes to generate the early stage predictions for each model. Table 6 show the comparison of all six models for the student success early prediction in first-10-minute observation windows, we reported the mean value and corresponding standard deviation (in parenthesis) for each evaluation metric.

Table 6 shows a similar pattern as we observed earlier in Table 5. In the group of *Last-Value* models, ASTNN outperforms Expert-LG and Token-LG. Specifically, ASTNN continues to achieve the best accuracy, Recall and F1 scores in the first 10 minutes, and Expert-LG has the best AUC and Precision scores. In the group of *temporal* models, Temporal-ASTNN based models are still the best overall, with higher scores on accuracy, AUC, Precison and F1. Additionally, Temporal-ASTNN$_{\text{Entire}}$ is shown to be slightly better than Temporal-ASTNN$_{\text{Trunc}}$ as it achieves higher accuracy, AUC and Precision.

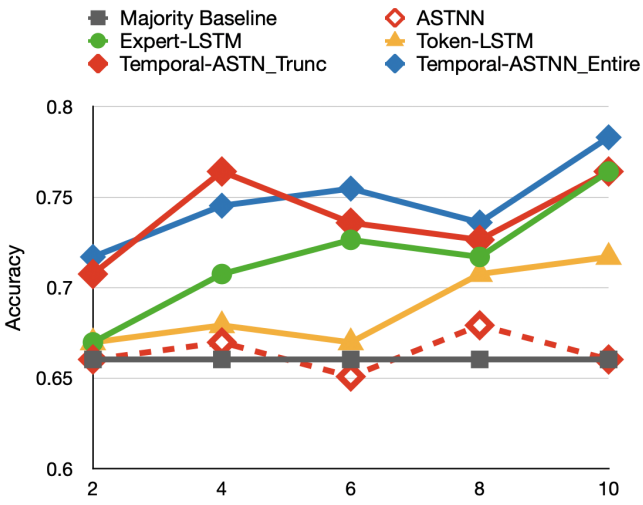
Both Figures 6 (a) and (b) show that Temporal-ASTNN$_{\text{Entire}}$ is the best model for student success early prediction as it stays on the top across all sizes of the observation window. As the length of observation window extends, all *temporal* models in general perform better, while the performance of *last-value* models fluctuates. This is because that training data includes more and more information and hereby the performance of *temporal* models improves over longer sequences. After 6 minutes, Expert-LSTM starts to perform as good as Temporal-ASTNN, which is not surprising. As the expert features are designed to detect student state for final grading, and student states will be more and more closer to their final submissions with the longer sequences. The fact that the best early predictions come from Temporal-ASTNN really suggests that addressing both *linguistic* and *temporal* nature of student code sequences brings us closer to the truth of student learning procession during programming, especially for the early stage (first 6 minutes).

5. RELATED WORK

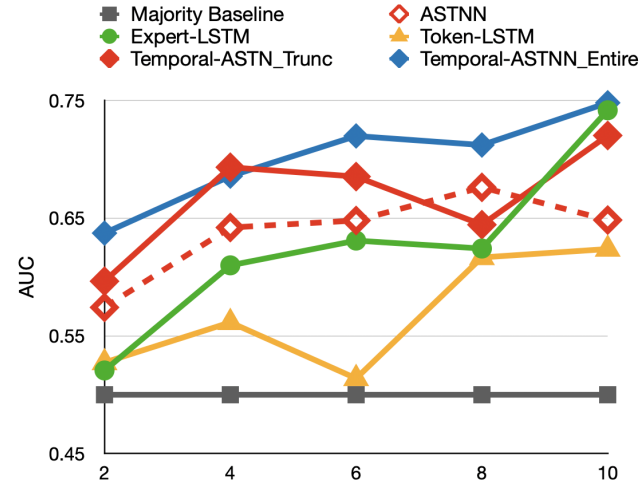
5.1 Linguistic-based Models for Programming

A wide range of work has applied NLP techniques for programming. Traditionally, some prior work directly uses the tokens of ASTs for source code tasks [38, 12], by treating programming languages as natural languages. Despite some similarities, programming languages and natural languages [25] differ in some important aspects. Programming is a complex activity, and thus programs contain rich and explicit structural information. Recently, deep learning models has shown the potential to grasp more information from AST in many tasks. For example, TBCNN [24] takes the whole AST of code as input and performs convolution computation over tree structures, and it outperforms token-based models in program functionalities classification and bubble-sort detection. In the educational domain, Piech et al. (2015) proposed NPM-RNN to simultaneously encode preconditions and postconditions into points where a program can be used as a linear mapping between these points [30]. Gupta et al. (2019) presented a tree-CNN based method, that can localize the bugs in a student program with respect to a failing test case, without running the program [14]. More recently, ASTNN and Code2Vec has shown great success.

Siting at the root of AST, ASTNN [42] was proposed to handling the long-term dependency problems when taking the large AST as input directly. AST is a form of representing abstract syntactic structure of the source code [5], and it



(a) Accuracy performance



(b) Area under ROC performance

Figure 6: Student Success Early Prediction on *iSnap*, last-value models are in dashed lines with empty symbols, temporal models are in solid lines with solid symbols, dark grey lines are from the majority baseline.

has been widely used in the domain of source code analysis. Similar to long texts in NLP, large ASTs can make deep learning models venerable to gradient vanishing problems. To address the issue, ASTNN splits the large AST of one code fragment into a set of small trees in statement-level and performs code vector embedding. It achieves state-of-the-art performance in both code functionalities classification and clone detection.

Code2Vec [1], on the other hand, utilizes AST-based paths and attention mechanism to learn code vector representation. Instead of a set of ST-trees, it takes a collection of leaf-to-leaf paths as input, and applies an attention layer to average those vectors. As a result, the attention weights can help to interpret the importance of paths. Code2Vec has shown to be very effective in predicting the names for program entities. Shi et al. (2021) also applied Code2Vec on a block-based programming dataset and used the learned embedding to cluster incorrect student submissions [34].

As far as we know, none of prior work has directly compared the effectiveness of ASTNN against Code2Vec. And in this work, we did extensive experiments across two programming domains: one is a block-based novice programming environment where the data size is relatively small; the other is a web programming platform in Java, in which more labeled data is available. Our results consistently suggest that ASTNN is able to capture more insights from student programs for correctness prediction.

5.2 Student Modeling for Programming

Student modeling has been widely and extensively explored by utilizing student temporal sequences. For example, BKT [8] and BKT-based models have been shown to be effective in predicting students' overall competence [26], predicting the students' next-step responses [41, 3, 27, 20], and the prediction of post-test scores [18, 22]. In recent years, deep learning models, especially Recurrent Neural Network (RNN) or RNN-based models such as LSTM have also been explored in student modeling [29, 36, 17, 39, 40, 19]. Some work showed that LSTM has superior performance over BKT-based models [22, 29] or Performance Factors Analysis [28]. However, it has also been shown that RNN and LSTM did not always have better performance when the simple, conventional models incorporated other parameters [17, 39].

In the programming domain, prior research has explored various temporal models for modeling student learning progression. For example, Wang et al. (2017) applied a recursive neural network similar to [30] as the embedding for student submission sequence, then feed them into a 3-layer LSTM to predict the student's future performance. Please note that the work is quite different from our proposed Temporal-ASTNN. In Temporal-ASTNN, all the components are optimized together during training, while they applied a global embedding to generate the input sequences for LSTM. On the other hand, Emerson et al. (2019) have utilized four categories of features: prior performance, hint usage, activity progress, and interface interaction to evaluate the accuracy of Logistic Regression models for multiple block-based programming activities [11]. In our earlier work, we have used the expert-designed features for a block-based programming problem to train various temporal models, then made early predictions on student learning outcomes [21, 23].

To our best knowledge, while most of the previous studies on analyzing student programming data treated student code as either *linguistic* or *temporal*, no prior work has combined the two characteristics of programming data for student learning progression. Thus our proposed Temporal-ASTNN is the first attempt to addressing *both* aspects in student code.

6. CONCLUSIONS

Tracing student learning progression at early stage is a crucial component of student modeling, since it allows tutoring systems to intervene by providing needed support, such as a hint, or by alerting an instructor. Both prediction tasks involved in this work are challenging, especially the early prediction task because: 1) the open-ended nature of programming environment hinders the prediction of student fi-

nal success, and 2) it is extremely hard to learn a meaningful representation from student code. In this work, we conducted a series of experiments to investigate the effectiveness of Temporal-ASTNN for student learning progression. We first evaluated ASTNN against Code2Vec on the task of classifying the correctness of student programs across two domains. Our results show that ASTNN consistently outperforms the other models including Code2Vec and other token-based baselines in both domains. And we can also find that AST-based models generally achieve better performance than token-based models, which is consistent with prior research [24, 42]. In the second task of student early prediction, we explored three different categories of features: expert, tokens, and ASTs. And further compared Temporal-ASTNN with other temporal models embedded with different feature set, as well as non-temporal baselines. Our findings can be concluded as follows: 1) temporal models usually outperforms non-temporal (last-value) models; 2) token-based models can only capture very limited information from student code; and 3) Temporal-ASTNN is the best out of all models in the early prediction task, it can achieve good performance with only the first-4-minute data.

Limitations: There are two main limitations in this work. First, we only explored the effectiveness of Temporal-ASTNN on one important student modeling task in one programming environment, and thus it is not clear whether the same results will hold for different tasks or in other programming domains. Second, time-aware LSTM [6] has shown to outperform LSTM on various early prediction tasks [23], while in this work we only compared our Temporal-ASTNN against normal LSTM without considering time-awareness. Nevertheless, one of the main goal in this work is to investigate the robustness of Temporal-ASTNN from both sequential and temporal embedding. Thus we have two different type of models (last-value vs. temporal) as well as another two different features (expert and tokens). Our experiments results have shown its superiority on both aspects, but still, we are not clear about the effects of time-awareness.

Future Work: An important direction for future work is to investigate the time-awareness on Temporal-ASTNN to determine how it contributes to the model in the same task. In addition, we are planning to employ Temporal-ASTNN to other temporal tasks or different domains to explore whether it continues to support improvement for programming environments. Also, this work will be applied to larger groups of students and longer programming tasks, along with integration of more informative features such as intervention and demographic features to develop more robust models.

ABSTRACT

Constructing effective and well-balanced learning groups is important for collaborative learning. Past research explored how group formation policies affect learners' behaviors and performance. With the different classroom contexts, many group formation policies work in theory, yet their feasibility is rarely investigated in authentic class sessions. In the current work, we define *feasibility* as the ratio of students being able to find available partners that satisfy a given group formation policy. Informed by user-centered research in K-12 classrooms, we simulated pairing policies on historical data from an intelligent tutoring system (ITS), a process we refer to as *SimPairing*. As part of the process for designing a pairing orchestration tool, this study contributes insights into the feasibility of four dynamic pairing policies, and how the feasibility varies depending on parameters in the pairing policies or different classes. We found that on average, dynamically pairing students based on their in-the-moment wheel-spinning status can pair most struggling students, even with moderate constraints of restricted pairings. In addition, we found there is a trade-off between the required knowledge heterogeneity and policy feasibility. Furthermore, the feasibility of pairing policies can vary across different classes, suggesting a need for customization regarding pairing policies.

Keywords

Peer tutoring, Learning Group formation (LGF), Pairing Policies, CSCL

1. INTRODUCTION

Constructing effective, well-balanced learning groups is an important task in computer-supported collaborative learning (CSCL) [1–3]. The importance of learning group formation (LGF) has been validated empirically [4,5]. For instance, Webb et al.'s experiment proved that group composition had a major impact on the quality of group discussion and students' test scores, both during group work and subsequent individual tests [5]. The majority of existing approaches to LGF, do not support *dynamic* group formation [1]. Dynamic group formation refers to the process of groups "created on demand while various domain-specific restrictions have to be considered" [6], or can "adapt to and benefit from previous information about group members and their abilities" [7,8]. Compared to static, pre-planned LGF, the dynamic composition of groups allows for quick regrouping of learners based on up-to-date information regarding their progress and struggle. Dynamic group formation is an interesting issue, as researchers start envisioning more sophisticated and personalized classroom interactions [9] and more fluid social transitions (i.e., student social transitions that occur not all at the same time for everyone in the class) [10], that are more challenging to orchestrate.

In the context of an Intelligent Tutoring System (ITS) that supports both individual and collaborative learning, it is useful to investigate whether dynamically switching students between the two modes, as the need arises, can be effective and feasible. Pairing policies that work well in practice ideally have characteristics of both effectiveness and feasibility. By effective we mean that the pairing policy leads to students' reaching desired learning goals, and by feasible we mean that enough partners can be found under the given grouping policies (i.e., good policy coverage). Specifically, we defined *feasibility* as the percentage of students who can be teamed up under a given pairing policy.

The feasibility of LGF is an important issue to investigate in designing orchestration tools for teachers, and can be a central concern at the initial stage of tool design. This is because during the initial design stages we often do not yet have data to rigorously evaluate the effectiveness of LGF, given testing the LGF requires human resources of learners, instructors, materials resources of devices, systems, and a long time period. Additionally, an effective pairing policy that only covers a small percentage of students in a classroom may have limited influence for the whole class. Thus, the feasibility of LGF can be important in providing context for the potential coverage of LGF in a class.

Literature on LGF in collaborative learning is vast. Researchers have paired students based on gender [11,12], learning style [13–16], students' social network [17], and their intelligence or task proficiency [18–20]. Heterogeneous and homogeneous group formation are two main approaches in team formation, and many studies have demonstrated their effectiveness in CSCL [1,8,18,20–22]. Students' knowledge level is argued to be the most suitable and important attribute to form educational groups [8]. Prior work has also used machine learning or other algorithms to incorporate multiple factors for optimizing team formation [23–26]. However, the literature on LGF provides little insight into the feasibility of these LGF policies, especially in the ITS context.

Evaluating the feasibility of LGF policies offline, prior to implementing them in real classrooms, is challenging, given a lack of readily accessible approaches. To address this problem, we adopt a process we call "*SimPairing*", to simulate pairing policies on authentic data and evaluate their feasibility. In this process, we used transaction data from several classes of students using an ITS, collected from classroom studies conducted in U.S. middle schools. We computed and analyzed how the feasibility of several LGF policies (described below) changed as each class progressed, and how the feasibility varied across different classes. Replaying historical data to simulate possible futures (e.g., Replay Enactment [27]), has been used as a method by researchers to design tools with similar data-driven, human-centered approaches [28]. Diana et al. [29], for instance, used machine learning (ridge regression) to predict students' grades based on historical data in CS education (i.e., programming). Based on these *predicted grades* and simulated *students' "helped" status,* they determined which students needed help and which may be able to provide help. They then used a network graph of code-state to search for potential peer tutors who shared a common ancestor node with the tutee. They found that grouping low-performing students together and using better model features can increase the number of students helped. Their findings suggest that using low-level log data to group and match low-performing students with a peer tutor may be an effective way to increase the amount of help given in a classroom. In contrast, we simulated different policies selected based on literature and teachers' common practice revealed in user-centered research with K-12 teachers [10,30,31], in a mathematics education context.

The current work is, to the best of our knowledge, *the first to look at dynamic pairing policies that consider students' in-the-moment wheel-spinning status.* Identifying students who are unproductively struggling, yet failing to master the skill, (i.e., wheel spinning) is a first step to getting them unstuck [32]. While there has been significant work on modeling and predicting wheel spinning [33–35], little work has been dedicated to developing interventions to get them unstuck, with a few recent exceptions [36,37]. While a typical classroom has students who are struggling on problems and those who have excelled on the same problem, the latter students' expertise is rarely utilized. Instead, often the only source of help is the instructor, who is likely unable to help all the students who need help within the time constraints of the class period [38]. Peer tutoring (i.e., pairing a struggling student with a peer tutor) could be an effective way to help get struggling students unstuck when the instructor has their hands full.

Lastly, instead of prescribing *a specific grouping criterion, our work envisions that instructors will customize pairing policies and parameters to their classroom contexts, which prior work argued to be especially helpful in the LGF process [1,8,30,39].* Amara et al. found that most of the proposed LGF solutions do not allow instructors to customize the grouping process [1]. They argued that it is less helpful to apply a grouping solution for all types of learners, and more useful to leave the choice to instructors. Instructors can then form groups according to different learning objectives, learners' needs, activity types, and customize the LGF process according to location and time [1]. Similarly, Echeverria et al. envision adaptability in an orchestration system, which "enables teachers to select the best pairing policies based on their particular goals, needs, and classroom dynamics" [30], to be helpful for different classrooms. In the current investigation, three of the four policies we studied involve an adjustable pairing threshold or parameter, which we simulated with various values.

In sum, the current work investigates the feasibility of four dynamic LGF policies derived from user research with math teachers. We investigate from three angles: overall session simulation, class-level variance, and session-level contrasting cases. This work contributes to the feasibility results of the dynamic pairing policies, recommendations for orchestration tool design, and highlights future work regarding tools supporting dynamic LGF.

2. STUDY CONTEXT

2.1 Intelligent Tutoring Systems

This study used student transaction data collected from classroom studies in U.S. middle schools (dataset link). This data logged students' interaction with an ITS called Lynnette, which offers guided practice to students in basic equation solving. ITS (also called AI-tutors) are increasingly common in K-12 classrooms to help teachers more effectively personalize instruction [40]. As shown in Figure 1, Lynnette provides step-by-step guidance, in the form of adaptive hints, correctness feedback, and error specific messages. Lynnette supports personalized mastery learning, and has been proven to improve students' equation-solving skills in several classroom studies [41–43].

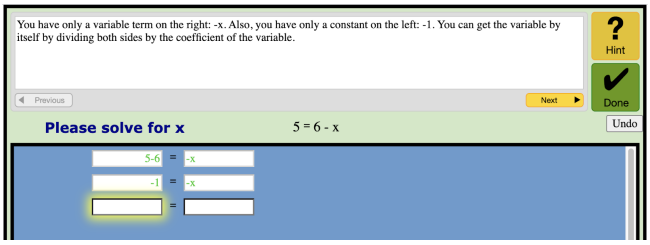

Figure 1. Example student interface for the ITS, Lynnette

The transaction data logs detailed events by the timestamp of students' interaction with the ITS, including but not limited to actions they take (e.g., requesting hints or attempting a step), knowledge components (KC) that a transaction involves, and skill mastery, calculated based on Bayesian Knowledge Tracing (BKT) student model, a two-state Hidden Markov Model. BKT is a popular student model that has been successful for various applications in the educational technology literature (e.g. [44]).

The current work lays a foundation to (in the future) use Lynnette in combination with a second ITS, APTA, which extends Lynnette's functionality to support reciprocal peer tutoring. APTA allows two students to respectively take the role of tutor and tutee. In APTA, the tutee can seek help from their partner, while the tutor can see the tutee's progress, and help them to make progress with the math problem at hand. APTA supports the peer tutor in

tutoring the tutee. Classroom studies with APTA have demonstrated that its adaptive support can improve the quality of help peer tutors give and improve students' domain learning [45,46]. A future effort for the current work is to implement feasible student pairing policies in an orchestration tool, to support teachers in dynamically pairing students to work collaboratively in APTA. Such a tool plays a key role in our vision for the smart classroom of the future, in which students alternate fluidly between individual and collaborative learning.

2.2 Wheel-Spinning Detector

Detectors have been developed to detect student behaviors of interest (e.g., gaming the system, struggling) from the transaction data. Such detectors have been used to design dashboards or tools that can alert teachers of certain student status (e.g., [9]). In our policies 1 and 2, we paired students based on their struggle status indicated by a wheel-spinning detector.

Wheel-spinning, as defined by Beck and Gong, denotes students who are failing to master a specific skill after many attempts in an intelligent tutoring system [32]. We utilized a detector that adopted the same criterion as defined by Beck and Gong [32]. The detector is embedded in LearnSphere, (i.e., a large learning analytics infrastructure) [47]. The detector considers students who have over ten practice opportunities yet still failing to reach a skill mastery on a specific knowledge component (KC) of above 0.95, to be wheel-spinning on this KC [9]. Such prolonged repeated struggles are likely to be an inefficient use of time for students [32] and may contribute to a lack of motivation for future learning [36]. Wheel-spinning is one type of unproductive struggle, and we use *struggling* and *wheel-spinning* interchangeably in this paper.

3. METHODS

We evaluated how feasible four pairing policies (described below) are, based on simulation with historical transaction data from Lynnette. We applied each pairing policy to data from each class session. For every minute in a session, we calculated the percentage of students who met the policy's criterion for being teamed up. Based on this calculation, we evaluated policy feasibility using two measures, FI_1 and FI_2, defined in 3.2. In the simulation process, we did not make assumptions about how long simulated collaboration episodes would last. We foresee that in any of these episodes, students will be given the task of collaboratively solving several math problems; it is hard to predict how long that will take them. We thus did not simulate taking tutors or tutees out of the pool of students available for teaming up, or returning them to this pool, at the beginning and end of collaborative episodes, respectively. Although this simplification might introduce some inaccuracy into the simulation results, it may be hard to do better. As well, the asymmetric roles that paired-up students have in the pairing policies may limit the inaccuracy. For example, simultaneously keeping a struggling student and a non-struggling in the pool instead of taking them both out might have offsetting effects in terms of feasibility.

Our simulation involved four pairing policies, namely:

Policy 1 - Struggle with Non-Struggle: Pairing students who are wheel-spinning (unproductive struggle) with students who are not wheel-spinning.

Policy 2 - Pairing with Restriction: Pairing students who are wheel-spinning with those who are not wheel-spinning, with a varying pairing restriction (PR) rate β. The PR rate simulates restrictions regarding who can collaborate with whom, which in real life would be provided by the teacher.

Policy 3 - Knowledge Difference Pairing: Pairing students whose knowledge levels (as measured by the tutor's BKT) differ by *more* than a certain threshold α.

Policy 4 - Knowledge Similarity Pairing: Pairing students whose knowledge levels (as measured by the tutor's BKT) differ by *less* than a certain ceiling γ.

The distinction in these policies aligns with Amara et al.'s categorization for dynamic group formation [1]: *intra-session* and *inter-session* grouping. Intra-session grouping allows for changing group members during the learning process, which is useful, for example, for synchronous mobile collaborative learning [1]. In *inter-session grouping,* groups are formed only before starting or after ending the learning process. Specifically, policies 1 and 2 fall under *intra-session* grouping since we simulated pairing students based on their in-the-moment struggle. These two policies also concern *fluid social transitions [10]*, since the students in a given class may transition from individual to collaborative learning at different times. Our pairing policies 3 and 4 concern inter-session grouping, and pair students based on their initial knowledge level. To apply these policies, teachers or the tutoring system would assess students' knowledge level, prior to (or at the beginning of) a class session.

The research questions we aim to answer are:

RQ1: Based on a pairing simulation done with students' historical transaction data, how feasible are the four pairing policies?

RQ2: How does varying the parameters in the pairing policies affect the feasibility of pairing students?

RQ3: Does the feasibility of the pairing policies vary for different classes or sessions, if so, how?

3.1 The Four Pairing Policies

3.1.1 Policy 1: Struggle with Non-Struggle

Description. Policy 1 utilizes the struggle detector (section 2.2) to pair students who are wheel-spinning with those who are not. The struggle detector assumes students' wheel-spinning status to be a binary value for a given timestamp. Inspired by the work of Diana et al. [29], we categorized students in the *Struggle Pool* if they were wheel-spinning on at least one KC, indicating they could need help from a partner. Students not wheel-spinning on *any* KC were categorized in the *Tutor Pool* and considered as available tutors. We simulated pairing students in the *Struggle Pool* with students in the *Tutor Pool*. To determine the feasibility of this policy, we calculated the percentage of struggling students who had a potential partner (for more detail, see below).

Rationale. Literature suggests that when students are wheel-spinning, giving them more of the same type of math problems to solve may not be productive [36]. When wheel-spinning, students would likely benefit from instructor attention or extra instruction. However, prior user research in the classroom (e.g. [9]) found that teachers often cannot help all struggling students. In this case, wheel-spinning students may benefit from a peer tutor's help, which leads to a policy that seeks to dynamically find them partners [36].

3.1.2 Policy 2: Pairing with Restriction

Description. Policy 2 is an extension to Policy 1, where we pair a struggling student with a non-struggling student, while enforcing a constraint that not all students are eligible for teaming up. The proportion of ineligible students is captured as the Pairing

Restriction (PR) rate. The PR rate is used to simulate situations where the teacher prefers that certain students do not work together. Specifically, we simulate pairing students in the *Struggle Pool* with students in the *Tutor Pool,* while enforcing the restriction that β% ($0 < \beta < 1$, step = 0.1) of students in the *Tutor Pool* are ineligible as partners. For example, a PR rate β of 0.2 means 20% of the students in *Tutor Pool* have been restricted from working with any students in *Struggle Pool*. It is important to know how these restrictions affect the feasibility of the policies.

Rationale. We designed this policy based on results found in a survey we conducted with 54 middle-school math teachers on their pairing preferences in collaborative learning [31] and semi-structured interviews conducted with middle school teachers. Teachers expressed a desire to set constraints so that certain pairs of students are restricted from working together. Previous studies and user research by Olsen et al. and Echeverria et al. also informed the idea of ruling out certain pairings in advance [10,30]. Such restrictions usually arise from information or concerns teachers have about their students' traits, behaviors and interpersonal relationships [8].

3.1.3 Policy 3: Knowledge Difference Pairing

Description. In Policy 3, we pair students who have *different* Initial Knowledge (IK) levels. In a practical scenario, teachers may assess students' knowledge through quizzes or exams. Alternatively, if the classrooms use ITS, teachers may have students practice several math questions individually, prior to transitioning into collaborative learning activities.

To simulate this policy without having pre-assessment data, we used data from the tutoring sessions (captured in the log data) to compute students' IK levels. Specifically, we computed a student's IK for each KC, as the average mastery for their first *three* opportunities for this KC. The reason is we want to use up only a small portion of the data from the tutoring session, so the measure represents initial knowledge. In our datasets, three opportunities generally fall in the first quartile (25%) of students' total number of opportunities for any given KC. Another reason we chose the cutoff of three is a previous EDM study with ASSISTments data showed student learning often appeared to occur, after students have had *ten* opportunities with the target knowledge [48]. Thus one may assume learners to have little learning on their first three times in transaction data practicing a KC. A student's overall IK S_j $(j \in N)$ is calculated as the average of their IK across KCs. To more accurately calculate students' *IK*, we limit our simulation to sessions that practiced the first (i.e., the most basic) level of KCs, involving 25 sessions.

KD was the difference between two students' IK, and denoted as S_{jk} $(j,k \in N)$, which was calculated as the absolute value of differences between two students' IK:

$$KD(S_{jk}) = |IK(S_j) - IK(S_k)|$$

Inspired by Huang and Wu's work that proposed a clustering LGF method that considers a threshold of learner heterogeneity [49], this work similarly considers a KD threshold. For this policy, the required KD of two students (S1, S2) should be a *minimum* of α ($0 < \alpha < 1$, step = 0.1) for them to be eligible to pair up.

Rationale. The heterogenous pairing policy was informed by findings from user research with math teachers. In the survey conducted with 54 math teachers, we found the most common way teachers paired students was pairing those who have a different level of knowledge (67%, N = 34) [31]. In our study, we use students' *mastery of knowledge components* (i.e., targeted math skills) calculated based on the BKT model to represent students' knowledge. In a systematic literature review on LGF in CSCL, Maqtary et al. found the knowledge level is the most commonly used attribute in LGF, which they claim to be the most suitable and important attribute to form educational groups because of its effects on the group process [8].

There is a range of research that shows heterogeneous grouping can promote positive interdependence, better group performance, and effective interactions [1,49–52]. Heterogeneous group composition not only enhances elaborative thinking, but also leads learners to deeper understanding, better reasoning abilities, and accuracy in long-term retention [49,50]. Research also suggests that collaborative learning with heterogeneous group composition by characteristics such as gender, ability, achievement, social-economic status (SES), or race, can be beneficial [51].

3.1.4 Policy 4: Knowledge Similarity Pairing

Description. Policy 4 is analogous to Policy 3, with the same definition of KD and IK as in Section 3.1.3. To pair students with *similar* knowledge, using the same calculation as Policy 3, this policy simulated pairing students that have *a small* KD. To be eligible for students to form a pair under this policy, the KD of two students (S1, S2) should be *less than or equal to* γ ($0 < \gamma < 1$, step = 0.1). For example, when γ = 0.2, two students with knowledge of 0.6 and 0.75 (KD = 0.15, below γ) would be eligible to pair, but another pair with knowledge of respectively 0.5 and 0.8 (KD = 0.3, above γ) would not be eligible.

Rationale. Policy 4 was inspired by prior literature and informed by user research. Literature suggests that homogenous groups can be beneficial for students' learning. For example, Fuchs et al. found homogenous dyads generated greater cognitive conflict and produced better quality work than heterogeneous groups [22]. Additionally, among 54 teachers we surveyed, 43% reported that they pair students with a similar level of knowledge [31]. This was the third most popular grouping method that teachers commonly adopt (43%, N = 23), following strategies of pairing students with different knowledge (Policy 3) and pairing students randomly *[31]*.

3.2 Metrics

In this section, we describe the metrics to evaluate the pairing policies. We discuss how prior work informed the metric definitions, and how different metrics could be suitable to evaluate different policies. We build on Diana et al.'s work [29], who defined an Efficiency Index (EI) as a measure of a pairing algorithm's performance, specifically:

$$EI = \frac{LowPerformingStudentsHelped/BeingHelped}{LowPerformingStudents}$$

We adapted EI into two metrics of interest for our pairing policies: Feasibility Index 1 and 2. FI_1 is the percentage of students who can be paired among all struggling students in a session.

$$Feasibility\ Index\ -\ 1\ (FI_1) = \frac{StrugglingStudentsCouldBeHelped}{TotalStrugglingStudents}$$

FI_2 is the ratio of paired students among all the students in a session.

$$Feasibility\ Index\ -\ 2\ (FI_2) = \frac{StudentsPaired}{TotalStudents}$$

For Policies 1 and 2: Given the goal to pair all struggling students in the session, FI_1 was a suitable measure for policy feasibility,

showing what percentage of students who are wheel-spinning can get help. *For Policies 3 and 4:* Given the goal to pair all students in the session who satisfied a certain KD, FI_2 was a suitable measure for policy feasibility, as it calculated the percentage of the paired students out of the total students.

3.3 SimPairing Approach

There are three main steps in *SimPairing*: 1) data cleaning and preprocessing, 2) policy simulation, and 3) policy evaluation. The data cleaning and preprocessing step consists of clustering student transaction data into meaningful class sessions based on meta-data (e.g., student transaction timestamp, classes), and examining the distribution of students per class session to detect outliers. The policy simulation step takes the preprocessed transactional data and applies a pairing policy to class sessions. In the policy evaluation step, we computed the policy feasibility based on the simulation results, using the corresponding feasibility index (FI_1 or FI_2). We also observed how the FI changed by varying the parameters (i.e., KD, and PR rate).

4. ANALYSIS AND RESULTS

4.1 Data Cleaning and Preprocessing

We first clustered student transaction data into meaningful class sessions, based on timestamp, student ID, and class. We visualized student engagement for all class sessions based on transaction data, which allowed us to ensure that the sessions we analyzed had a continuous student interaction with the system, and helped us check for outliers (e.g., unusually short sessions). We excluded four outlier sessions: 2 sessions that had only 1 student, 2 sessions that lasted less than 15 min, as sessions commonly lasted 40 minutes or more.

Transaction data of a total of 68 sessions, from six middle school math classes, collected from 2013 to 2014 were used for policy simulation. It consists of 894 students and 197,234 rows of transactions. The average number of students in a session was 13 (*Min* = 5, *Max* = 24, *SD* = 25.3); the average duration of class session was 41.9 minutes (*Min* = 10, *Max* = 81, *SD* = 9.42); the average number of sessions in a class was 11 (*Min* = 3, *Max* = 23, *SD* = 9.33).

4.2 Overall SimPairing Analysis

In this section, we present, for each policy, the SimPairing analysis and the results. The goal for this analysis was to evaluate the overall feasibility of the four pairing policies (RQ1) and see how the feasibility depends on policy parameters (RQ2).

4.2.1 Policy 1: Struggle with Non-Struggle

We simulated Policy 1 for every minute in a given class session, which returned the number of struggling students who did or did not have a potential partner. Based on this we calculated the FI_1 for every minute in a class session. We then averaged FI_1 across the length of each class session, to obtain an average FI_1 for a given session. We refer to it as the Average Number of Struggling Students (ANSS). We then took the average of the ANSS across all sessions, to obtain an overall simulation result for all 68 sessions. Figure 2 (green area) shows the average FI_1 for all sessions was 0.94 (*SD* = 0.007). Thus, on average, across time, 94% of struggling students could be paired with a partner who was not struggling.

4.2.2 Policy 2: Pairing with Restriction

The Policy 2 simulation process is similar to Policy 1, with the addition of enforcing a varying PR rate. PR rate specifies a percentage of students in *Tutor Pool* as restricted from partnering with students in the *Struggle Pool*. We computed FI_1 with varying PR rates. As shown in Figure 2 (white area), FI_1 dropped as the PR rate increased, as expected. However, even with a relatively high PR rate of, for example, 0.4, meaning, 40% of non-struggling students are restricted from working with struggling students, we still get a high average FI_1 of around 0.80, (i.e., 80% of struggling students could be paired). The simulation result means that teachers can afford to set moderate restrictions for pairings, without compromising too much of the pairing policy's feasibility.

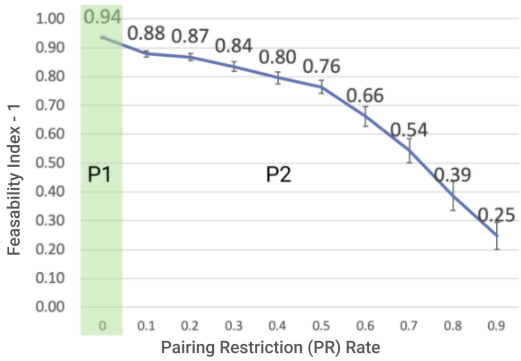

Figure 2. FI_1 for Policies 1 and 2

4.2.3 Policy 3: Knowledge Difference Pairing

Policy 3 requires students to be above a given *minimum* distance in their IK to be eligible for pairing up. We simulated this policy by computing FI_2 with varying values for the KD distance threshold α. We simulated these sessions to calculate the FI_2. As in Figure 3 (blue line), FI_2 dropped rather quickly as the required knowledge distance threshold went up. For example, the simulation results show that if we want to ensure an average of 80% of paired ratio, the KD threshold should be set to less than approximately 0.1 (i.e., a very strict bar).

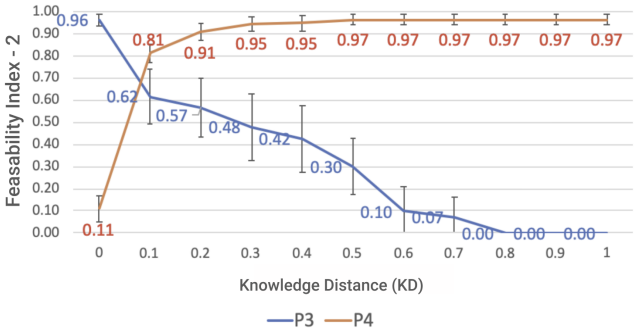

Figure 3. FI_2 for Policies 3 and 4

4.2.4 Policy 4: Knowledge Similarity Pairing

Policy 4 requires students to be below a *maximum* distance in their IK to be eligible for being paired up. We simulated this policy and computed FI_2 with different values for the KD distance ceiling γ. We found that this policy would work well even with a low, strict ceiling for the knowledge distance (Figure 3, red line). For example, when γ was 0.1, (i.e., two students' knowledge distance can be at most 0.1 for them to be teamed up), the average FI_2 was still 0.81 (*SD* = 0.08) across the class sessions involved. When γ was set to above 0.3, 95% of students in class could find an eligible partner.

4.3 Class-Level Variance Analysis

We explored how the four pairing policies worked for different classes and whether the pairing policies should be adapted to class-level differences (RQ3).

4.3.1 Class-level Differences

Based on Echeverria et al.'s insight that pairing support for teachers should ideally be adaptable to different classroom contexts [30], we analyzed, first, if there were systematic differences between different classroom contexts, and second, if these differences relate to policy feasibility differences. The main context variables taken into account by our pairing policies are *students' struggle status* (Policies 1 and 2) and *initial knowledge* (Policies 3 and 4). We thus analyzed if the classes had different *struggle statuses* and *initial knowledge (IK)*.

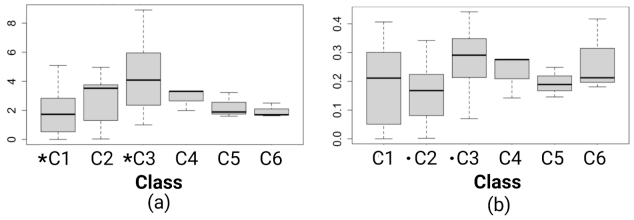

Figure 4. ANSS (a) and ASSRs (b) for Six Classes

***Student struggle status*:** We first calculated the number of students in wheel-spinning status for every minute within each class session. We then computed ANSS (section 4.2.1), and the *Average struggling students ratio (ASSR)= ANSS / total number of students in the session*. Histograms for ANSS and ASSR for all sessions show they follow the normal distribution. We conducted one-way ANOVAs, respectively taking the *ANSS* and *ASSR* as outcome variables and *Class* as the explanatory variable. The results showed a significant difference for ANSS among classes (Figure 4, a) [$F(5,62) = 4.34$, $p < 0.001$]. *Post hoc* Tukey tests showed C3 and C1 have significant differences (*diff* = 2.55, $p < 0.001$). All *post hoc* pairwise tests conducted in this study were corrected for multiple comparisons. The ANOVA result indicated that the classes differed with marginal significance [$F(5,62) = 1.94$, $p < 0.1$] (Figure 4, b). *Post hoc* Tukey tests showed a marginal difference in the ASRR between C3 and C2 (*diff* = 0.10, $p = 0.08$). Thus, there were class-level differences with respect to students' struggle status.

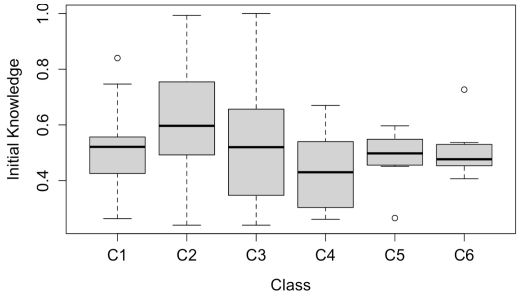

Figure 5. Initial Knowledge for Six Classes

Initial Knowledge: We calculated each student's IK for all KCs involved (defined in section 3.1.3). The histogram for all students' IK shows it follows the normal distribution. We then conducted one-way ANOVAs using *IK* as the outcome variable, and *Class* as the categorical explanatory variable. The results indicated a significant effect of classes on IK for the six classes [$F(5, 320) = 5.895$, $p < 0.05$], and the IK for the six classes were not all equal. From the *post hoc* Tukey tests comparing knowledge level between each pair of the classes, we saw significant differences between classes C2 and C1 (*diff* = 0.12, $p < 0.05$), C3 and C2 (*diff* = -0.095, $p < 0.05$), and C4 and C2 (*diff* = -0.189, $p < 0.05$). C2 had the highest median of student IK (Figure 5), and a significantly higher level of IK than C1 and C3, and C4.

Having characterized struggle and IK at a class level, we compare the policies' feasibility across classes.

4.3.2 Policies 1 and 2

Policy 1 had an average FI_1 above 0.85 (Figure 6, green area). We statistically compare if Policy 1 behaved differently for each class and see whether this policy should be adaptable for each class. Using session as the unit of analysis, we conducted a one-way ANOVA using the FI_1 for each session as the outcome variable, and *Class* as the categorical explanatory variable. The results indicated that there was not a significant effect of class on FI_1 [$F(5,62) = 1.24$, $p = 0.30$]. This result showed that Policy 1 was relatively consistent across the six classes, suggesting that Policy 1 may not need to be adaptable to classes.

For Policy 2, with increasing PR rate, the FI_1 decreases at a different speed for different classes, indicating some degree of class-level difference (Figure 6, white area). We conducted ANCOVAs with *Class* being the categorical explanatory variable, the *PR rate* as the quantitative explanatory variable, and FI_1 being the quantitative outcome variable. We first compared the model with and without a Class × PR rate interaction term. The model comparison result showed no evidence of an interaction effect among explanatory variables ($F = 1.63$, $p = 0.15$). We thus perform ANCOVA using an additive model. Results indicated there were eight pairs of classes that had significant differences in FI_1 for this pairing policy ($p < 0.05$). The eight pairs were C1-C2, C1-C3, C1-C6, C2-C3, C2-C6, C3-C5, C4-C6, and C5-C6.

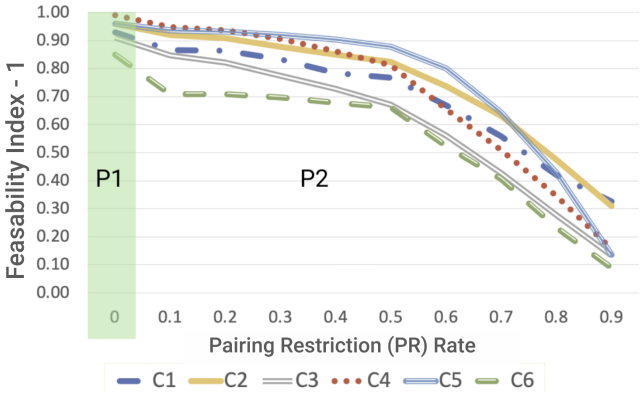

Figure 6. FI_1 of Policies 1 and 2 for Six Classes

Next, we looked at possible relations between the class-level feasibility variance of policies 1 and 2, and the class-level differences in *struggle status* (section 4.3.1). We found that for classes that differed with respect to the number of struggling students (C3-C2) and the average ratio of student struggle (C3-C1), the feasibility of Policy 2 tended to differ as well. This finding suggests that 1) Policy 2 may benefit from being adaptable to class-level characteristics, and 2) variables characterizing a class's struggle status (e.g., ANSS and ASSR) may have value in indicating how Policy 2 should be adaptable. On the other hand, the feasibility of Policy 2 was different in Class 6 compared to all other classes except C3, yet Class 6 did not differ in number or

ratio of struggle students from other classes. Thus, students' struggle status alone may not provide enough information to fully decide whether and how P2 should be adaptable.

4.3.3 *Policies 3 and 4*

For Policy 3, the classes shared a downward trend in FI_2 with different slopes for each class (Figure 7). For example, when the KD was 0.1, we saw the FI_2 values for class 6 (green dotted-line) drop to as low as 50%, but the other five classes have FI_2 above 75%. This shows that policy feasibility may be differently affected by the knowledge heterogeneity threshold in each class.

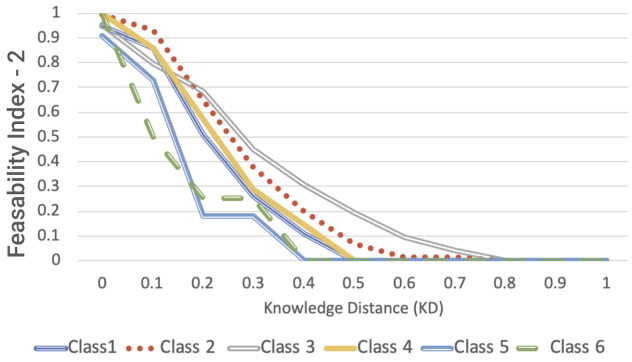

Figure 7. FI_2 of Pairing Policy 3 for Six Different Classes

To test whether Policy 3 behaved differently for each class, we conducted ANCOVAs with *Class* as a categorical explanatory variable, *KD* as a quantitative explanatory variable, and FI_2 in each session as the outcome variable. We first compared the model with and without a Class × KD interaction term. Results indicated no evidence supporting the interaction effect ($F = 0.81$, $p = 0.54$). We performed an ANCOVA using an additive model. Results indicated that three pairs of classes had significant differences in FI_2 ($p < 0.05$), and that two pairs of classes were marginally different ($p < 0.1$). They were C1-C3, C3-C5, C3-C6 ($p < 0.05$) and C2-C5, C2-C6 ($p < 0.1$) .

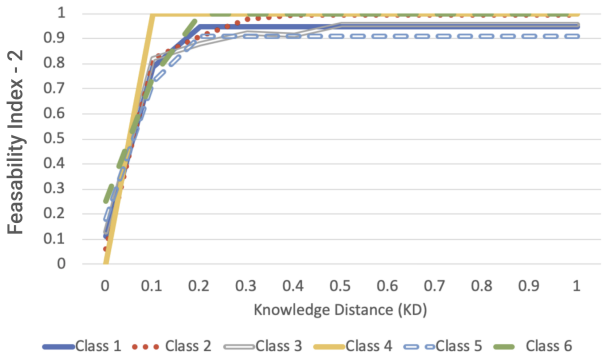

Figure 8. FI_2 of Policy 4 for Six Different Classes

For Policy 4 (Figure 8), the six classes were more convergent and clustered closer together than Policy 3 (Figure 7). This indicated the class level difference may not be as strong as that in Policy 3, which our ANCOVA tests confirmed. Similar to Policy 3, we compared whether Policy 4 behaved differently for each class. We conducted an ANCOVA, with *Class* as a categorical explanatory variable, *KD* as a quantitative explanatory variable, and FI_2 as the outcome variable. We first compared the model with and without a Class × KD interaction term. No evidence supporting interaction effect among explanatory variables ($F = 0.13$, $p = 0.99$). We then performed ANCOVA using an additive model. Results indicated that there were no significant differences in FI_2 ($p > 0.05$) for Policy 4. We confirmed a smaller class-level difference as compared to Policy 3, in KD's effect on policy feasibility. From this result, we conclude Policy 4 performed quite consistently across classes, and no significant evidence showed that Policy 4 should be adaptable to classes.

Analogous to policies 1 and 2, we then looked at relations between feasibility variance for policies 3 and 4 and class-level IK characteristics in Section 4.3.1. We observed significant differences in IK between C2-C1, C3-C2, and C4-C2. However, the differences in IK for two classes cannot accurately predict whether they had different feasibility in Policy 3 and Policy 4, and other classroom characteristics may be needed to accurately represent the class-variance of feasibility.

4.4 Analysis of Contrasting Cases

We conducted a case study to understand how policies may perform dynamically (e.g., across every minute during class time) and differently in different class sessions (RQ3). For every policy, we selected a *typical* case and an *extreme* case in terms of the policy feasibility simulation results. For the *typical* case for all four policies, we selected a session (Session 1, C1) that had an average length of time (i.e., 41 minutes), an average number of students (i.e. 13 students). In the session, policies performed typically (as by visually comparing the simulation results of each policy for all sessions). As for the *extreme case*, we examined the simulation results for each policy on each session, and identified different sessions where each policy performed surprisingly or differently from the common trend. The extreme case can be a worst case scenario (Policies 1, 2 and 3) or a case that works surprisingly well (Policy 4). Below, we present the analysis and results for these contrasting cases for each policy.

4.4.1 *Policy 1*

In Policy 1, we chose the extreme case (Session 19, C3) as it was a session that this policy has the worst performance on, and thus it had the most different FI_1 trend, from examining visualizations of FI_1 for all sessions involved. We compare the typical case and extreme case by first contextualizing the struggle status of the two cases, and comparing the visualization of feasibility (for each minute) in the two sessions. Figure 9 depicts the *ratio of struggling students* (among all students in the class session) for the contrasting cases. For Policy 1 simulation (Figure 10), we obtained, for every minute in the class session, three values regarding policy feasibility: the number of students who were not wheel-spinning on any KCs (green bar), the number of students who were struggling, and *had* a potential partner (yellow bar), and the number of students who were struggling and *did not have* a potential partner (red bar).

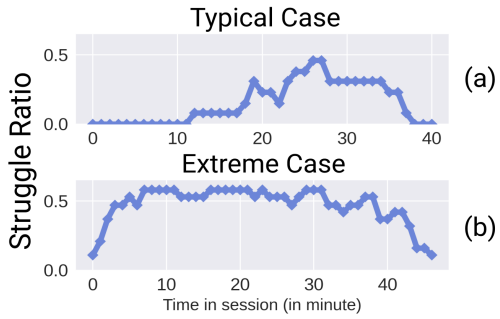

Figure 9. Struggle Ratio of a Typical (a) and Extreme (b) Case

Typical Case. In the typical case, students started to struggle after 10 minutes, as shown in Figure 9 (a) and Figure 10 (a). In all instances of wheel-spinning, a potential partner was available (i.e., $FI_1 = 1$ for any minute in this session). The typical case aligned with the overall simulation results from Policy 1, which showed that, for an average class, most struggling students could find potential partners, the minute they struggled.

Extreme Case. Among all sessions in our dataset, the per-minute struggle ratio rarely goes over 50%. By contrast, the extreme case session had more struggling students than non-struggling students in 27 out of 46 minutes, indicated by a struggle ratio of above 0.5, as shown in Figure 9 (b). This resulted in lower feasibility for Policy 1. The extreme case differs from the typical case in two aspects. First, unlike the typical case, almost as soon as the class began, students started wheel-spinning. Second, there were wheel-spinning students without potential partners in almost every minute of the session (indicated by red bars in Figure 10 (b)).

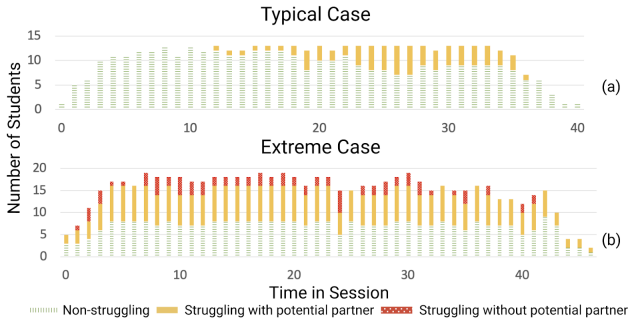

Figure 10. Policy 1 for a Typical (a) and an Extreme Case (b)

4.4.2 Policy 2

Same as in Policy 1, we chose this extreme case (Session 19, C3) as this policy had the worst performance on this session. This session also had the most different FI_1 trend. We simulated Policy 2 and calculated FI_1 for every minute in the two contrasting class sessions. Figure 11 showed the typical and extreme case, of how FI_1 changed when different PR rates were simulated. We plotted four different PR rates in the figure.

Typical Case. We saw two patterns in the Policy 2 simulation for the typical case. Firstly, the policy was typically robust in maintaining high feasibility with a non-zero (albeit low) PR rate. In Figure 11(a), lines with PR rate 0.1 and PR rate 0 completely overlapped. With these PR rates, there were no instances of struggle without a potential partner (i.e., feasibility was 1 across the whole session). Secondly, when the PR rate was high (0.5 or 0.8), FI_1 exhibited a sharp decrease, when there was an increase in student struggle. For instance, in Figure 9 (a) at minute 19, the struggle ratio increased from 0.07 to 0.23, as the number of wheel-spinning students went from 1 to 3. In Figure 11 (a) at the same time (t = 19 min), we saw a sharp decrease in FI_1 when the PR rate was 0.8.

Extreme Case. As shown in Figure 11 (b), the extreme case exhibited very different patterns compared to the typical case, mainly in three aspects. First, given it had a higher struggle ratio, even when there was no pairing restriction (i.e., PR rate = 0), we observed the FI_1 was not always 1 or even close to 1, as we saw in the typical case. Second, even a slight PR rate of 0.1 further worsened the policy feasibility and lowered the FI_1, unlike the typical case which showed resistance to a low PR rate. Third, if a class had a higher struggle ratio, the PR rate had a stronger effect on worsening FI, than for a session that had a lower struggle ratio. This effect was especially prominent when the PR rate was high (e.g., 0.5 or 0.8). This contrast means that the instructors may afford to set a higher PR rate without affecting the FI_1 too much, for a common session that has a moderate struggle ratio. However, the instructors may need to consider lowering the PR rate for a high-struggle session.

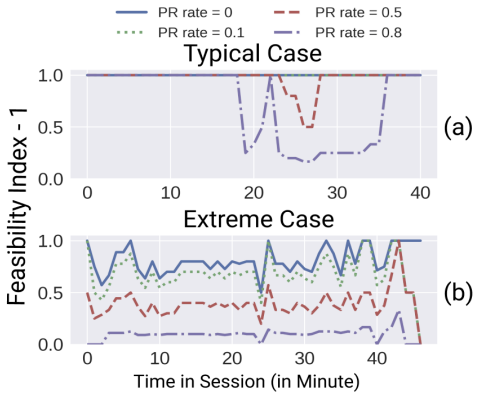

Figure 11. Policy 2 for a Typical (a) and Extreme (b) Case

4.4.3 Policy 3

In Figure 12 we present the results for Policy 3 simulation on two contrasting cases, plotting FI_2 for every step of the knowledge distance threshold for that session. The extreme case was chosen for having the most different FI_2 trend, from examining visualizations of FI_2 for all sessions involved.

Typical Case. As shown in Figure 12 (a), for the typical case, the FI_2 dropped gradually as the required KD threshold increased, which aligned with the overall simulation result. To pair students based on different knowledge (Policy 3), the instructors need to balance the required heterogeneity (i.e., higher knowledge distance threshold) and the desired paired ratio of the whole class. In this typical case, if a teacher selects a threshold of 0.5 or higher, none (0%) of students in the class session would be paired.

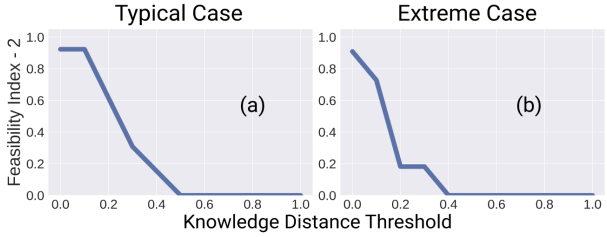

Figure 12. Policy 3 for a Typical (a) and Extreme (b) Case

Extreme Case. As shown in Figure 12 (b), for the extreme case (Session 1, C5), while the downward trend was similar, we observed a more rapid decrease as compared to the typical case. Specifically, the FI_2 dropped to only 20% when the KD threshold was as low as 0.2, compared to 60% of FI_2 at the same KD threshold in the typical case. This comparison indicated that some class sessions were more heavily influenced by the parameter of the required knowledge distance threshold, and the effect may differ from session to session.

4.4.4 Policy 4

From the previous analyses, we noted that Policy 4 performed reliably and similarly across classes, making it harder to select an

extreme case or a worst case scenario. We selected a session where Policy 4 performed surprisingly well (Session 2, C3). In Figure 13 we visualized Policy 4 simulation on two contrasting cases, plotting FI_2 for every step of the knowledge distance ceiling γ for that session.

Typical Case. The tradeoff between knowledge homogeneity and policy feasibility was less prominent than under Policy 3. This means that instructors can afford to choose a stricter (i.e., lower) ceiling so students have a very small knowledge distance, and still achieve high feasibility (FI_2). For example, in Figure 12 (a), we saw that even if the instructor chooses a very strict threshold of $\gamma = 0.1$, nearly 95% of students were able to find a potential partner.

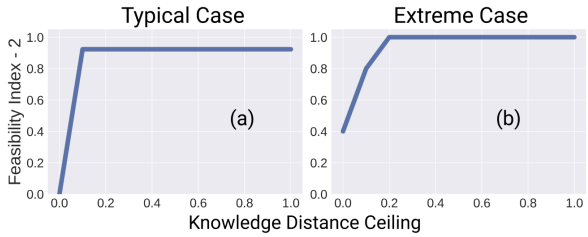

Figure 13. Policy 4 for a Typical (a) and Extreme (b) Case

Extreme Case. In Figure 13 (b), even when the KD ceiling was set to 0 (which means students must have the same level of mastery to be paired up), 40% of the students can still be paired, unlike typical cases where usually no two students have the exact same IK. Another noteworthy distinction is, while the typical case did not reach $FI_2 = 1$ with any ceiling of KD, the extreme case successfully paired all students ($FI_2 = 1$) with a relatively low ceiling of 0.2.

5. DISCUSSION

In line with previous LGF research [8], this work introduces four dynamic LGF policies contextualized in ITS and grounded in user research with K-12 teachers [10,30]. In this section, we discuss our main findings for research questions, grounded design recommendation for pairing orchestration tools, and future research direction for dynamic LGF.

5.1 Main Findings for Research Questions

Regarding the feasibility of the pairing policies (RQ1) and how the feasibility may depend on parameters of the pairing policies (RQ2), we found that *averaged across time and sessions,* it is generally feasible (93.6%) to team up struggling students with non-struggling students, the minute they struggle (Policy 1). This result remains true even when a high percentage of students is deemed ineligible for being teamed up with struggling students (Policy 2). Specifically, the average feasibility remains above 80% of struggling students across all sessions unless the pairing restriction rate is above 40%. However, as we see in our case study, there can be sessions and moments with high struggle ratios (hence, low feasibility) when using Policy 1. Relatedly, sessions with very high struggle seem more susceptible to the influence of the PR rate in Policy 2 than a typical session.

When pairing students based on whether their knowledge levels are different (Policy 3) or similar (Policy 4), the policy feasibility is highly dependent on the required KD. For Policy 3, there is a tradeoff between the desired heterogeneity (i.e., the knowledge distance threshold) and the policy's feasibility. This means instructors cannot set a high threshold for the KD if they want to pair most students. In Policy 4, the corresponding tradeoff (between homogeneity in knowledge and policy feasibility) is less prominent. Instructors may choose a stricter ceiling for students' similarity in knowledge levels and still achieve high policy feasibility. In the case study, we found that the policy feasibility in different sessions can be differently influenced by the required KD threshold or ceiling, depending on how closely clustered together students' IK is. For a given, fixed KD threshold (ceiling), a class of students closely clustered IK may result in higher feasibility for Policy 4 and lower feasibility for Policy 3. Presumably, the feasibility of these policies also depends on class size. For example, from our analysis, we hypothesize that for larger classes, the feasibility of pairing policies may change less drastically, when the policy parameters change or as the class progresses.

Regarding policy feasibility by class (RQ3), our results show no significant difference among classes for Policy 1 (Struggle with non-struggle) or Policy 4 (Knowledge similarity pairing). However, we observed significant differences among classes for Policy 2 (Pairing with restriction) and Policy 3 (Knowledge difference pairing). Although different classes have significantly different initial knowledge and struggle status, these differences in IK and struggle status are not always correlated with the feasibility of policies for that class. For example, classes that have different IK may not always have different feasibility for Policy 3 or 4.

5.2 Recommendations for Tool Design

The current study aims to inform the design of an orchestration tool that can help pair students dynamically. We aim to lessen teachers' orchestration load when managing *fluid social transitions*. Such a tool plays a key role in our vision for the smart classroom of the future, in which students alternate fluidly between individual and collaborative learning. Here, we highlight three design implications grounded in findings from the current work. These design implications may inform tools that aim to help teachers manage fluid social transitions, and ensure the feasibility of dynamic LGF policies. It may also offer inspirations, more broadly, for orchestration tools that aim to team up students in CSCL.

Firstly, technology could be used to automatically adjust the parameters used in LGF policies. Our study suggests that the four pairing policies studied provide a promising foundation for an orchestration tool, but greater flexibility is needed to deal with a wide range of circumstances than each individual policy provides. While some policies (e.g., Policies 1 and 2) explored in this study, have a good chance of working well during many class sessions, any given instantiation of a policy (with fixed parameter settings) does not fully deal with class variability and extreme cases. One way to compensate might be to have the tool automatically loosen policy parameters as needed. For example, the tool may gradually loosen the KD threshold or ceiling for policies 3 and 4, when it senses the pairing feasibility to be low.

Secondly, technology could use multiple LGF criteria in cascading fashion, to achieve high feasibility. Specifically, the tool may start out using the ideal pairing policies, and then iteratively try "more loose" criteria if the previous one fails to pair up all students. For example, the tool may first attempt to team up students based on struggle on specific KCs - a criterion that is more specific (and restrictive) than Policy 1, but one that could potentially be more effective for helping struggling students. If that fails, then it might pair up students based on their general struggle (Policy 1). If that fails again then the tool could try to

pair students based on knowledge distance. The tool could also customize its pairing criteria such as using students characteristics that make the most sense in the given classroom context.

Lastly, technology could be used to recommend LGF policies or policy parameters with high feasibility to teachers. Instead of relying solely on the teachers to make pairing decisions, the tool may adopt *SimPairing* to automatically calculate and maximize policies' feasibility based on classroom contexts and recommend them to teachers. For example, if the tool determined, using historical transaction data, that students in a given class have consistently low struggling ratios and fewer wheel-spinning students than non-wheel-spinning ones, it may advise that teachers adopt pairing Policy 1 as it has high feasibility. In addition, our findings open up the potential for the tool to help teachers make informed decisions about parameter configuration, by notifying them of expected feasibility. For example, if a teacher severely restricts the acceptable pairings, the tool could alert teachers of the low feasibility of the pairing policy, and ask if the teacher might want to loosen the restrictions. Running such simulations and providing notification can inform the teachers about the outcomes of the policy feasibility in their classroom, prior to implementing them. This may prevent teachers from choosing policy configurations that are misaligned with their goals.

5.3 Future Research Directions of Dynamic LGF

Building on our investigation, we outline four potential directions for how future research could further explore dynamic LGF policies.

Firstly, in addition to inter-session pairing based on knowledge distance (Policies 3 and 4), future work could explore *intra-session grouping based on knowledge level,* which allows forming pairings during the learning process. Researchers should explore how it would differ from our inter-session grouping and which approach better supports teachers' needs.

Secondly, the current policies identify the students to be wheel-spinning if they struggle on *any* of the KCs. Future work could explore whether teachers prefer to pair students based on their KC-specific struggle status. For example, to help a student struggling on the KC *combine constant terms* in equation solving, teachers may prefer to find a partner who has already mastered the same KC, or at minimum is not struggling on the same KC; they may (or may not) might find it acceptable, if the partner is struggling on another KC, e.g., *divide by variable coefficient*. Relatedly, teaming up students who are both struggling, but struggling on different knowledge components, may have benefits. Such a pair of students may have complementary knowledge and strength, and may help each other get unstuck and stop wheel-spinning. Such pairing criterion opens up good opportunities for tutor-tutee role-switching and mutual peer tutoring.

Thirdly, analogous to pairing based on KC-specific struggle status, instead of using the mean of students' mastery on different KCs to represent their knowledge, future work could explore to what extent *pairing students based on KC-specific knowledge distance* can be more effective, feasible, or preferable for teachers. KC-specific knowledge pairing might be useful for Policy 3, if teachers want two students who have very different skill levels on one specific KC so that the one with higher mastery on that KC can tutor the one with lower mastery.

Lastly, in addition to knowledge level and struggle status, which this work investigated for dynamic grouping, future work can investigate *other student characteristics* (e.g., history of collaborative episodes, preferences for working individually or collaboratively) or other *sources for knowledge level* (e.g., exams or quizzes score) for dynamic pairing. It may also be especially promising to further study pairing based on dynamic student behaviors that can be detected real-time by ITS from interaction data, to allow fluid social transitions and dynamic pairing.

5.4 Limitations

There is uncertainty in the *SimPairing* process in that we do not have a good way of estimating how long any given collaborative episode will last. Thus, *SimPairing* does not simulate students' being unavailable for pairing while they are working collaboratively, until they finish the collaborative episode. There is some reason to think that the resulting inaccuracy in the feasibility results is not severe, as argued, but we do not have a good way of investigating that issue in depth. Additionally, feasibility of pairing policies, while important, is just one piece of the puzzle. It is important, as well, to understand if students *learn better* with these pairing policies (effectiveness). Future research should validate these pairing policies in classroom studies, testing both their effectiveness and feasibility.

6. CONCLUSION

We study the feasibility of pairing policies in the context of ITS, to inform the design of a tool for orchestrating fluid transitions between individual and collaborative learning. Our findings show that on average, dynamically pairing students based on their in-the-moment wheel-spinning status results in good pairing feasibility for struggling students on average, even with moderate restrictions on the allowed pairings. We also found the trade-off between the *required knowledge distance* and *the policy feasibility,* is more prominent in heterogeneous grouping than in homogeneous grouping. However, any given instantiation of a policy (with fixed parameter settings) does not fully deal with class variability and extreme cases, as policies have different feasibility for different classes and sessions. This suggests optimization for policy feasibility (e.g., through gradually loosening parameters) or classroom customization need to be taken into consideration. Methodologically, this research extends previous work (e.g., Replay Enactments) that used authentic data and algorithms as design materials to augment designers' intuitions for designing future tools [27].

This work has several novel elements. First, using the *SimPairing* approach, our work explores the *feasibility* of LGF policies derived from user research with math teachers. In addition, to the best of our knowledge, this is the first study that considers students' in-the-moment wheel-spinning status in dynamic pairing policies. Finally, our work addresses a gap in the literature for dynamic intra-session LGF [1] and envisions how instructors and/or an orchestration tool will customize pairing policies and parameters to specific classroom contexts, which prior work argued to be especially helpful in the LGF process [1,8].

In sum, theoretically, this work bridges the literature gap on its investigation of the *feasibility* of user-centered dynamic pairing policies. Practically, we contribute grounded design directions for pairing orchestration tools, and *SimPairing* as an approach, to evaluate dynamic LGF policies, which may generalize to other online educational software that have transaction data.

ABSTRACT

The state of the art knowledge tracing approaches mostly model student knowledge using their performance in assessed learning resource types, such as quizzes, assignments, and exercises, and ignore the non-assessed learning resources. However, many student activities are non-assessed, such as watching video lectures, participating in a discussion forum, and reading a section of a textbook, all of which potentially contributing to the students' knowledge growth. In this paper, we propose the first novel deep learning based knowledge tracing model (DMKT) that explicitly model student's knowledge transitions over both assessed and non-assessed learning activities. With DMKT we can discover the underlying latent concepts of each non-assessed and assessed learning material and better predict the student performance in future assessed learning resources. We compare our propose method with various state of the art knowledge tracing methods on four real-world datasets and show its effectiveness in predicting student performance, representing student knowledge, and discovering the underlying domain model.

Knowledge Tracing, Multiple Learning Resource Types, Non-Assessed Learning Resources, Memory Augmented Neural Networks, Domain Knowledge Modeling, Student Knowledge Modeling

1. INTRODUCTION

As the education landscape shifts toward distance learning, the online learning systems advance in complexity and capacity. They can handle more students, evaluate students through different kinds of assessments, and offer various types of learning resources to them. In such systems, a student can study a reading section, take a quiz, watch a video lecture, and practice programming in an embedded development environment. As a result, students learn from heterogeneous types of activities in modern online learning systems, among which some can be assessed and some cannot.

Despite this heterogeneity in learning resource types, current student knowledge tracing models mostly focus on assessed learning resources, ignoring the non-assessed ones. In the assessed learning resource types, such as quizzes and assignments, students' performance can be evaluated given their answers and solutions. These kinds of learning resources provide a window to student knowledge through observing their performance. Conversely, in the non-assessed learning resources, such as readings and video lectures, such an observation does not exist. Hence, evaluating student knowledge and performance while interacting with these learning resources is a difficult task [4, 11, 10].

Indeed, because current knowledge tracing approaches do not model non-assessed learning resources, identifying their underlying concepts, finding the similarities between these learning resources, and in general domain knowledge modeling for such non-assessed learning materials is still a challenging problem. That is, many modern knowledge tracing models do not rely on a predefined domain knowledge model, such as a Q-matrix, and can identify the "latent concepts" that are being evaluated in problems, quizzes, or assignments [20, 23, 21, 7, 9]. This is particularly useful when annotating learning materials with their concepts is expensive or infeasible. However, discovering such latent concepts in non-assessed learning resources is an under-explored research area. Some recent works have aimed in identifying such latent concepts [19] and similarities [17] between assessed and non-assessed learning materials. However, their findings were according to static student performance, ignoring the sequential learning data of students.

In this paper, we argue that modeling non-assessed learning materials is essential and non-dispensable in tracing student knowledge. Students learn from all types of activities and ignoring a large portion of student activities is a missed opportunity in student knowledge tracing. Especially that previous research has shown that working with various learning activity types has considerable benefits for student learning [15, 2, 1, 12]. Hence, modeling both assessed and non-assessed learning activities should result in a more accurate estimation of student knowledge state and prediction of their performance on future assessed learning resources.

Accordingly, we propose Deep Multi-type Knowledge Trac-

Chunpai Wang, Siqian Zhao and Shaghayegh Sahebi "Learning from Non-Assessed Resources: Deep Multi-Type Knowledge Tracing". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 195-205. https://educationaldatamining.org/edm2021/

ing (DMKT) model, which not only traces student knowledge states over various learning activity types but also provides a feasible solution to discovering underlying patterns or concepts for both assessed and non-assessed learning resources. To this end, DMKT estimates student knowledge gain between every two consecutive assessed learning activities according to student performance on them. At the same time, it distributes this estimated knowledge gain among the in-between non-assessed learning activities and the latest assessed activity. We use an attention mechanism for this distribution. As a result, DMKT can model the underlying latent concepts for each of the assessed and non-assessed learning resources, evaluate student knowledge after interacting with these learning resources and predict student performance on the assessed ones.

We evaluate our proposed model on four real-world datasets, showing the significant effect of modeling various learning resource types on the task of student performance prediction. Also, we showcase the interpretability of DMKT by visualizing student knowledge while working with various learning resource types. Finally, we demonstrate the power of DMKT in discovering the learning resources' similarities and underlying latent concepts.

2. RELATED WORK

Student knowledge tracing aims to capture the student's knowledge state and knowledge state transition patterns, which could be further used for tasks like students' performance prediction, intelligent curriculum design, and interpretation and discovery of structure in student tasks.

Traditional knowledge tracing methods modeled knowledge transition on assessed learning resources using predefined domain knowledge models (concepts of learning resources). For example, Drasgow et al. proposed IRT that leverages the structured logistic regression to model student's dichotomous responses and estimates the student's ability, learning resource difficulty [8]. BKT uses binary variables for modeling whether student acquires a concept or not, and a Hidden Markov Model is used to update the probability that student answers a question correctly [6, 22]. However, since annotating a domain knowledge model can be expensive and time consuming, in many real-world scenarios, such predefined domain knowledge models are not be provided. To solve this problem, new approaches turn to investigate modeling student knowledge and domain knowledge at the same time. For example, Lan et al. utilized the matrix factorization to model the student knowledge and concept-question association, assuming the sparse association between concepts and questions [14]. As another example, Doan et al. model student learning with a tensor factorization in which the student knowledge is having an increasing trend using a rank-based constraint [7].

At the same time, in the past few years with the advance of deep neural networks, deep knowledge tracing methods have emerged. For example, DKT [18] utilizes LSTM to model students' knowledge transition over time. Recently, transformer-based neural networks have been successfully applied to model the different knowledge transitions of different students' historical interactions on learning resources [5, 9]. SAKT [16] uses the self-attention mechanism to model the interdependencies among interactions on the sequence. In [23], Zhang et al. proposed a Dynamic Key-Value Memory Networks based method (DKVMN), which integrates the memory augmented neural networks with the attention mechanism, to exploit the relationships between underlying concepts for better students' skill acquisition modeling. Yeung et al. extended DKVMN, by integrating the one-parameter logistic item response theory to provide better interpretability [21]. However, none of the deep knowledge tracing models have focused on modeling the non-assessed learning activities and tracing student knowledge on such activities.

Knowledge Tracing using Multiple Learning Resource Types. Previous approaches ignored the effect of learning activities on non-assessed learning resources, none of the methods mentioned above consider both assessed and non-assessed learning resources at the same time. However, in reality, students not only learn from practicing assessed learning resources (such as questions) but also learn by studying the non-assessed one, such as watching video lectures, reading textbooks, and discussing with others. One reason for not modeling the non-assessed activities is that reliable student performance observations are missing in these activities. This makes modeling the knowledge transition from these non-assessed learning activities difficult. To the best of our knowledge, the only existing work that models non-assessed learning activities along with the assessed ones is Multi-View Knowledge Model (MVKM) [25]. MVKM models multiple learning resources jointly using tensor factorization to capture latent students' features and latent learning resource concepts, assuming that latent concepts are shared by different learning resource types. However, this method can only capture the linear dependencies between variables, as the latent students' features and latent learning resource concepts are multiplied via linear matrix and tensor products. On the other hand, due to the large memory cost of tensor factorization, MVKM can not handle the datasets with very large student and learning resource numbers. Unlike MVKM, our proposed method in this paper considers the non-linear relationships between variables, and handles large datasets, while modeling student knowledge gain from multiple learning resource types (both assessed and non-assessed).

3. DEEP MULTI-TYPE KNOWLEDGE TRACING (DMKT)

3.1 Problem Formulation

A standard knowledge tracing (KT) problem is to predict student performance or response on an upcoming question, given the learner's performance records on previously solved questions. These records typically consist of a sequence of questions and responses at each discrete time step, denoted as a tuple (q_t^s, r_t^s) for student s at time step t. Since we only discuss how to predict future performance for a single student, we omit the superscript s in the following sections. Therefore, given students' past history records up to time $t-1$ as $\{(q_1, r_1), \cdots, (q_{t-1}, r_{t-1})\}$, the goal of KT is to predict their response r_t to question question q_t at the current time step t.

In this paper, we aim to incorporate students' non-assessed

learning activities and model student knowledge transition over both assessed and non-assessed learning resources, such as solving quizzes, watching video lectures, viewing annotated examples or hints, and participating discussion forums. Therefore, given student's past historical responses to assessed learning materials as well as past history of non-assessed learning activities, we would like to estimate student knowledge and predict their performance in the next assessed learning resource. To do this, assuming L distinct non-assessed learning resources and Q distinct assessed ones, we represent students' historical records up to time $t-1$ as $\{(q_1, r_1), \mathcal{L}_1, (q_2, r_2), \mathcal{L}_2, \cdots, (q_{t-1}, r_{t-1}), \mathcal{L}_{t-1}\}$, in which $\mathcal{L}_t = \{l_t^1, l_t^2, \cdots, ...l_t^n\}$ at each time step t denotes the sequence of n non-assessed learning activities (e.g., watching video lectures) between the assessed activities (e.g., answering questions) q_t and q_{t+1}. Our goal is to predict student performance on assessed learning material q_t at each time step t, model student knowledge at and between time steps in interaction with q_t and all l_t^is, and discover the underlying latent concepts of assessed qs and non-assessed l^is.

3.2 The Base Model

We base our DMKT model upon a recent successful deep knowledge tracing model: DKVMN [23]. DKVMN is a special type of memory-augmented neural networks (MANN) for knowledge tracing which has one static key matrix to store the knowledge concepts and one dynamic value matrix to store students' updated mastery levels of those corresponding concepts. Assuming that there are N latent concepts $\{c^1, \cdots, c^N\}$ for each learning resource, and each latent concept can be represented by d_h-dimensional embeddings, similar to DKVMN, DMKT has the key matrix $\mathbf{M}^k$ of size $N \times d_h$ to store the N knowledge concepts. Similarly, the value matrix $\mathbf{M}_t^v$ of size $N \times d_h$ stores the student's mastery levels of each concept, at time step t.

However, DKVMN only supports updating knowledge states $\mathbf{M}_t^v$ on assessed learning materials, and lacks the ability to leverage the abundant of data other than student responses on assessed learning materials. To overcome this limitation, our proposed DMKT updates $\mathbf{M}_t^v$ with an additional internal component that employs the attention mechanism to process the non-assessed learning activities between any two assessed ones and use the updated $\mathbf{M}_t^v$ to predict student's performance on upcoming assessed learning resource. This component contains two functionalities, one is to update student knowledge state on non-assessed learning activities, and another is to summarize all activity contexts before an assessed activity to help accurate prediction of student performance.

One may think that a straightforward solution to integrate the non-assessed learning resources would be to consider them as student interaction features. However, since the non-assessed learning activities are not explicitly represented in such models, their contribution to student knowledge could be assessed. Also, such an approach cannot model student's knowledge transition between different non-assessed learning activities. In the following, we introduce our novel updating and summarizing functionalities that help DMKT to model all learning activity types. An overview of DMKT's architecture can be found in Figure 1[1].

3.3 Learning Resource Attention Weights

For the simplicity of illustration, let us assume that there is only one non-assessed learning activity, e.g., watching a video lecture, between solving two problems q_{t-1} and q_t, that is $\mathcal{L}_{t-1} = \{l_{t-1}\}$. DMKT assumes that student knowledge gets updated as the student interacts with l_{t-1} and q_t, weighted by their corresponding attention weights. So, in each step, DMKT uses attention weights from q_t and l_{t-1} to update the student knowledge in the concepts' embeddings, $\mathbf{M}_t^v$.

To compute the attention weights, DMKT first embeds all questions into an embedding matrix $\mathbf{A}^q \in \mathbb{R}^{Q \times d_h}$, and all video lectures in another embedding matrix $\mathbf{A}^l \in \mathbb{R}^{L \times d_h}$. At each time step, DMKT extracts the embedding vector of q_t ($\mathbf{k}_t \in \mathbb{R}^{d_h}$) from $\mathbf{A}^q$, as well as the embedding vector $\mathbf{k}_{t-1}^l \in \mathbb{R}^{d_h}$ of l_{t-1} from $\mathbf{A}^l$. Then, it uses these embedding vectors to query the key memory matrix $\mathbf{M}^k$ to obtain the attention weights $w_t^q(i)$ and $w_t^l(i)$ respectively as follows:

$$w_t^q(i) = \text{Softmax}\left(\mathbf{k}_t^{q\top} \mathbf{M}^k(i)\right) \tag{1}$$

$$w_{t-1}^l(i) = \text{Softmax}\left({\mathbf{k}_{t-1}^l}^{\top} \mathbf{M}^k(i)\right) \tag{2}$$

The attention weight in $\mathbf{w}_t^q$ and $\mathbf{w}_{t-1}^l$ can be viewed as respectively the correlation between question q_t and lecture l_{t-1} with each of the N latent concepts. Notice that, $w_t^q(i)$ and $w_{t-1}^l(i)$ are the i-th element in the attention weight vectors $\mathbf{w}_t^q$ and $\mathbf{w}_{t-1}^l$ respectively, and for interpretability purposes the attention weights sum to one ($\sum_{i=1}^N w_t^q(i) = \sum_{i=1}^N w_{t-1}^l(i) = 1$).

3.4 Student Performance Prediction

At each time step t, DMKT aims to predict the student's performance on q_t. Since the predicted performance is a result of student knowledge that is gained by interacting with both problems and lectures, it is intuitive to aggregate these knowledge gains and predict the student performance accordingly. Remember that the memory value matrix $\mathbf{M}_t^v \in \mathbf{R}^{N \times d_h}$ is used to represent student's knowledge state on each concept embedding. So, to summarize the student's mastery level of question q_t and lecture l_{t-1} in the N concepts, we compute the weighted sum of all memory slots in the value matrix using attention weight vectors $\mathbf{w}_t^q$ and $\mathbf{w}_{t-1}^l$, respectively.

$$\mathbf{r}_t^q = \sum_{i=1}^{N} w_t^q(i) \mathbf{M}_t^v(i) \tag{3}$$

$$\mathbf{r}_{t-1}^l = \sum_{i=1}^{N} w_{t-1}^l(i) \mathbf{M}_t^v(i) \tag{4}$$

Then, we concatenate the latent knowledge states or mastery levels $\mathbf{r}_t^q$ and $\mathbf{r}_{t-1}^l$ on question q_t and lecture l_{t-1} with question embedding $\mathbf{k}_t^q$ as well as lecture embedding $\mathbf{k}_{t-1}^l$

[1]The source code is provided at: `https://github.com/persai-lab/EDM2021-DMKT`

vertically and pass them into a fully connected layer with a Tanh activation to obtain a summary vector $\mathbf{f}_t$

$$\mathbf{f}_t = \text{Tanh}\left(\mathbf{W}_1^\top \left[\mathbf{r}_t^q, \mathbf{r}_{t-1}^l, \mathbf{k}_t^q, \mathbf{k}_{t-1}^l\right] + \mathbf{b}_1\right) \tag{5}$$

where $[\cdot]$ denotes concatenation. This summary vector $\mathbf{f}_t$ contains a summary of all information, such as student ability and the relationship between question q_t and lecture l_{t-1}, to predict student response at time t accurately. Finally, the student's performance in query question q_t is calculated by passing the feature vector $\mathbf{f}_t$ through another fully connected layer with a Sigmoid activation as follows:

$$p_t = \text{Sigmoid}\left(\mathbf{W}_2^\top \mathbf{f}_t + \mathbf{b}_2\right) \tag{6}$$

3.5 Student Knowledge Update

DMKT tracks the student knowledge states by updating the memory value matrix $\mathbf{M}_t^v$ after each learning activity on q_t and l_t so as to predict student performance on q_{t+1} using the updated $\mathbf{M}_{t+1}^v$.

For assessed learning activities, we first retrieve an embedding vector of (q_t, r_t), denoted by $\mathbf{v}_t^q \in \mathbb{R}^{d_h}$, from a response embedding matrix $\mathbf{B}$ of size $2Q \times d_h$. This embedding $\mathbf{v}_t$ contains the information about how much student knowledge should be updated after working on question q_t with outcome r_t^q. We also use the *erase-followed-by-add* mechanism to update the memory value matrix, that is to erase the memory first using erase vector $\mathbf{e}_t^q \in [0,1]^{d_h}$ before adding new information with the add vector $\mathbf{a}_t^q \in \mathbb{R}^{d_h}$. This update of each value memory slot could be summarized as an erase step and an add step as follows:

Erase Step:

$$\begin{aligned} \mathbf{e}_t^q &= \text{Sigmoid}\left(\mathbf{E}^\top \mathbf{v}_t^q + \mathbf{b}_\mathbf{e}^q\right) \\ \tilde{\mathbf{M}}_t^v(i) &= \mathbf{M}_{t-1}^v(i) \otimes [\mathbf{1} - w_t^q(i)\mathbf{e}_t^q] \end{aligned} \tag{7}$$

Add Step:

$$\begin{aligned} \mathbf{a}_t^q &= \text{Tanh}\left(\mathbf{D}^\top \mathbf{v}_t^q + \mathbf{b}_\mathbf{a}^q\right)^T \\ \mathbf{M}_t^v(i) &= \tilde{\mathbf{M}}_{t-1}^v(i) + w_t^q(i)\mathbf{a}_t^q \end{aligned} \tag{8}$$

where $\mathbf{1}$ is a vector of all ones, and $\otimes$ represents the element-wise multiplication.

For each non-assessed activity, we follow a similar erase-followed-by-add steps in Eq.(7) and Eq.(8), except that we use $\mathbf{k}_t^l$ directly instead of a new response embedding.

Erase Step on Non-assessed Resources:

$$\begin{aligned} \mathbf{e}_t^l &= \text{Sigmoid}\left(\mathbf{H}^\top \mathbf{k}_t^l + \mathbf{b}_\mathbf{e}^l\right) \\ \tilde{\mathbf{M}}_t^v(i) &= \mathbf{M}_{t-1}^v(i) \otimes \left[\mathbf{1} - w_t^l(i)\mathbf{e}_t^l\right] \end{aligned} \tag{9}$$

Add Step on Non-assessed Resources:

$$\begin{aligned} \mathbf{a}_t^l &= \text{Tanh}\left(\mathbf{G}^\top \mathbf{k}_t^l + \mathbf{b}_\mathbf{a}^l\right)^T \\ \mathbf{M}_t^v(i) &= \tilde{\mathbf{M}}_{t-1}^v(i) + w_t^l(i)\mathbf{a}_t^l \end{aligned} \tag{10}$$

3.6 Network Architecture and Extension

The neural network architecture of DMKT is shown in Figure 1. For illustration simplicity, this figure assumes that there is only one non-assessed learning resource l_t between q_t and q_{t+1}. This architecture mainly contains two components: *read* component for making a prediction on input question q_t and *write* component for updating the value matrix after interacting with l_t and q_t.

When there are multiple non-assessed learning activities between q_t and q_{t+1}, that is $\mathcal{L}_t = \{l_t^1, \cdots, l_t^n\}$, we can simply extend the model by looping over each activity to generate $\mathbf{k}_t^{l^i}$ as well as $\mathbf{r}_t^{l^i}$ using equation (4) for $i \in \{1, \cdots, n\}$. When making predictions, we use $\sum_{i=1}^n \mathbf{k}_t^{l^i}$ to represent $\mathbf{k}_t^l$ and $\sum_{i=1}^n \mathbf{r}_t^{l^i}$ to represent $\mathbf{r}_t^l$ in the architecture. When updating the knowledge, the value matrix is updated sequentially over all activities as described in the previous subsection.

3.7 Training

All learnable parameters , i.e. $\mathbf{A}^q, \mathbf{A}^l, \mathbf{B}$, in the entire DMKT model are trained in end-to-end manner by minimizing the binary cross-entropy loss of all students' assessed responses, i.e.,

$$\ell_{BCE} = -\sum_t \left(o_t \log p_t + (1 - o_t) \log (1 - p_t)\right) \tag{11}$$

where o_t denotes the observation of correctness on assessed response at time t and p_t denotes the prediction of correctness of DMKT at time t.

3.8 Knowledge State Calculation

DMKT is capable of tracing and depicting knowledge concept mastery level for each student. A student's knowledge state before each assessed or non-assessed learning activity can be obtained in the *read* process using the following steps.

Assume that there are N dummy query questions q^is, each of them only using one concept, for the purpose of knowledge state calculation. Each of dummy questions can obtain a designed embedding $\mathbf{k}^i$ such that the correlation weight vector $\mathbf{w}^i$ is "one-hotted", that is $\mathbf{w}^i = [0, \cdots, w_i, \cdots, 0]$ where w_i of concept c^i is equal to 1. Then, we can use each of these one-hot correlation weight vectors to access value matrix state on each slot $\mathbf{M}_t^v(i)$ to obtain $\mathbf{r}_t^i$ for each concept c^i. In other words, $\mathbf{r}_t^i = \mathbf{M}_t^v(i)$ for q^i.

Then, we can predict the student knowledge purely based on $\mathbf{r}_t^i$ by masking the weight of the input content embedding in Eq. (5), which ends up as:

$$\mathbf{f}_t^i = \text{Tanh}\left(\left[\mathbf{W}_1^{r^i}, \mathbf{0}, \mathbf{0}, \mathbf{0}\right]^\top \left[\mathbf{r}_t^i, \mathbf{r}_{t-1}^l, \mathbf{k}_t^i, \mathbf{k}_{t-1}^l\right] + \mathbf{b}_1\right) \tag{12}$$

where $\mathbf{W}_1$ is split into four parts including $\mathbf{W}_1^{r^i}$, $\mathbf{W}_1^{k^i} = \mathbf{0}$, $\mathbf{W}_1^{r^l} = \mathbf{0}$, and $\mathbf{W}_1^{k^l} = \mathbf{0}$. Finally, a scalar value p^i is output as in Eq.(6) to be the predictive mastery level of concept c^i. We repeat this process N times with N numbers of one-hot correlation weight vectors to obtain student's knowledge state vector with size $1 \times N$ after each learning activity.

4. EXPERIMENTS

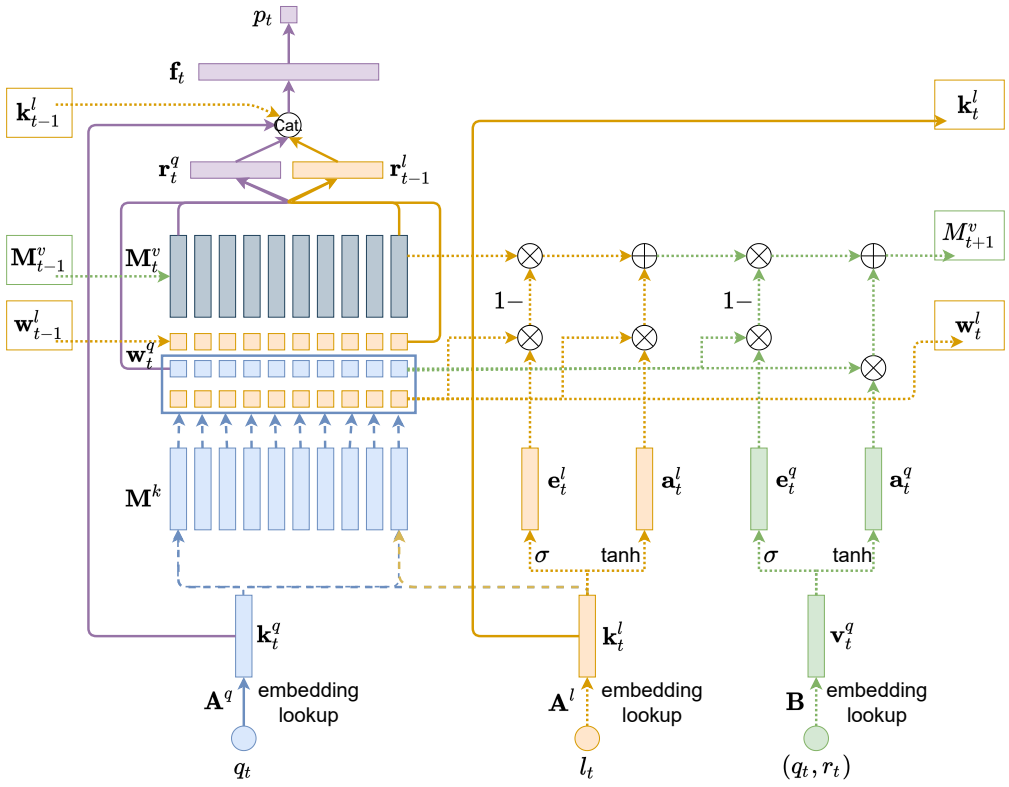

Figure 1: Neural Network Architecture of DMKT.

To evaluate our proposed model, we conduct three kinds of experiments. First, we compare it with state-of-the-art baselines in the student performance prediction task. Second, we analyze the discovered student knowledge transition patterns in terms of assessed and non-assessed learning activities. Last but not least, we validate the non-assessed learning resources' latent concepts discovered by the proposed method.

4.1 Datasets

We use three real-world datasets to evaluate the proposed model:

MORF[2] is an open online course dataset from Coursera [3]. In this course, students can watch lecture videos and work on problems. Each problem is a full complex course assignment. These video lectures and assignments are published in sequential order in this dataset, but students can have multiple attempts on each assignment and watch any video at any time. Students' scores are normalized into $[0, 1]$.

EdNet[3] is collected by Santa[4], a multi-platform AI tutoring service for students to prepare TOEIC English testing. We use the problem explanation documents as the non-assessed learning resources. There are $297,915$ user records in the full dataset, and we randomly extract $1,000$ users' records for experiments.

Junyi[5] is a dataset that comes from a Chinese e-learning website. Students work on problems from 8 math areas. Each problem has several hints, students can request hints when solving problems. We consider the problems as the assessed learning resources and the associated problem hints as the non-assessed learning resources. There are $25,925,922$ records in total from $247,606$ users in the full dataset. We extract two subsets of this full dataset for experiments. One is called Junyi2063, which contains 2063 users' records on 3760 questions and 1432 hints. A smaller dataset named Junyi1564, which consists of 1564 users' records on 142 questions and 116 hints, is extracted to serve the purpose of visualization on concept discovery results. The descriptive statistics of these four datasets are shown in the table 1.

4.2 Baseline Methods

In experiments of performance prediction, we compare with 13 baseline methods on the task of student performance prediction on assessed learning resources, including six state-of-the-art deep learning based knowledge tracing models, one existing tensor factorization based knowledge tracing model supporting multiple learning resource types, and seven extended deep learning based models utilizing non-assessed learning resources as additional input features. These methods are:

Table 1: Descriptive Statistics of 3 Datasets.

Dataset	Users	Questions	Question Records	Mean Question Responses	STD Question Responses	Correct Question Responses	Incorrect Question Responses	Non-gradable Materials	Non-gradable Records
MORF	686	10	12031	0.7763	0.2507	N/A	N/A	52	41980
EdNet	1000	11249	200931	N/A	N/A	118767	82184	8324	150821
Junyi1564	1564	142	120984	N/A	N/A	86654	34328	116	16389
Junyi2063	2063	3760	290754	N/A	N/A	193664	97090	1432	69050

- DKT [18]: is a pioneer deep learning based knowledge tracing method that uses LSTM to model students' knowledge transition over time.
- DKVMN [23]: is a variant of memory augmented neural networks that model the latent knowledge concept and dynamic student knowledge state over time.
- DeepIRT [21]: is an extension of DKVMN that integrates the one parameter logistic item response theory (1PL-IRT) to provide better interpretability, which could reduce the overfitting issue.
- SAKT [16]: is an attention-based method that leverages the self-attention mechanism to model the interdependencies among interactions on the sequence.
- SAINT [5]: is a transformer-based deep knowledge tracing method, two multi-head attention mechanisms are used to model exercise and response separately.
- AKT [9]: is a variant of transformer-based deep knowledge tracing method that using a monotonic attention mechanism to model the different knowledge transition of students' each historical performance on questions.

In addition to those baselines that support assessed learning materials, we also compare our method with some baselines that either can leverage additional students' non-assessed learning activities by design, or we modify them to consider such non-assessed activities as features of the assessed ones and predict students' future performance. These methods are:

- MLP-M: is a simple multi-layer perceptron that could take query question ID, user ID, and user's 3 past historical records on current query question, as well as 3 most recent non-assessed learning activities as input, and output a probability of user's mastery level on query question.
- DKT-M [24]: is an enhanced DKT model that could incorporate additional question features by concatenating the feature embeddings with exercise response embedding as the input of vanilla DKT.
- SAINT-M [5]: is a variant of SAINT that summing over all embeddings of non-gradable activities along with position encoding as the input of SAINT.
- MVKM [25]: is state of the art method on modeling student knowledge transition over multiple learning resource types based on multiview tensor factorization.

Inspired by the DKT-M [24], we apply the same strategy to DKVMN to incorporate additional non-assessed learning activities as features to end up with method DKVMN-M. Also, inspired by the way of SAINT-M [5] to incorporate rich features into transformer-based model, we apply same strategy as described in the paper into SAKT and AKT to incorporate additional non-assessed learning activities as response features that ends up with baseline methods SAKT-M and AKT-M, respectively.

4.3 Implementation Details

For binary response datasets, including EdNet and Junyi datasets, we convert the response tuple (q_t, r_t) into a single value $z = q_t + r_t \times Q \in \{1, \cdots 2Q\}$ as the lookup key of embedding layer. For numerical response MORF dataset, we feed the tuple (q_t, r_t) into a linear layer to get the embedding. For the question q_t and non-assessed learning resource l_t, we feed their ID into the embedding layers.

For evaluation purpose, we perform the 5-fold user stratified cross-validation for all models and all datasets. Hence, for each fold, 60% users are used as the training set, 20% are validation set, and the rest 20% as test set. For each fold and every method, we use the validation set to tune the hyper-parameters and record the optimal training loss as the condition of early stopping.

We utilize the Gaussian distribution with 0 mean and 0.2 standard deviation to initialize the values of $\mathbf{M}^k$ and $\mathbf{M}_0^v$. We learn the model using the Adam optimization with a learning rate of 0.01 and reduce the learning rate by half once the training loss increases, with the minimal learning $1e$-5 for all methods in 200 max epochs. We also utilize the norm clipping threshold to 50.0 to avoid gradient exploding for all methods. In addition, we follow the general processing steps for knowledge tracing that truncate long sequence and pad short sequence with 0s. The length of sequence is considered as a hyper-parameter of all models which needs to tune. In addition, we also tune the max sequence length of non-assessed learning activities between two assessed learning activities $\mathcal{L}_t$. If the length of non-assessed learning activities is over the maximum size, then we take the most recent ones. Similarly, if the length is less than the required sequence length, we pad with 0s. The table 2 shows the best hyper-parameters of our DMKT on 4 datasets.

We implement the models using PyTorch on a computer with a single NVIDIA Tesla-K80 GPU. For DKT and DKT-M, our implementation is different from the original paper [18], and we follow the same idea suggested by [23] that use norm clipping and early stopping, which could ease the gradient exploding as well as overfitting issues of LSTM. Xavier

Table 2: Hyperparameters of DMKT

Dataset	d_h	N	seq. len.	$\lvert\mathcal{L}_t\rvert$
MORF	128	8	50	8
EdNet	128	8	50	2
Junyi1564	256	8	50	2
Junyi2063	256	32	50	2

initialization is also used to initialize the parameters in DKT and DKT-M. All the baseline methods are implemented in PyTorch and tested to achieve similar performance as reported in the original paper except the SAINT ans SAINT-M. For SAINT, we borrow the implementation from github[6] and extend it to the SAINT-M, since the authors did not release the code.

4.4 Student Performance Prediction

The results of predicting students' performance in the assessed learning resources, including their 95-percentile confidence intervals, are shown in Table 3. The RMSE is measured to evaluate the prediction performance on MORF dataset due to numerical user responses, and the AUC is measured on EdNet and Junyi datasets. A low RMSE score indicates a high prediction performance. An AUC of 0.5 represents the model's performance is equivalent to a random guess model. A high AUC score accounts for a high prediction performance. As you can see, our proposed method, DMKT, achieves the best performance over all baseline methods on all four datasets. This shows that explicitly modeling non-assessed learning materials, along with the assessed ones, is essential in capturing the variations in student performance data.

We can also see that by simply incorporating the non-assessed activities between two assessed activities as additional input features (the "-M" models) the prediction performance is improved in some methods, such as AKT-M on MORF, EdNet, and Junyi datasets. However, unlike attention-based methods which could learn interaction correlation in a long sequence, this kind of simple integration strategy does not improve and may harm the prediction performance in other methods, such as in DKT-M and DKVMN-M, which tend to summarize past historical records as context embeddings. The reason we believe is this trivial integration of non-assessed activities not only loses a large amount of sequential information to model student knowledge transition over time, but also could introduce more noisiness on the data. We conclude that *simply adding the non-assessed learning activities as features, without modeling them explicitly is not enough and may even harm the prediction performance in some models.*

SAINT and SAINT-M have transformer based architecture, which can stack multiple encoders and decoders. However, in our EdNet dataset that contains only $1,000$ users with $200,931$ records on $11,249$ questions, and without additional constraints or regularization as proposed in AKT (another transformer based model), SAINT and SAINT-M can easily overfit the data. MVKM is the only existing baseline method that can explicitly model multiple learning resource types. We can see that it can outperform the deep knowledge tracing methods that uses non-assessed learning materials as features in MORF, which is a mid-size datasets. However, it cannot efficiently run in the larger datasets as the memory usage and linear time complexity over number of interaction records in MVKM limits its applicability on large datasets, such as EdNet and Junyi. Therefore, due to long running time on EdNet and Junyi datasets, we only report its performance in the MORF dataset.

It is worth noting that when our model is fed with assessed learning resources only, it will be equivalent to DKVMN. However, as presented in the table, our proposed model DMKT achieves a better performance over DKVMN as well as DKVMN-M, because DMKT explicitly models the student knowledge transition on non-assessed learning activities, which provides a more accurate encoded information to make the predictions accurately.

4.5 Student Knowledge State Visualization

To see how intractable the discovered student knowledge states are, we visualize the students' knowledge states. Basically, knowledge state visualization shows student's knowledge mastery level on each concept before each attempt on a non-assessed or an assessed learning activity. This provides a useful tool to monitor student knowledge coverage over different concepts and helps instructors to analyze the student's lacking concepts so as to provide tailored instructions for each student. To visualize student knowledge states, we follow the steps in section 3.8 to calculate knowledge state values over all concepts across the student sequence for each student. We show visualization of one example student's knowledge states in the MORF dataset in figure 2. As you can see in the figure, the top x-ticks are labeled with student learning activities. Assessed learning materials (assignments) start with A and non-assessed ones (lecture videos) are annotated by the week they are scheduled and the sequence of video lecture within the week. For example W4V0 means the student has watched week 4 video lecture 0 and A1B denotes the Assignment-1B in week 1. The bottom x-ticks are labeled by either student performance (grade) in the assessed learning materials, or an icon indicating the non-assessed learning resource type. Each row represents one latent concept. In the figure, this student starts with a randomly initialized value memory matrix $\mathbf{M}_0^t$ at time step 0 before working on $A1B$. After finishing the A1B, student's knowledge is updated and increased a little on concept 3 and 6 before working on A3. Student's knowledge grows gradually by working on assignments $A3$ and watching video lectures in week 4. However, student's knowledge drops a little before working on assignment $A4$ and it explains the reason why that student only receives a score 0.3 at the first attempt. Student's knowledge on all concepts grow by working on the assignments until the student started watching video lecture $W6V1$. We can see a slight drop in student's knowledge of some of the concepts (e.g., 7) and increase in other concepts (e.g., 1) while they are watching these videos. One potential reason for the decrease on concept 7 could be the lack of practice with assignments. Watching video lectures indeed improve student knowledge on concept 1 and 2. Another reason for the drop in concept 7 could be related to the student's problem solving ability which results

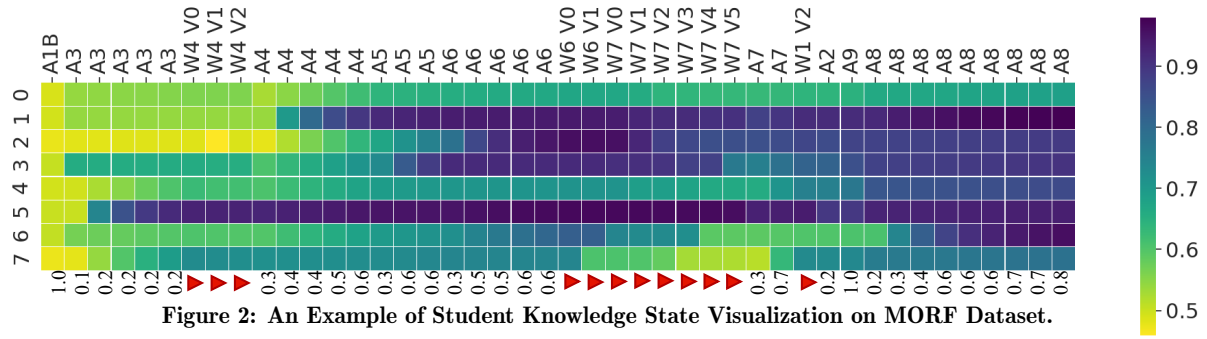

Figure 2: An Example of Student Knowledge State Visualization on MORF Dataset.

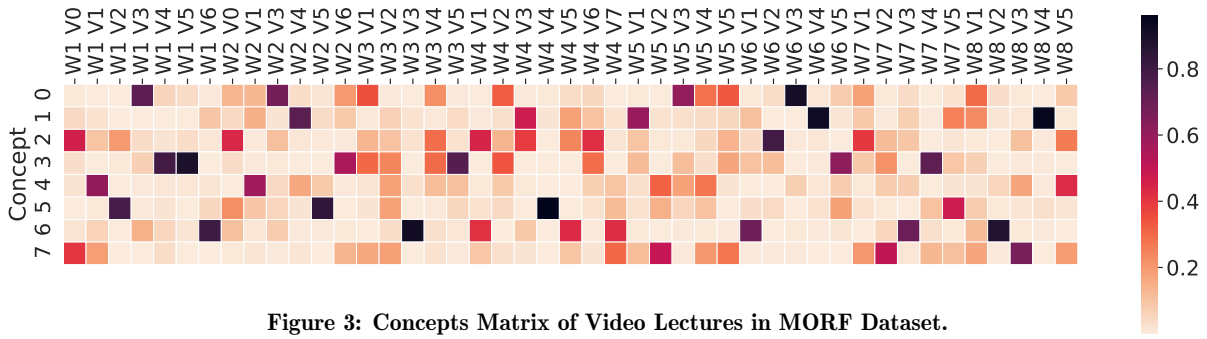

Figure 3: Concepts Matrix of Video Lectures in MORF Dataset.

in their first attempt on Assignment $A7$ to have a score of 0.3. Once the student's first attempt on $A7$ is done, this student quickly masters concept 7 again and their knowledge on all concepts continues to grow along different activities. In this example, it seems *the assessed learning material improves student knowledge more than watching video lectures, which is inline with the previous literature* [10, 13]. Another observation is that this student skips watching video lectures in weeks 1, 2, and 3 before working on assignment $A3$. Similarly, they did not watch videos in week 5 and 6 before trying $A5$ and $A6$. This may explain that this student is not interested in watching video lectures and may not be fully present during watching video lectures which results in tiny knowledge growth over watching them.

4.6 Concept Discovery

In addition to tracing student knowledge over various types of learning activities, DMKT can provide a feasible solution to discovering underlying patterns or concepts for both assessed and non-assessed learning resources. In other words, the correlation weights $\mathbf{w}$ and $\mathbf{w}^l$, can be interpreted as the importance of latent concepts in each assessed, and non-assessed learning activity respectively. Meaning that, since the key matrix $\mathbf{M}^k$ is used to model the knowledge concepts on the full course, the correlation weight between the learning resources and the concepts implies the strength of

their inner relationship. *Not only we can use the correlation weight as latent concepts, we can also use them to find similar learning resources by clustering them over these correlation weights.*

For example, in Figure 3, we visualize the importance of each concept in each of the MORF dataset video lectures. The X-axis ticks show the video lecture weeks and numbers and the Y-axis shows the latent concepts. *As we can see, the concept matrix is relatively sparse, showing that most video lectures strongly belong to 2-3 concepts, while they do have a soft memberships in other concepts too. Many video lectures in the same week have similar concept structures.* For example videos 3, 4, and 5 of week 5 all have a strong representation of concept 0 and videos 0, 1, and 2 of week 1 all are having high correlation weights with concept 2. Given that the course schedule is designed by the instructor, such similarities between the concepts in videos of the same week are expected. *Another interesting observation is the strong appearance of some concepts in videos of different weeks.* For example, concept 1 can be seen in both video 4 of week 8 and video 4 of week 6. This shows that these two video lec-

tures share some similarities that are not represented in class schedule. Looking at the video titles from this course (right-hand side of Figure 5) we can see that the video titles are *State Space Diagrams* and *Hidden Markov Models*, respectively, which are two very closely-related topics To better understand such similarities, we look at grouping of videos according to their discovered concepts in the following.

To this end, we follow the clustering procedures as in [23] to group the learning materials according to the discovered latent concepts. At the same time, we compare these groupings by looking at the problem name associated with each hints and lecture titles for Junyi1564 and MORF datasets in Figures 4 and 5, respectively. To do the clustering, we first assign each learning resource with the concept ID that contains the largest correlation weight as the cluster label. Since there are 8 concepts in total, it results in 8 clusters. Then, we use t-SNE to visualize the clusters, which are shown in the left sides of Figures 4 and 5 for Junyi1564 and MORF datasets, respectively.

As we can see, the resulting t-SNE clusters are more distinct in the Junyi1564 dataset compared to MORF. *In other words, most of clusters in Junyi1564 dataset could be easily separated and distinguished. This implies that the discovered concept matrix of the Junyi1564 dataset is more sparse than the one from the MORF dataset, leading to more outstanding clusters than in MORF, as shown in Figure 4.* Indeed we have seen from Figure 3 that each video lecture in MORF is associated with two to three latent concepts rather than having only one distinct concept. This finding matches these datasets' properties: in the MORF dataset, each assessed learning material is a full complex course problem set which is assigned to students every week, and each non-assessed learning resource is a video lecture that covers multiple knowledge concepts. On the contrary, the assessed learning materials in Junyi1564 dataset are simple math problems, with close-to atomic concept coverage, and the non-assessed resources are hints associated with these problems.

As another result of this clustering, and similar to our findings in Figure 3, we can see that *the more similar or related non-assessed learning materials are clustered together*. For example, in Figure 5, video lectures from week 5 are clustered together, showcasing the similarity between latent concepts in video lectures that are scheduled to be presented together in week 5 of the course. Additionally, video lectures that are conceptually similar to each other can be found grouped together. For example, video lectures from week 6 (*V4 - State Space Diagrams*) and week 8 (*V4 - Hidden Markov Models*), from week 1 (*V2 - Regressors*) and week 7 (*V5 - Factor Analysis*), and from week 1 (V6 - Case Study - San Pedro) and week 8 (*V2 - Case Study - Discovery with models*) are grouped together which are conceptually similar.

These findings are also in accordance with the previous findings in the literature on the MORF dataset [25] and show that DMKT can efficiently discover the underlying concepts presented in the non-assessed learning materials, even though student performance on them is not observable.

5. CONCLUSION AND FUTURE WORK

In this paper, we proposed DMKT, the first deep learning based knowledge tracing model that can model and trace student knowledge in both assessed and non-assessed learning resources, find the underlying connects and similarities between learning resources, and predict student performance in the assessed ones. We evaluated DMKT extensively, on four real world datasets and demonstrated that because of its explicit modeling of non-assessed learning materials, its ability in representing non-linear relationships and its capacity in handling larger amounts of data, it outperforms all the baselines, in accurately predicting student performance. We further showcased DMKT's ability in meaningfully tracing student knowledge over assessed and non-assessed learning resources, and the potential effect that each of them can have on student knowledge. In our particular example, we showed that solving problems is a more effective way to learn for our selected student, compared to watching video lectures. Finally, we presented that DMKT can find interpretable latent concepts of non-assessed learning materials, that can be used to group them into meaningful clusters. In the future work, we would like to explore this model on various of learning activities to learn hidden patterns on different learning resources so as to provide tailored learning resource recommendations.

ABSTRACT

This paper drills deeper into the documented effects of the Cognitive Tutor Algebra I and ASSISTments intelligent tutoring systems by estimating their effects on specific problems. We start by describing a multilevel Rasch-type model that facilitates testing for differences in the effects between problems and precise problem-specific effect estimation without the need for multiple comparisons corrections. We find that the effects of both intelligent tutors vary between problems– the effects are positive for some, negative for others, and undeterminable for the rest. Next we explore hypotheses explaining why effects might be larger for some problems than for others. In the case of ASSISTments, there is no evidence that problems that are more closely related to students' work in the tutor displayed larger treatment effects.

Causal impact estimates,multilevel modeling,intelligent tutoring systems

1. INTRODUCTION: AVERAGE AND ITEM-SPECIFIC EFFECTS

The past decade has seen increasing evidence of the effectiveness of intelligent tutoring systems (ITS) in supporting student learning [7][13]. However, surprisingly little detail is known about these effects such as which students experience the biggest benefits, under what conditions. This paper will focus on the question of which areas of learning had the largest impact in two different year-long randomized trials: of the Cognitive Tutor Algebra I curriculum (CTA1) [17] and of the ASSISTments ITS [22].

Large-scale efficacy or effectiveness trials in education research, including evaluations of ITS [17][18][22], often estimate the effect of an educational intervention on student scores on a standardized test. These tests consist of many items, each of which tests student abilities in, potentially, a separate set of skills. Prior to estimating program effects, analysts collapse data across items into student scores, often using item response theory models [25] that measure both item- and student-level parameters. Then, these student scores are compared between students assigned to the intervention group and those assigned to control.

This approach has its advantages, in terms of simplicity and (at least after aggregating item data into test scores) model-free causal identification. If each item is a measurement of one underlying latent construct (such as "algebra ability") aggregating items into test scores yields efficiency gains. However, in the (quite plausible) case that posttest items actually measure different skills, and the impact of the ITS varies from skill to skill, item-specific impacts can be quite informative.

In the case of CTA1 and ASSISTments, we find that, indeed, the ITS affect student performance differently on different posttest items, though at this stage it is unclear why the affects differed.

The following section gives an overview of the two large-scale ITS evaluations we will discuss, including a discussion of the available data and of the two posttests. Next, Section 3 will discuss the Bayesian multilevel model we use to estimate item-specific effects, including a discussion of multiple comparisons; Section 4 will discuss the results—estimates of how the two ITS impacted different posttest items differently; Section 5 will present a preliminary exploration of some hypotheses as to why ASSISTments may have impacted different skills differently; and Section 6 will conclude.

2. THE CTA1 AND ASSISTMENTS TRIALS

This paper uses data from two large-scale field trials of ITSs CTA1 and ASSISTments. The CTA1 intervention consisted of a complete curriculum, combining the Cognitive Tutor ITS, along with a student-centered classroom curriculum. CTA1 was a created and run by Carnegie Learning; an up-

dated version of the ITS is now known as Mathia. The Cognitive Tutor is described in more detail in [2] and elsewhere, and the effectiveness trial is described in [17]. ASSISTments is a free online-homework platform, hosted by Worcester Polytechnic Institute, that combines electronic versions of textbook problems, including on-demand hints and immediate feedback, with bespoke mastery-based problem sets known as "skill builders." ASSISTments is described in [10] and the efficacy trial is described in [22].

This section describes the essential aspects of the field trials and the data that we will use in the rest of the paper.

2.1 The CTA1 Effectiveness Trial

From 2007 to 2010, the RAND Corporation conducted a randomized controlled trial to compare the effectiveness of the CTA1 curriculum to business as usual (BaU). The study tested CTA1 under authentic, natural conditions, i.e., oversight and support of CTA1's use was the same as it would have been if there was not a study being conducted. Nearly 20,000 students in 70 high schools ($n = 13,316$ students) and 76 middle schools ($n = 5,938$) located in 52 diverse school districts in seven states participated in the study. Participating students in Algebra I classrooms took an algebra I pretest and a posttest, both from the CTB/McGraw-Hill Acuity series.

Schools were blocked into pairs prior to randomization, based on a set baseline, school-level covariates, and within each pair, one school was assigned to the CTA1 arm and the other to BaU. In the treatment schools, students taking algebra I were supposed to use the CTA1 curriculum, including the Cognitive Tutor software; of course, the extent of compliance varied widely [12][11].

Results from the first and second year of the study were reported separately for middle and high schools. In the first year, the estimated treatment effect was close to zero in middle schools and slightly negative in high schools. However, the 95% confidence intervals for both these results included negative, null, and positive effects. In the second year, the estimated treatment effect was positive–roughly one fifth of a standard deviation—for both middle and high schools, but it was only statistically significant in the high school stratum.

In this study, we make use of students' overall scores on the pretest, anonymized student, teacher, school, and randomization block IDs, and an indicator variable for whether each student's school was assigned to the CTA1 or BaU, along with item-level posttest data: whether each student answered each posttest item correctly. For the purposes of this study, skipped items were considered incorrect.

2.1.1 Posttest: The Algebra Proficiency Exam

The RAND CTA1 study measured the algebra I learning over the course of the year using the McGraw-Hill Algebra Proficiency Exam (APE). This was a multiple choice standardized test with 32 items testing a mix of algebra and pre-algebra skills. Table 1, categorizes the test's items by the algebra skills they require, and gives an example of a problem that would fall into each category. The categorization was taken from the exam's technical report [6].

2.2 The Maine ASSISTments Trial

From 2012–2014, SRI International conducted an randomized field trial in the state of Maine to estimate the efficacy of ASSISTments in improving 7th grade mathematics achievement. Forty-five middle schools from across the state of Maine were randomly assigned between two conditions: 23 middle schools were assigned to a treatment condition; mathematics teachers in these schools were instructed to use ASSISTments to assign homework, receiving support and professional development while doing so. The remaining 22 schools in the BaU condition were barred from using ASSISTments during the course of the study but were offered the same resources and professional development as the treatment group after the study was over. The study was conducted in Maine due to the state's program of providing every student with a laptop, which allowed students to complete homework online.

The 45 participating schools were grouped into 21 pairs and one triplet based on school size and prior state standardized exam scores; one school in each pair, and two schools in the triplet, were assigned to the ASSISTments condition, with the remaining schools assigned to BaU. Subsequent to random assignment, one of the treatment schools dropped out of the study, but its matched pair did not. Although the study team continued to gather data from the now-unmatched control school, that data was not included in the study. However, we are currently unable to identify which of the control schools was excluded from the final data analysis, so the analysis here includes 44 schools, while [22] includes only 43.

The study measured student achievement on the standardized TerraNova math test at the end of the second year of implementation, and estimated a treatment effect of 0.18 ± 0.12 standard deviations.

In this study, we make use of anonymized student, teacher, school, and randomization block IDs, and an indicator variable for whether each student's school was assigned to the ASSISTments or BaU, along with item-level posttest data: whether each student answered each posttest item correctly. For the purposes of this study, skipped items were considered incorrect. The initial evaluation included a number of student-level baseline covariates drawn from Maine's state longitudinal data system, include prior state standardized test scores. We do not currently have access to that data; the only covariate available was an indicator of whether each student was classified as special education.

2.3 The TerraNova Test

The primary outcome of the ASSISTments Maine trial was students' scores on the TerraNova Common Core assessment mathematics test, published by Data Recognition Corporation CTB. The TerraNova assessment includes 37 items, 32 of which were multiple choice and 5 of which were open response. Unfortunately, we detected an anomaly in the item-level data for the open-response questions, so this report will focus only on the 32 multiple choice questions.

The items are supposed to align with the Common Core State Standards, but the research team was not given a document aligning CCSS with the test items. Instead, a

Objective	Items	Example
Functions and Graphs	6, 8, 19, 20, 22, 23, 27, 31, 32	Which of these points is on the graph of [function]
Geometry	12, 18, 24, 29	Find the length of the base of the right triangle shown below
Graphing Linear Equations	5, 9, 15, 17, 26	Which of the lines below is the graph of [linear equation]?
Quadratic Equations and Functions	2, 25, 28, 30	Which of these shows a correct factorization of [quadratic equation]?
Solving Linear Equations and Linear Inequalities	1, 4, 11, 13, 16	Solve the following system of equations
Variables, Expressions, Formulas	3, 7, 10, 14, 21	Which of these expressions is equivalent to the one below?

Table 1: Objectives required for the 32 items of the Algebra Proficiency Exam, the posttest for the CTA1 Evaluation

member of the ASSISTments staff with expertise in middle school education aligned them according to her best judgment. Table 2 gives this alignment. More information on specific standards can be found at the CCSS website [16].

3. METHODOLOGY: MULTILEVEL EFFECTS MODELING

In principal estimating program effects on each posttest item is straightforward: the same model used to estimate effects on student overall scores could be used to estimate effects on each item individually (perhaps—but not necessarily—adapted for a binary response). However, estimating 32 separate models for each stratum of the CTA1 study, and 32 separate models for the ASSISTments study ignores multilevel structure of the dataset, and leads to imprecise estimates. Moreover, doing so invites problems of multiple comparisons—between the four strata of the CTA1 study and the ASSISTments study, there are 160 separate effects to estimate. If each estimate is subjected to a null hypothesis test at level $\alpha = 0.05$, even if neither ITS affected test performance at all, we would still expect to find roughly eight significant effects.

Instead, we estimated item-specific effects with a multilevel logistic regression model model [8], based roughly on the classic "Rasch" model of item response theory [25][20]. That is, we estimated all item-specific effects for a particular experiment simultaneously, with one model, in which the item-specific effect estimates are random effects. The separate effects were modeled as if drawn from a normal distribution with a mean and standard deviation estimated from the data. This normal distribution can be thought of as a Bayesian prior distribution; the fact that its parameters are estimated from the data puts us in the realm of empirical Bayes [5]. This prior distribution acts as a regularizer, shrinking the several item-specific effect estimates towards their mean [15]. Although doing so incurs a small amount of bias, it reduces standard errors considerably while maintaining the nominal coverage of confidence intervals [23].

Gelman, Hill, and Masanao [9] argue that estimating a set of different treatment effects within a multilevel model also obviates the need for multiplicity corrections. Generally speaking, the reason for spurious significant results is that as a group of estimates gets larger, so does the probability that one of them will exceed the test's critical value. In other words, as a the set of estimates grows, so does their maximum (and their minimum, in magnitude). Multilevel modeling helps by shrinking the most extreme estimates towards their common mean. Since extreme values are less likely in a multilevel model, so are spuriously significant effect estimates.

A small simulation study in the Appendix (mostly) supports Gelman et al.'s argument. As the number of estimated effects grows, the familywise error rate (i.e. the probability of *any* type-I error in a group of tests) grows rapidly if effects are estimated and tested separately, but not if they are estimated simultaneously in a multilevel model. However, the error rates for the multilevel model effect estimates are slightly elevated—hovering between 0.05 and 0.075 throughout. There is good reason to believe that a fully Bayesian approach will improve these further (see, e.g., [21], p. 425).

3.1 The Model for the CTA1 Posttest

For the CTA1 RCT, we estimated a separate model for high school and middle school, but we combined outcome data across the two years. Let $Y_{ij} = 1$ if student i answered item j correctly, and let $\pi_{ij} = Pr(Y_{ij} = 1)$. Then the multilevel logistic model was:

$$\begin{aligned} logit(\pi_{ij}) &= \beta_0 + \beta_1 Year2_i + \beta_2 Trt_i + \beta_3 Pretest_i \\ &+ \beta_4 Year2_i Trt_i + \beta_5 Year2_i Pretest_i \\ &+ \gamma_{j0} + \gamma_{j1} Trt_i + \gamma_{j2} Year2_i + \gamma_{j3} Year2_i Trt_i \\ &+ \delta_i + \eta_{cls[i]} + \epsilon_{sch[i]} \end{aligned} \quad (1)$$

Where $Year2_i = 1$ if student i was in the 2nd year of the study and 0 otherwise, $Trt_i = 1$ if student i was in a school assigned to treatment, and $Pretest_i$ is i's pretest score. The coefficients β_0–β_5 are "fixed effects," that is, they are not given any probability model. γ_{j0}–γ_{j3} vary with posttest item j, and are modeled jointly as multivariate normal: $\boldsymbol{\gamma} \sim MVN(\mathbf{0}, \Sigma)$, where Σ is a 4×4 covariance matrix for the γ terms. Similarly, the random intercepts δ_i, $\eta_{cls[i]}$, and $\epsilon_{sch[i]}$, which vary at the student, classroom, and school level, are each modeled as univariate normal with mean 0 and a standard deviation estimated from the data.

Collecting like terms in model (1), note that for a student in the first year of the study, the effect of assignment to the CTA1 condition is $\beta_2 + \gamma_{j1}$ on the logit scale; in other words, the effects of assignment to CTA1 in year 1 are mod-

eled as normal with a mean of β_2 and a variance of Σ_{22}. The variance Σ_{22} estimates the extent to which the effect of assignment to the CTA1 condition varies from one problem to another. If the effect were the same for every posttest problem, we would have $\Sigma_{22} = 0$. For students year 2, the effect on problem j is $\beta_2 + \beta_4 + \gamma_{j1} + \gamma_{j3}$ on the logit scale—the effects are normally distributed with a mean of $\beta_2 + \beta_4$ and a variance of $\Sigma_{22} + \Sigma_{44} + 2\Sigma_{24}$. The Σ matrix also includes the covariance between the effects of the intervention on items in year 1 and the effects on the same items in year 2 as

$$Cov(\gamma_{j1}, \gamma_{j1} + \gamma_{j3}) = Var(\gamma_{j1}) + Cov(\gamma_{j1}, \gamma_{j3}) = \Sigma_{22} + \Sigma_{23}$$

Likelihood ratio tests using the χ^2 distribution can test the null hypothesis that the variance of treatment effects are 0. For simplicity, we did so using separate models for the two years, rather than the combined model (1).

The treatment effects themselves are estimated using the BLUPs (best linear unbiased predictors) for the random effects $\boldsymbol{\gamma}$. In many contexts, random effects are considered nuisance parameters, and primary interest is in the fixed (unmodeled) effects $\boldsymbol{\beta}$. However, there is a long tradition, mostly in the Bayesian and empirical Bayes literature, of using BLUPs for estimation of quantities of interest. The models were fit in `R` [19] using the `lme4` package [3], which provides empirical Bayesian estimates of the conditional (or posterior) variance of the BLUPs, which we use (in combination with the estimated standard errors for fixed effects) in constructing confidence intervals for item-specific effects.

3.2 The Model for the ASSISTments Posttest

The model for estimating item-specific effect of ASSISTments on TerraNova items was highly similar to model (1). There were three important differences: first, there was only one year of data. Second, we did not have access to pretest scores, but we did include an indicator for special education status as a covariate. Lastly, the hierarchical variance structure for student errors was somewhat different—we included an error term for teacher instead of classroom, and included random intercepts for randomization block.[1]

[1]In linear models it is typically recommended to include fixed effects for randomization block [4]. In logistic regression, including a large number of fixed effects violates the assumptions underlying the asymptotic [1]. We tried it both ways and found that it made little difference.

All in all, the model was:

$$\begin{aligned} logit(\pi_{ij}) &= \beta_0 + \beta_1 Trt_i + \beta_2 SpEd_i \\ &+ \gamma_{j0} + \gamma_{j1} Trt_i \\ &+ \delta_i + \eta_{tch[i]} + \epsilon_{sch[i]} + \zeta_{pair[i]} \end{aligned} \quad (2)$$

where $SpEd_i = 1$ if student i is classified as needing special education, $\eta_{tch[i]}$ is a random intercept for i's teacher, and $\zeta_{pair[i]}$ is a random intercept for i's school's randomization block. The rest of the parameters and variables are defined the same as in (1). The treatment effect on problem j is modeled as $\beta_1 + \gamma_{j1}$ for multiple choice items. The random effects $\boldsymbol{\gamma} \sim N(\mathbf{0}, \Sigma)$ where Σ is a 2×2 covariance matrix.

4. MAIN RESULTS: ON WHICH ITEMS DID ITSS BOOST PERFORMANCE?

4.1 CTA1

Figure 1 gives the results from model (1) fit to the middle school and to the high school sample. Each point on the plot represents the estimated effect of assignment to the CTA1 condition on the log odds of a correct answer on one posttest item. The estimates are accompanied by approximate 95% confidence intervals.

It is immediately clear that the effect of assignment to CT vary between posttest items–indeed the χ^2 likelihood ratio test rejects the null hypothesis of no treatment effect variance with $p < 0.001$ in all four strata.

In the middle school sample, the average treatment effect across items was close to 0 for both years (-0.08 in year 1 and 0.03 in year 2 on the logit scale), and not statistically significant. However, the standard deviation of treatment effects between problems was much higher—0.31 in year 1 and 0.29 in year 2, implying that assignment to CTA1 boosted performance on some problems and hurt performance on others. To interpret the standard deviation of effects on the probability scale, consider that for a marginal student, with a 1/2 probability of answering an item correctly, a difference of 0.3 between two treatment effects would correspond to a difference in the probability of a correct answer of about 7.5% (using the "divide by 4 rule" of [8] p. 82). The effects are also moderately correlated across the two years, with $\rho \approx 0.4$—items that CTA1 impacted in year 1 were somewhat likely to be similarly impacted in year 2.

Many of the treatment effects in the upper pane of Figure 1 are estimated with too much noise to draw strong

Figure 1: Estimated treatment effects of CTA1 for each level—high school or middle school—implementation year, and posttest item, with approximate 95% confidence intervals

conclusions—the sample size was substantially smaller in the middle school stratum than in the high school stratum. However, some effects are discernible: in year 1, effects were negative, and on the order of roughly 0.4 on the logit scale (0.1 on the probability scale for a marginal student) on items 1, 2, 9, 10, 12, 19, 22, and 25, and on the order of approximately 0.7 for item 17 (which asks students to match a linear equation to its graph), and similarly-sized positive effects on items 27, 30, and 32. In year 2 there were fewer clearly negative effects—on items 1 and 7—and more positive effects, such as on items 16, 18, 22, 29, and 32. There is a striking difference between the year 1 and year 2 effects on item 22, which asks students to match a quadratic expression to its graph—the effect was quite negative in year 2 and quite positive in year 2.

In the high school sample, the average treatment effect across items was roughly -0.1 in year 1 and 0.13 in year 2, on the logit scale, neither statistically significant–though the difference between the average effect in the two years was significant ($p < 0.001$). The effects varied across items, though less widely in high school than in middle school—in both years the standard deviation of item-specific effects was roughly 0.17. Item-specific effects were more highly correlated across years ($\rho \approx 0.69$)—at some points in the lower pane of Figure 1 it appears as though the curve from year 2 was simply shifted up from year 1.

The item-specific effects in the high school sample were estimated with substantially more precision than in the middle school sample, due to a larger sample size. In year 1, there were striking negative effects on items 2, 14, and 25 which ask students to manipulate algebraic expressions, and on item 12, which ask students to calculate the length of the side of a triangle. In year 2, these negative effects disappeared. Instead, there were positive effects, especially on items 8 and 22, which both ask about graphs of algebraic functions, and on a stretch of items from 15–22. The difference in the estimated effects between years was positive for all items and highest for problems 2, 20, and 25, which ask students to manipulate or interpret algebraic expressions, and 12, the triangle problem. In items 2, 12, and 25, the effect was significantly negative in year 1 and closer to zero in year 2, while for item 20 the effect was close to zero in year 1 and positive in year 2.

Figure 2 plots the estimated effect on each posttest item as a function of the item's objective in Table 1. Some patterns are notable. There was a wide variance in the effects on the four geometry problems for middle schoolers in year 1, but in year 2 all the effects on geometry items were positive and roughly the same size. The geometry items in the high school sample follow a similar, if less extreme, pattern. Across both middle and high school, the largest positive effects were for Functions and Graphs problems, especially item 22 for year 2; on items 23, 27, 31 and 32, middle schoolers—especially in year 2—saw positive effects while high schoolers saw effects near 0.

4.2 ASSISTments

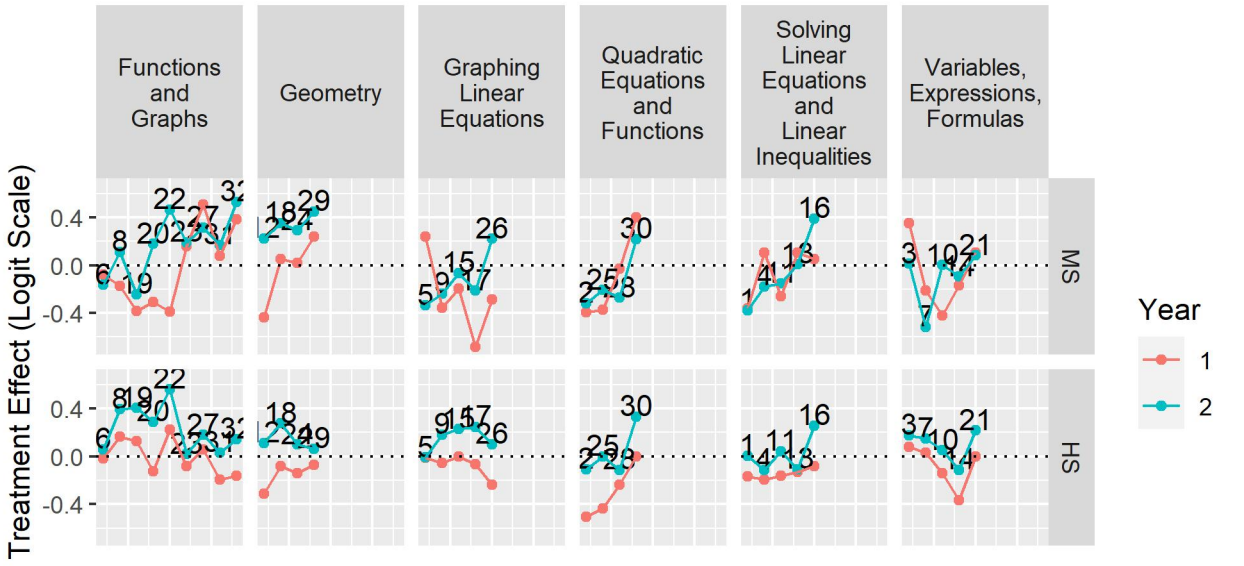

Figure 2: Estimated treatment effects of CTA1 posttest items arranged by the group of skills each item is designed to test. See Table 1 for more detail.

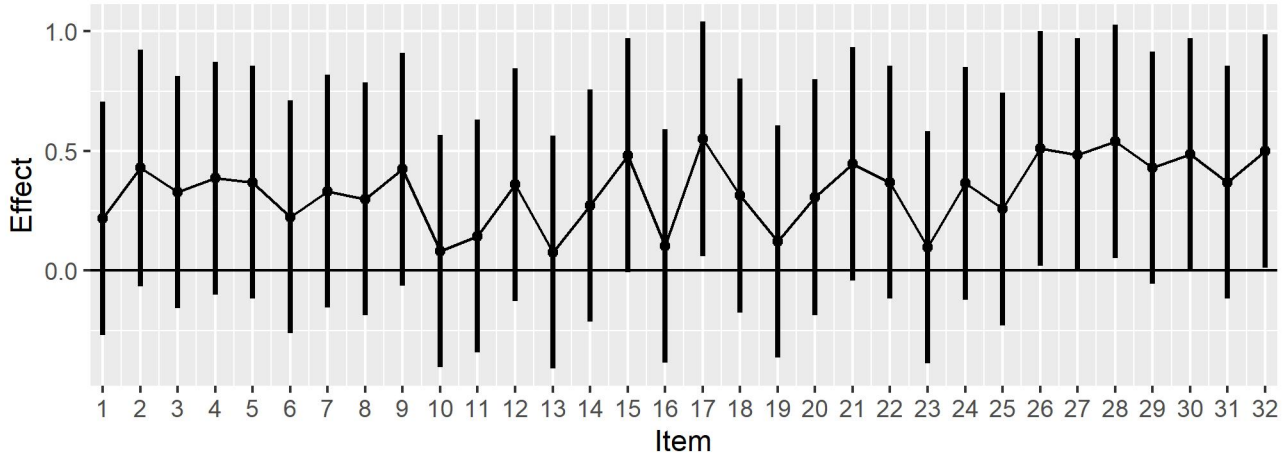

Figure 3: Estimated treatment effects of ASSISTments for each multiple choice posttest item, with approximate 95% confidence intervals

Figure 3 gives the results from model (2), plotting item-specific effect estimates with approximate 95% confidence intervals for each multiple choice TerraNova posttest item. The model estimated an average effect of 0.33, with a standard error of 0.23, for multiple choice problems. The standard deviation of item-specific effects was positive ($p<0.001$) but less than for the CTA1 items: it was estimated as 0.16 on the logit scale. The confidence intervals in Figure 3 are also much wider than those for CTA1; we suspect that a large part of the reason is that we did not have access to pretest scores, an important covariate.

The largest effects on the multiple choice items were 28 and 17, which both required students to plug in values for variables in algebraic expressions. The confidence intervals around the effects for items 26 and 32 also exclude 0.

Figure 4 plots item-specific effects for multiple choice TerraNova items grouped according to their CCSS, as in Table 2, with the non-grade-7 standards grouped together as "Other." Interestingly, the largest effects tended to be for items in this "Other" category—as did the smallest effect, for item 13. Effects for problems in the "Number System" and "Ratios and Proportional Relationships" categories had the most consistent effects, between 0.2 and 0.4 on the logit scale.

5. EXPLORING HYPOTHESES ABOUT *WHY* ASSISTMENTS EFFECTS DIFFERED

Researchers on the ASSISTments team have built on the CCSS links of Table 2, linking TerraNova posttest items to data on student work within ASSISTments, for students in the treatment condition. This gives us an opportunity to use student work within ASSISTments to explain some of the variance in treatment effects.

Like TerraNova items in Table 2, ASSISTments problems are linked with CCSS. By observing which problems treatment students worked on, and using this linkage, we could observe which Common Core standards they worked on the most within ASSISTments. We hypothesized that treatment effects might be largest for the TerraNova problems that were linked with the Common Core standards students spent the most time working on. In other words, we linked TerraNova items with worked ASSISTments problems *via* Common Core standards. The Common Core linkage we used in this segment was finer-grained than Table 2, so TerraNova items in the same category in Table 2 may not be linked with the same problems in this analysis.

We examined our hypothesis in two ways: examining the relationships between treatment effects and the number of related ASSISTments problems students in the treatment group worked, and the number of related ASSISTments problems students in the treatment group worked *correctly*. This analysis includes two important caveats: first, the linkages, both between TerraNova items and CCSS, and between ASSISTments problems and CCSS, were subjective and error-prone, possibly undermining the linkage between TerraNova items and ASSISTments problems. Secondly, student work in ASSISTments is necessarily a post-treatment variable—it was affected by treatment assignment. If the treatment randomization had fallen out differently, different schools would have been assigned to the ASSISTments condition and different ASSISTments problems would have been worked. Including the number of worked or correct related problems as a predictor in a causal model risks undermining causal interpretations [14].

Figures 5 and 6 plot estimated item-specific effects for multiple choice TerraNova items against the number of ASSISTments problems that students in the treatment arm worked or worked correctly, respectively, over the course of the RCT. The X-axis is on the square-root scale, and a loess curve is added for interpretation. Little, if any, relationship is apparent in either figure, suggesting either the lack of a relationship between specific ASSISTments work and posttest items, or issues with the linkage. This is hardly surprising, given both the difficulty in linking ASSISTments and TerraNova problems, and given the fact that topics in mathematics are inherently connected, so that improving one skill tends to improve others as well.

6. CONCLUSIONS

Education researchers are increasingly interested in "what works." However, the effectiveness of an intervention is necessarily multifaceted and complex—effects differ between students, as a function of implementation [24], and, potentially, as a function of time and location. In this paper we explored a different sort of treatment effect heterogeneity—differences in effectiveness for different outcomes—specifically, different posttest items measuring different skills. Collapsing item-level posttest data into a single test score has the advantage of simplicity (which is nothing to scoff at, especially in complex causal scenarios) but at a cost. Analysis using only summary test scores squanders a potentially rich source of variability and information about intervention effectiveness that is already at our fingertips. There is little reason *not* to examine item-specific effects.

In this paper, we showed how to estimate item specific effects using a Bayesian or empirical Bayesian multilevel modeling approach that, we argued, can improve estimation precision and avoid the need for multiplicity corrections. The estimates we provided here combine maximum likelihood estimation and empirical Bayesian inference; there is good reason to suppose that a fully Bayesian approach would provide greater validity, especially in standard error estimation and inference. However, fitting complex multilevel models using Markov Chain Monte Carlo methods is computationally expensive, and can be very slow, even with the latest software. We hope to explore this option more fully in future work.

While estimating item-specific effects is relatively straightforward, interpreting them presents a significant challenge. This is due to a number of factors: first, when looking for trends in treatment effects by problem attributes, the sample size is the number of exam items, not the number of students, so patterns can be hard to observe and verify. Secondly, there is a good deal of ambiguity and subjectivity involved in defining and determining item attributes and features, which is exacerbated by the fact that standardized tests generally cannot be made publicly available. Lastly, since student ITS work over the course of a study is necessarily post-treatment assignment, careful causal modeling (such as principal stratification [24]) may be necessary. Ex-

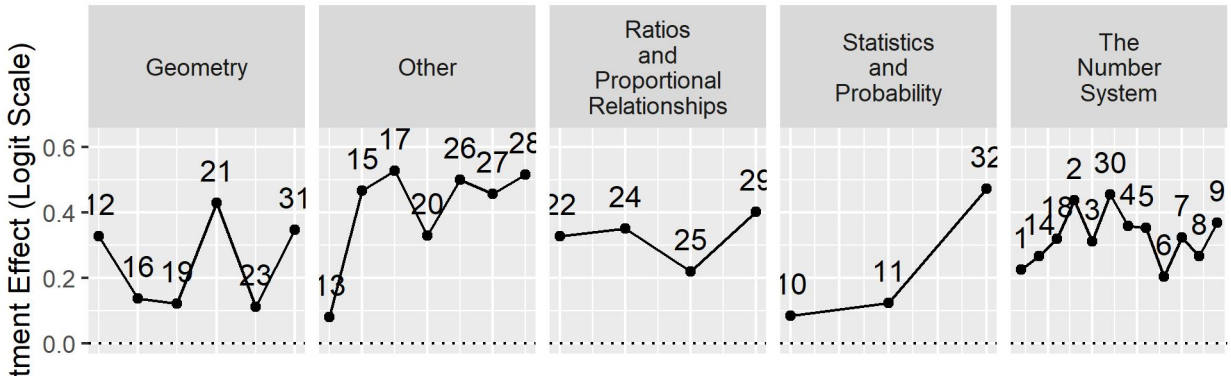

Figure 4: Estimated treatment effects of ASSISTments for each multiple choice posttest item, arranged according to CCSS, as in Table 2. The "Other" category includes Functions and the two Mathematical Practice standards, "make sense of problems and persevere in solving them" and "reason abstractly and quantitatively".

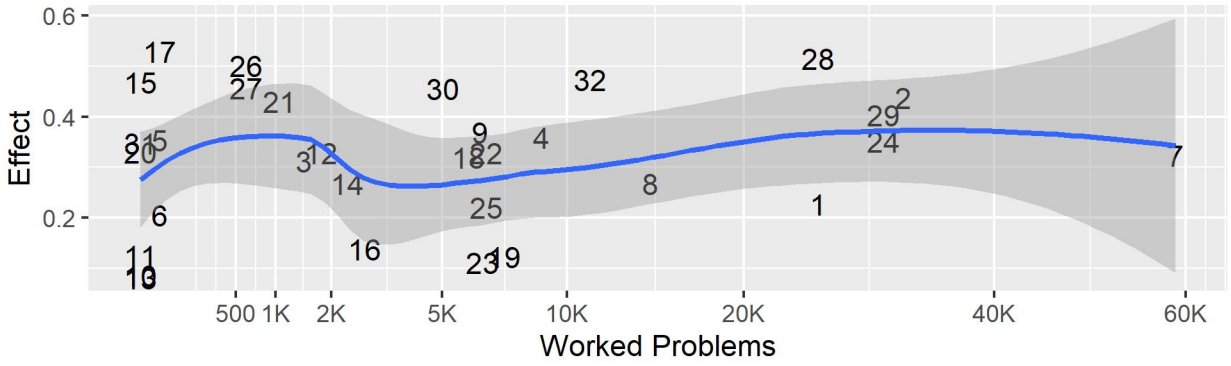

Figure 5: Estimated effects on multiple-choice TerraNova items plotted against the number of related ASSISTments problems that students in the treatment arm worked over the course of the study. The X-axis is plotted on the square-root scale, and a non-parametric loess fit is added for interpretation.

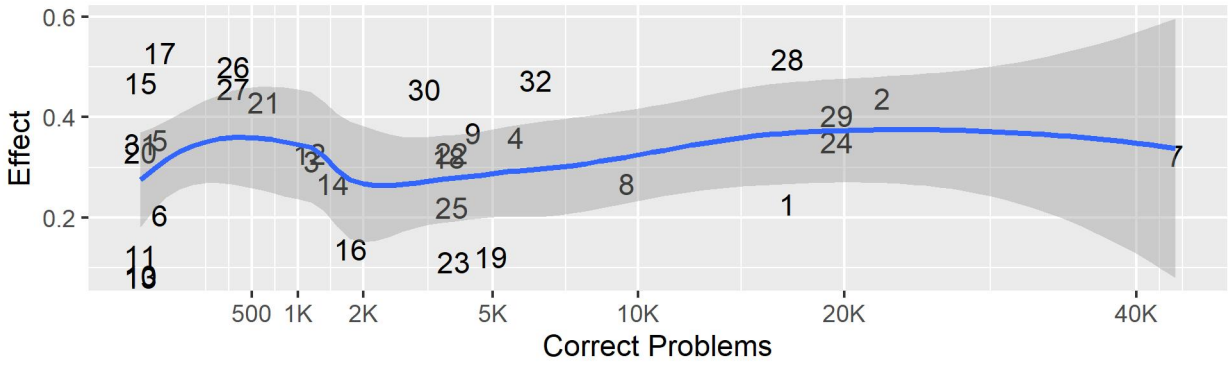

Figure 6: Estimated effects on multiple-choice TerraNova items plotted against the number of related ASSISTments problems that students in the treatment arm worked correctly over the course of the study. The X-axis is plotted on the square-root scale, and a non-parametric loess fit is added for interpretation.

amining heterogeneity between item-specific treatment effects may play a larger role in helping to generate hypotheses about ITS effectiveness than in confirming hypotheses.

Despite those difficulties, the analysis here uncovered important information about the CTA1 and ASSISTments effects. First, the discovery that the effects vary between items is notable in itself. In our analysis of CTA1 we noticed that some of the largest effects—and differences between first and second-year effects— were for posttest items involving manipulating algebraic expressions and interpreting graphs. In our analysis of ASSISTments, we discovered a large difference between negative effects on open-ended questions and positive effects on multiple choice questions, and also that the largest effects were on problems requiring students to plug numbers into algebraic expressions.

We hope that this research will serve as a proof-of-concept and spur further work delving deeper into data we already have.

APPENDIX

A. A SIMULATION STUDY OF MULTIPLE COMPARISONS

We ran a small simulation study testing [9]'s assertion that multiplicity corrections are unnecessary when estimating different effects from BLUPs in a multilevel model. [9] stated their case in terms of fully Bayesian models, whereas we used an empirical Bayesian approach that may differ somewhat.

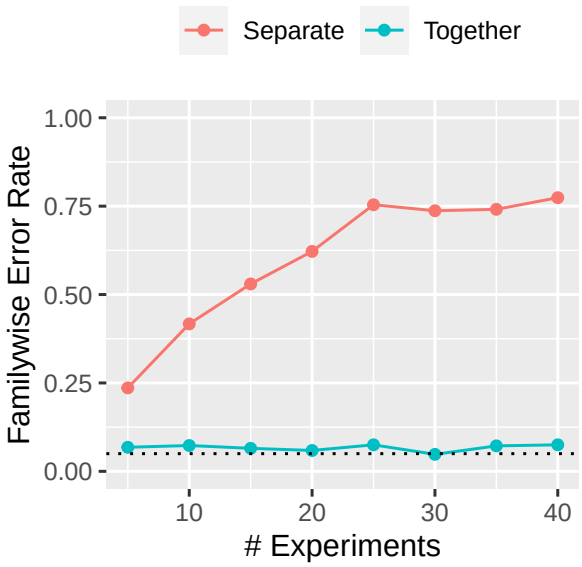

Figure 7: United we stand: results from a simulation of familywise error rate using separate t-tests for each experiment or using multilevel modeling.

In our simulation, in each simulation run, we generated data on $Nexpr$ experiments, where $Nexpr$ was a parameter we varied. In each experiment, there were $n = 500$ simulated subjects, half assigned to treatment and half to control. They were given "outcome" data $Y \sim N(0, 1)$, with no treatment effect.

We analyzed the experiment data in two ways. First, we estimated a p-value for each experiment separately, using t-tests. This is the conventional approach. Then, we we estimated a multilevel model:

$$Y_{ij} = \beta_0 + \gamma_{1j} Expr_j + \gamma_{2j} Trt_i + \epsilon_{ij}$$

where β_0 is an intercept, γ_{1j} are random intercepts for experiment, γ_{2j} is the treatment effect for experiment j, and ϵ_{ij} is a normally-distributed error term. $\boldsymbol{\gamma} \sim MVN\left(\{0, \gamma_{20}\}, \Sigma\right)$ where γ_{20} is the average effect across all experiments. The number of experiments in each simulation run, $Nexpr$, was varied from 5 to 40, in increments of 5. In each case, we estimated the familywise error rate, the probability of at least one statistically significant effect estimate (at $\alpha = 0.05$) across the $Nexpr$ experiments.

The results are in Figure 7. As expected, the familywise error rate increased rapidly when effects were estimated and tested separately in each of the $Nexpr$ experiments. When effects were estimated jointly in a multilevel model, in a way analogous to the method described in Section 3, the familywise error rate remained roughly constant as $Nexpr$ increased. However, the familywise error rate in the multilevel modeling approach was slightly elevated, ranging from roughly 0.05 to 0.075.

Math Operation Embeddings for Open-ended Solution Analysis and Feedback

Mengxue Zhang[1], Zichao Wang[2], Richard Baraniuk[2], Andrew Lan[1*]
[1]University of Massachusetts Amherst, [2]Rice University

ABSTRACT

Feedback on student answers and even during intermediate steps in their solutions to open-ended questions is an important element in math education. Such feedback can help students correct their errors and ultimately lead to improved learning outcomes. Most existing approaches for automated student solution analysis and feedback require manually constructing cognitive models and anticipating student errors for each question. This process requires significant human effort and does not scale to most questions used in homeworks and practices that do not come with this information. In this paper, we analyze students' step-by-step solution processes to equation solving questions in an attempt to scale up error diagnostics and feedback mechanisms developed for a small number of questions to a much larger number of questions. Leveraging a recent math expression encoding method, we represent each math operation applied in solution steps as a transition in the math embedding vector space. We use a dataset that contains student solution steps in the Cognitive Tutor system to learn implicit and explicit representations of math operations. We explore whether these representations can i) identify math operations a student intends to perform in each solution step, regardless of whether they did it correctly or not, and ii) select the appropriate feedback type for incorrect steps. Experimental results show that our learned math operation representations generalize well across different data distributions.

1. INTRODUCTION

Math education is of crucial importance to a competitive future science, technology, engineering, and mathematics (STEM) workforce since math knowledge and skills are required in many STEM subjects [11]. One important way to help struggling students improve in math is to diagnose errors from student answers to math questions and deliver personalized support to help them correct these errors [1]. In short-answer questions, feedback of various types [39] can be deployed according to the specific incorrect final answers students submit, while in open-ended questions, feedback can be deployed at intermediate solution steps according to the specific actions they take and their outcomes [22]. In traditional educational settings, this feedback process relies on teachers going over student work, identifying errors, and providing feedback [15], which results in a labor-intensive process and a slow feedback cycle for students. Such a setting is even more limited as a result of the COVID-19 pandemic, which introduced new barriers to face-to-face interactions between teachers and students.

In intelligent tutoring systems, a more scalable approach to math feedback is to automatically deploy feedback based on students' final answers or certain incorrect intermediate solution steps. For example, in ASSISTments [12], teachers can create hints and feedback messages for specific incorrect student answers to short-answer questions that they anticipate [28], which the system can automatically deploy when students submit these incorrect answers. This crowdsourcing approach efficiently scales up teachers' effort so that they can benefit a large number of students without putting in additional effort. In many other systems such as Cognitive Tutor [34] and Algebra Notepad [27], researchers use cognitive models to anticipate student errors as results of buggy production rules or insufficient knowledge on key math concepts [20, 24]. They then develop corresponding feedback for intermediate solution steps in multi-step questions (e.g., those on equation solving). This cognitive model-based approach requires significant effort by domain experts and has shown to be highly effective in large-scale studies.

However, these approaches for student feedback are still limited in their generalizability to many math questions deployed in daily homeworks and practices. For the teacher crowdsourcing approach, hint and feedback messages have to be written for each individual question (or group of questions generated from the same template with different numerical values). For the cognitive model-based approach, a rigorous solution process has to be specified for each question with annotations on the math operations that should be applied at each solution step. However, questions used in many real-world educational settings do not come with such information; teachers simply adopt them from sources

such as textbooks and open education resources and assign them to students without developing corresponding feedback mechanisms. Moreover, past research has shown that a large portion of incorrect student answers cannot be anticipated by cognitive models [43], teachers/domain experts [8], or numerical simulations [37]. Therefore, it may be hard for high-quality feedback developed for questions used in intelligent tutoring systems to generalize to questions in the wild.

1.1 Contributions

In this paper, we develop *data-driven* methods that enable us to analyze step-by-step solutions to open-ended math questions. In contrast to existing methods that rely on a *top-down* approach, i.e., defining the structure of the solution process and anticipating student errors, we propose a *bottom-up approach*, i.e., using learned representations of *math expressions* and *math operations* to predict i) math operations in student solution steps and ii) the appropriate feedback for incorrect solution steps. We restrict ourselves to the specific domain of *equation solving* where the solution process consists of applying specific math operations between math expressions in consecutive steps; other subdomains of math such as algebra word problems [45] and questions involving graphs and geometry [16] are left as future work. Specifically, our contributions are:

- First, we characterize math operations by how they *transform* math expressions in the math embedding space in each solution step. We leverage recent work on learning *math symbol embeddings* from large-scale scientific formula data [46] to encode math expressions in student solutions: each math expression is mapped to a point in the *math embedding vector space*. We use synthetically generated data as well as solution steps generated by real students to learn the representation of each math operation. We explore several methods for learning both implicit and explicit math operation representations: a classification-based method that does not explicitly impose a structure on math operations, a linear model that assumes each operation is characterized by an *additive vector* in the embedding space, and a nonlinear model where math operations live in their own, interconnected embedding spaces.
- Second, we apply these math operation representation learning methods to a real-world student step-by-step solution dataset collected while student learn equation solving in an intelligent tutoring system, Cognitive Tutor [34]. We validate our math operation representation learning methods via two tasks: i) predicting the specific math operation the student intended to apply in a solution step from the math expressions before and after the step and ii) predicting the appropriate feedback deployed to students from the incorrect math expressions they enter. Quantitative results show that tree embedding-based math expression encoding methods outperform other encoding methods since they are able to explicitly capture the semantic and structural characteristics of math expressions. They also have better generalizability across different data distributions and remain effective across different question difficulty levels and even when student solutions steps contain errors.

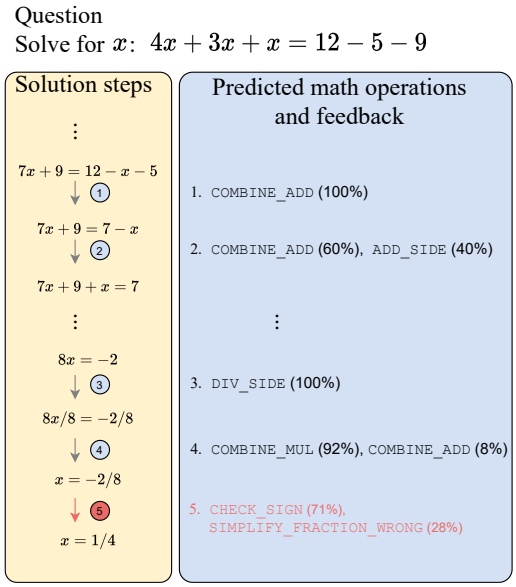

Figure 1. Demonstration of the generalizability of our math operation representations to other data sources for a solution process provided on Algebra.com. Our methods can successfully predict the math operations applied in each step and the appropriate feedback type in an incorrect step.

1.2 Use Case

Before diving into the technical details, we first illustrate a potential use case for our math operation representation learning methods and corresponding operation/feedback classifiers. Our goal is to transfer expert designs in intelligent tutoring systems for math education to questions in the wild. Specifically, we apply the math operation representations learned from student solution steps and corresponding labels (step name, feedback message) in the highly structured Cognitive Tutor system to environments that are not highly structured. Figure 1 shows the solution process to an equation solving question on Algebra.com[1] and the corresponding math operation and feedback predictions at each step. We see that our math operation representation learning methods can accurately predict the math operations applied in solution steps 1, 3, and 4 using the operation names provided in the Cognitive Tutor system. Even in step 2 where two different math operations are combined into a single step, i.e.,

$$
\begin{aligned}
&7x + 9 = 7 - x \\
&\downarrow \text{ADD } x \text{ TO BOTH SIDES} \\
&7x + 9 + x = 7 - x + x \\
&\downarrow \text{COMBINE TERMS ON RIGHT SIDE} \\
&7x + 9 + x = 7,
\end{aligned}
$$

despite only training on steps in Cognitive Tutor that involve only one math operation, the classifier is able to recognize both of them with high predictive probability for both. We

[1]The original question and the solution process can be found at `https://www.algebra.com/algebra/homework/equations/Equations.faq.question.4872.html`.

also change one of the solution steps, i.e., step 5, to make it incorrect and test our feedback classifier. In this case, the classifier is able to recognize the error in this step and find the corresponding feedback types in Cognitive Tutor. This potential use case demonstrates the utility of our math operation representation learning methods: by transferring knowledge learned in well-designed, highly-structured systems such as Cognitive Tutor, especially on what feedback to deploy for each student error, to other domains such as online math Q&A sites, we are *scaling up* the effort domain experts put into the design of these feedback mechanisms.

2. RELATED WORK

One related body of work in math education that studies student solution processes to identify student strategies and assess errors. Specifically, [33] uses inverse Bayesian planning to learn solution strategies (i.e., policies) in equation solving and capture student misunderstandings in a Markov decision process framework. Our work focuses on a different aspect of the solution process: the representation of the math expressions at each solution step and the modeling of the transitions between different math expressions under math operations. [9] uses basic math operations to construct programs to understand errors that students make in their solutions to arithmetic questions. Our work focuses on equation solving, which is a more difficult problem in which students responses are are more diverse and are less structured than arithmetic calculations.

Another related body of work focuses on learning representations of student answers to short-answer questions. [21] analyzes incorrect student answers across multiple questions, learn representations of errors, and generalize misconception feedback across questions. Our work analyze the full math expressions in intermediate solution steps while their work represents short answers according to the frequency they occur in an answer pool. [8] uses trained word embeddings to represent short answers for automated grading purposes. Our work focuses on learning transitions of math expressions across solution steps instead of learning representations of only the final answer.

In domains other than math education, there exist methods for automated feedback generation, including programming [30, 31, 40] and essays [35]. However, transferring these methods to math solutions is not trivial since i) open-ended math solutions are less structured than programming code and ii) data-driven representations of math symbols have not been developed until recently [46] whereas such representations have been studied for a long time in natural language processing [6, 7, 26].

Another body of remotely-related work focuses on using computer vision techniques to identify math expressions from images for similar math expression retrieval [29], turning hand-written math expressions into LaTeX [47], and automatically identifying and correcting student errors [14]. These works often bypass the inherent structure of math expressions and directly use an end-to-end model for their tasks, which means that they cannot be used to analyze student knowledge. Nevertheless, these techniques can be used to build large-scale datasets containing hand-written student solutions which we can use in the future.

3. BACKGROUND: EMBEDDING MATH EXPRESSIONS INTO VECTOR SPACES

In this section, we provide an overview of a recent method that we developed to embed math expressions into a vector space, i.e., a math embedding space. Doing so turns discrete, symbolic math expression representations into continuous, distributed representations [2], which enables us to manipulate math expressions in a manner compatible with modern machine learning methodologies.

Our embedding method is a *tree-structured* encoder illustrated in Figure 2. The key observation is that any math expression has a corresponding symbolic *tree-structured* representation in the *operator tree* format. In the operator tree, the non-terminal (non-leaf) nodes are math operators, i.e., addition and subtraction, and terminal (leaf) nodes are numbers or variables; See Figure 2 for an illustration. Thus, an operator tree explicitly captures the semantic and structural properties of a math expression. A number of existing works have demonstrated the superior performance of using operator tree representations of math expressions compared to other math expression representations in applications such as automatic math word problem solving [32, 48, 51] and math formulae retrieval [5, 25, 49, 50].

Therefore, we built a math expression encoder that leverages the operator tree representation of math expressions. Specifically, during the encoding process, it first converts a math expression into its corresponding tree format, using the parser introduced in [5]. It then linearizes the tree by depth first search that enables us to process nodes as a sequence in which each math symbol is associated with its own trainable embedding. Next, it leverages positional encoding, similar to [44, 38], to retain the relative position of each node in the tree. The output of our encoder is a fixed-dimensional embedding vector that represents the input math expression, which we will use to learn representations of math operations for the math operation classification and feedback prediction tasks. We pretrain the encoder on a large corpus of math expressions extracted from Wikipedia and arXiv articles and demonstrated superior performance in reconstructing math expressions (and scientific formulae) and retrieving similar expressions. See the anonymized version of our work at [46]. We will refer to the trained encoder as the *math expression encoding method* in what follows.

4. LEARNING REPRESENTATIONS OF MATH OPERATIONS

In this section, we detail methods we use to learn both implicit and explicit math operation representations by studying how they transform math expressions in each solution step in the math embedding space. In these methods, we leverage the math expression encoding method developed in our prior work that we reviewed above to embed math expressions into vectors and work with these embedding vectors. However, since these embeddings are trained on math expressions that are very different from those occurring in actual student solution steps, we use an additional trainable, fully-connected neural network to adapt these embeddings to our dataset, following a popular approach in natural language processing [13]. Specifically, we have $\mathbf{e} = g_{\boldsymbol{\gamma}}(\mathbf{m})$ where $\mathbf{m}$ and $\mathbf{e}$ are the embedded vector of a math expression

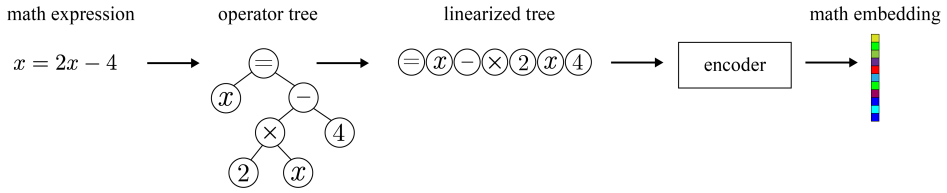

Figure 2. Illustration of the math expression encoding method that we employ in this work.

in our dataset before and after the adaptation, respectively. $\boldsymbol{\gamma}$ denotes the set of parameters in the fully-connected network that we will learn during the training process.

We define a step in a student's solution to open-ended math questions as a tuple $(\mathcal{E}_1, \mathcal{E}_2, z)$, where $z \in \mathbf{Z}$ is the math operation applied in this step, with $\mathcal{Z}$ denoting the set of possible math operations. $\mathcal{E}_1 \in \mathbf{E}$ and $\mathcal{E}_2 \in \mathbf{E}$ denote the math expressions involved in this step before and after applying this math operation, i.e., the step can be expressed as $\mathcal{E}_1 \xrightarrow{z} \mathcal{E}_2$. $\mathbf{E}$ denotes the set of all unique math expressions (across all steps in a dataset). For simplicity, we assume that only one math operation is applied in each step; an extension to cases where multiple math operations is trivial and will be discussed in what follows. $\mathbf{e}_1 \in \mathbb{R}^D$ and $\mathbf{e}_2 \in \mathbb{R}^D$ are the fine-tuned embedding vectors that correspond to math expressions $\mathcal{E}_1$ and $\mathcal{E}_2$, respectively, where D is the dimension of the embedding.

4.1 Math Operation Classification

The first task we will study in this paper is to classify the math operation applied in a solution step given the math expression embeddings before and after appliying it, $\mathbf{e}_1$ and $\mathbf{e}_2$. The same notations and approaches also apply to our second task, feedback classification. This task can simply be solved using a supervised learning method, e.g., a regression model where the predicted probability of predicting a math operation $\hat{z}$ is given by

$$p(\hat{z} = z) = \text{softmax}(\mathbf{v}_z^T[\mathbf{e}_1^T,\ \mathbf{e}_2^T]^T),$$

where softmax$(\cdot)$ is the softmax function for multi-label classification [10]. $\mathbf{v}_z$ is a parameter vector associated with each math operation z, which is used to compute an inner product with the concatenation of $\mathbf{e}_1$ and $\mathbf{e}_2$ before being fed into the softmax function. On a training dataset with given tuples $(\mathbf{e}_1, \mathbf{e}_2, z)$, we can learn the parameters $(\mathbf{v}_z)$ by minimizing the cross-entropy loss [10] between the predicted math operation $\hat{z}$ and the actual math operation. This approach can be seen as learning *implicit* representations of math expressions since they are captured by the classifier parameters.

4.2 Learning Math Operation Representations

The classification approach we detailed above can help us classify the math operation applied in a solution step but falls short on learning *explicit* representations of math operations. The latter is important, however, to help us understand students' math solution processes and diagnose their errors. We now detail a series of methods for us to learn explicit representations of math operations.

4.2.1 Translating embeddings

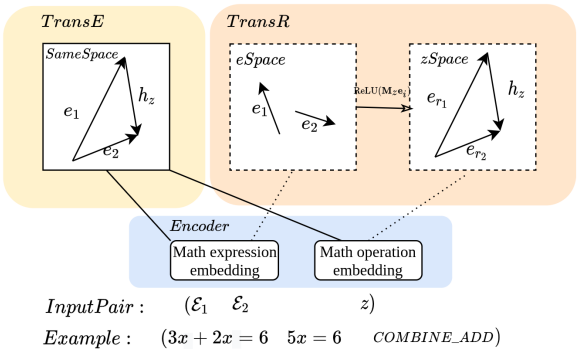

Figure 3. Illustration of the TransE and TransR frameworks. TransE puts the embeddings of equations e_1, e_2, and math operation z in the same embedding space, whereas TransR puts them in their own embedding spaces.

We will leverage the translating embedding (TransE) framework [3] that has found success in embedding entities and characterizing relationships between entities in multi-relational data. Our key assumption here in this framework is that math operations are *linear and additive*, i.e., the relationship between math expressions before and after a math expression satisfy

$$\mathbf{e}_2 \approx \mathbf{e}_1 + \mathbf{h}_z,$$

where $\mathbf{h}_z \in \mathbb{R}^D$ is the embedding of the *math operation* z. In other words, we assume that the effect of a math operation is characterized by the difference in the embedding vectors between the math expressions before and after it in a single step; adding it to the embedded vector of $\mathcal{E}_1$ results in the embedded vector of $\mathcal{E}_2$ after the step.

To learn these math operation embeddings from data, we use two loss functions. The first loss function promotes this linear and additive relationship between embeddings of the math expressions and operations on the training data. To this end, we define a distance function as $d(\mathbf{e}_1, \mathbf{e}_2, \mathbf{h}_z) = \|\mathbf{e}_1 + \mathbf{h}_z - \mathbf{e}_2\|_2^2$ and define the loss function as

$$L_1 = \sum_{(\mathcal{E}_1, \mathcal{E}_2, z)} d(\mathbf{e}_1, \mathbf{e}_2, \mathbf{h}_z).$$

The second loss function pushes counterfeit step tuples that are generated by replacing elements in an observed step tuple with other ones in the dataset to not satisfy the aforementioned linear and additive relationship. To this end, we minimize the pairwise marginal distance ranking-based loss

given by

$$L_2 = \sum_{(\mathcal{E}_1,\mathcal{E}_2,z)\in\mathbf{S}} \sum_{(\mathcal{E}_1',\mathcal{E}_2',z')\in\mathbf{S}'_{(\mathcal{E}_1,\mathcal{E}_2,z)}} [\gamma + d(\mathbf{e}_1,\mathbf{e}_2,\mathbf{h}_z) - d(\mathbf{e}_1',\mathbf{e}_2',\mathbf{h}_z')]_+,$$

where $[x]_+ = x$ when $x > 0$ and 0 otherwise and $\gamma > 0$ is a hyper-parameter that controls the margin of the distance ranking. $\mathbf{S}$ denotes the set of steps in the dataset and $\mathbf{S}'_{(\mathcal{E}_1,\mathcal{E}_2,z)}$ is a set of counterfeit steps that are perturbed versions of the actual step $(\mathcal{E}_1,\mathcal{E}_2,z)$, generated by randomly replacing one of the triplet elements in the step by a different math expression or math operation from another step, i.e.,

$$\begin{aligned}\mathbf{S}'_{(\mathcal{E}_1,\mathcal{E}_2,z)} &\sim A\cup B\cup C,\\ \text{where } A &= \{(\mathcal{E}_1',\mathcal{E}_2,z) : \mathcal{E}_1' \neq \mathcal{E}_1 \in \mathbf{E}\}\\ B &= \{(\mathcal{E}_1,\mathcal{E}_2',z) : \mathcal{E}_2' \neq \mathcal{E}_2 \in \mathbf{E}\}\\ C &= \{(\mathcal{E}_1,\mathcal{E}_2,z') : z' \neq z \in \mathbf{Z}\}.\end{aligned}$$

Intuitively speaking, our objective encourages the distance function calculated on an actual tuple in the dataset to be smaller than that calculated on a perturbed version of it. Figure 3 illustrates the whole process.

The final loss function that we minimize is simply the combination of these two loss functions as $L = L_1 + L_2$. Using the learned embeddings of each math operation, we can classify them from the math expressions $\mathcal{E}_1$ and $\mathcal{E}_2$ using the nearest neighbor classifier, i.e., $\hat{z} = \text{argmin}_z d(\mathbf{e}_1,\mathbf{e}_2,\mathbf{h}_z)$.

4.2.2 Learning Entity and Relation Embeddings

Despite potentially exhibiting excellent interpretability, TransE's assumption that math operations are linear and additive in the math expression embedding space may be too restrictive. This assumption puts math operations are vectors in the same latent space where similar math expressions will be close to each other. However, different math operations are fundamentally different and can transform the same math expression into dramatically different math expressions that are far apart in the embedding space. For example, different math operations can focus on transforming different parts of the same math expression. The steps $(3+5+2x = x+1,\ 8+2x = x+1$, combine similar terms) and $(3+5+2x = x+1,\ 3+5+2x-x = x+1-x$, subtract from each side) have the same starting math expression $\mathcal{E}_1$. In the first step, only similar terms on the left hand side of the equation are combined, regardless of the other side of the equation. In the second step, we subtracted x from both sides of the equation, which is a consequence of the equality symbol in the equation, which means that subtracting the same term on both sides of the equation but not what exactly is on each side. Therefore, TransE's linear and additive assumption means that the resulting $\mathcal{E}_2$ in these steps will be very different due to the different math operations applied, which conflicts with the observation that they are very similar. To address this limitation, we explore the Learning Entity and Relation Embeddings (TransR) [23] model, which models math expressions and math operations in different spaces, i.e., there will be a shared embedding space for all math expressions but separate relation spaces for different math operations.

TransR learns the embeddings of math operations by projecting them to their corresponding relation spaces and then learning translations between those projected expressions. For each math operation z, we set a projection matrix $\mathbf{M}_z \in \mathbb{R}^{D\times D}$ that projects a math expression to its relation space. To make this projection nonlinear, we apply the rectified linear unit (ReLU) activation function [10] to it and define the corresponding distance function as

$$d_z(\mathbf{e}_1,\mathbf{e}_2,\mathbf{h}_z) = \|\text{ReLU}(\mathbf{M}_z\mathbf{e}_1) + \mathbf{h}_z - \text{ReLU}(\mathbf{M}_z\mathbf{e}_2)\|_2^2.$$

Correspondingly, the two loss functions in the TransR framework are given by

$$\begin{aligned}L_1 &= \sum_{(\mathcal{E}_1,\mathcal{E}_2,z)} d_z(\mathbf{e}_1,\mathbf{e}_2,\mathbf{h}_z),\\ L_2 &= \sum_{(\mathcal{E}_1,\mathcal{E}_2,z)\in\mathbf{S}} \sum_{(\mathcal{E}_1',\mathcal{E}_2',z')\in\mathbf{S}'_{(\mathcal{E}_1,\mathcal{E}_2,z)}} [\gamma + d_z(\mathbf{e}_1,\mathbf{e}_2,\mathbf{h}_z) - d_z(\mathbf{e}_1',\mathbf{e}_2',\mathbf{h}_z')]_+.\end{aligned}$$

The projection matrices $\mathbf{M}_z$, $\forall z \in \mathbf{Z}$ are included as part of the trainable parameters. The rest of the training and resulting math operation classification procedure remains unchanged from the TransE framework.

5. EXPERIMENTS

We now detail a series of quantitative and qualitative experiments that we have conducted to validate the learned representations of math operations. Using the Cognitive Tutor 2010 equation solving (CogTutor) dataset,[2] we focus on two tasks: i) classifying the math operation a student applies in a solution step and ii) classifying the feedback category corresponding to certain types of incorrect steps, from the math expressions the student enters before and after the step.

5.1 Dataset

We use the CogTutor dataset which we accessed via the PSLC DataShop [19]. The dataset contains detailed tutor logs generated as students in a school use the Cognitive Tutor system [34] for their Algebra I class. These logs contain the students' step-by-step solutions to equation solving problems, where each step is a tuple with three elements: a *math expression* $\mathcal{E}_1$ at the beginning of the step, the *step name* z, i.e., the math operation the student selected to apply to this math expression, and the resulting math expression $\mathcal{E}_2$ after the step. Students can select math operations from a built-in list in Cognitive Tutor: COMBIN_ADD, COMBINE_MUL, ADD_SIDE, SUB_SIDE, MUL_SIDE, DIV_SIDE, and DISTRIBUTE; see Table 1 for an illustration of these operations and some examples of the corresponding math operations before and after them in a step.

There are a total of 50,406 steps in this dataset that can be further divided into three subsets according to their outcomes: `OK` (43,413 steps), `ERROR` (6,377 steps), and `BUG` (5,744 steps). The `OK` subset contains steps that are correct, i.e., the student both selected the correct math operation and arrived at the correct math expression. The `BUG` and `ERROR` subsets contain incorrect student steps, either because the operation they selected was incorrect or

[2] `https://pslcdatashop.web.cmu.edu/DatasetInfo?datasetId=660`

Step (Math operation)	Description	Example
COMBINE_ADD	combine two similar terms with add/sub operator	$3x + 2x \rightarrow 5x$
COMBINE_MUL	combine two similar terms with multiply/divide operator	$x * x \rightarrow x^2$
ADD_SIDE	add a math term on each side	$x = 1 \rightarrow x + 1 = 1 + 1$
SUB_SIDE	subtract a math term on each side	$x = 1 \rightarrow x - 1 = 1 - 1$
MUL_SIDE	multiply a math term on each side	$x = 1 \rightarrow x * 2 = 2$
DIV_SIDE	divide a math term on each side	$x = 1 \rightarrow x/2 = 1/2$
DISTRIBUTE	distribute(expand) the terms	$(x + 1)x \rightarrow x * x + x$

Table 1. Detailed descriptions and examples for each math operation in the CogTutor dataset.

because they selected the correct operation but did not apply it correctly, i.e., arriving at an incorrect math operation after the step. The difference between these two subsets is that `BUG` contains steps that fit one of the predefined error templates in the Cognitive Tutor system; in this case, the system can automatically diagnose the error and deploy a predefined feedback. On the other hand, `ERROR` contains incorrect steps that Cognitive Tutor could not automatically diagnose the underlying error. The `OK` subset can be further split into six predefined difficulty levels (named as ES_01,ES_02, ES_03 ,ES_04, ES_05, and ES_07), with 2,068, 7,546, 8,183, 13,393, 5,484, and 2,801 steps, respectively. We do not further split the `BUG` and `ERROR` subsets for the math operation classification task due to their limited sizes.

To learn the representation of math operations, we need examples of how they transform one math expression into another. However, the CogTutor dataset may not contain enough data that is rich in both quantity and diversity for neural network-based models to learn from. Therefore, we designed a synthetic data generator stemming from the math question answering dataset created by DeepMind [36]. The generator can generate steps by first generating the initial math expression and then applying math operations listed in Table 1 to arrive at a resulting math expression. We have full control over the generated steps through the entropy, degree, and flip parameters. Increasing entropy introduces more complexity to the math expressions as numerical constants generated get larger. Increasing the degree parameter introduces monomials of higher degrees and also adds more terms in the math expression. Finally, the flip parameter allows us to control which side of an equation has a higher chance to be more complicated than the other. Tuning these parameters within this flexible synthetic data generation method enables us to generate a large amount of steps that closely resembles those in the CogTutor dataset.

5.2 Methods

To fully evaluate the effectiveness of our math operation representations, we also experiment with two other ways of encoding math expressions commonly used in natural language processing tasks, in addition to the tree embedding-based and translation-based encoder that we introduced in Section 4.2. These two encoders include a gated recurrent unit (GRU)-based encoder [4] and a convolutional neural network (CNN)-based encoder [17]; we will use the output of these encoders to replace $[\mathbf{e}_1^T,\ \mathbf{e}_2^T]^T$ as input to the classifier detailed in Section 4.1.

Specifically, these two encoders first concatenates the two math expressions before and after the step, i.e., $\mathcal{E} = [\mathcal{E}_1, \mathcal{E}_2]$. For each character x_t in $\mathcal{E}$, we compute its embedding

$$\boldsymbol{x}_t = \mathbf{W}^T \text{onehot}(x_t)\,,$$

where $\mathbf{W}$ is a trainable embedding matrix. Using these character embeddings, the GRU encoder computes

$$\boldsymbol{h}_t = \text{GRU}_\theta(\boldsymbol{x}_t, \boldsymbol{h}_{t-1})\,,$$

where θ represents all the trainable parameters in GRU. We then replace $[\mathbf{e}_1^T,\ \mathbf{e}_2^T]^T$ with $\boldsymbol{h}_T$ as input to the classifier where T is the total number of characters in $\mathcal{E}$. Similarly, the CNN encoder computes

$$\boldsymbol{h} = \text{max\_pool}(\text{CNN}_\phi([\boldsymbol{x}_1, \cdots, \boldsymbol{x}_T]))\,,$$

where CNN_ϕ represents a 2D CNN with parameters ϕ and max_pool is a 1D max pooling operator. Combined, they return a fixed dimensional feature vector $\boldsymbol{h}$ that replaces $[\mathbf{e}_1^T,\ \mathbf{e}_2^T]^T$ as input to the classifier. For each of these two models, we learn its parameters jointly with the classification task using the cross-entropy loss that we described in Section 4.1.

Overall, we test five different methods for the math operation classification and feedback classification tasks. The first three methods use different encoding methods in conjunction with a classifier: i) using the GRU encoder to encode math expressions as input to the classifier, which we dub **GRU+C**, ii) using the tree embedding-based encoder instead, which we dub **TE+C**, and iii) using the CNN encoder instead, which we dub **CNN+C**. These methods do not learn explicit representations of math operations. The next two methods use the TransE and TransR frameworks to learn these representations using tree embeddings: iv) using tree embedding-based encoder as input to the TransE framework in conjunction with a nearest neighbor classifier, which we dub **TE+TransE**, and v) using the TransR framework instead of the TransE framework to study math operations in multiple relation spaces, which we dub **TE+TransR**.

5.3 Experimental Setup

We first test our math operation representation learning methods on the `OK` subset via 5-fold cross-validation, i.e., training on 80% of steps in the subset to learn representations of math operations and testing them on the remaining 20%. We also test the generalizability of the learned representations to incorrect steps, i.e., replace the test set with the `ERROR` and `BUG` subsets, and check whether we can still recognize the math operation a student applied in an incorrect step. The results are detailed in Section 5.4.1.

Since the distribution of math expressions in the `OK`, `ERROR` and `BUG` data subsets are mostly similar with minor differ-

	OK	ERROR	BUG
GRU+C	99.18 ± 0.23	93.87 ± 0.66	95.89 ± 0.63
TE+C	99.82 ± 0.04	93.30 ± 0.65	95.38 ± 0.62
CNN+C	95.37 ± 0.44	86.82 ± 1.38	91.02 ± 0.59
TE+TransE	96.27 ± 0.17	86.32 ± 1.23	84.21 ± 2.13
TE+TransR	99.17 ± 0.21	91.28 ± 1.12	91.31 ± 1.87

Table 2. Math operation classification accuracy for all methods training on the OK subset of the CogTutor dataset and testing on different data subsets. Accuracy is high across the board, while GRU-based encoding and tree embedding-based encoding in conjunction with a classifier result in the best performance.

ences, the previous experiment does not give us a good idea on the generalization ability of our math operation representation learning methods. Therefore, we further divide the OK subset into six smaller subsets, each corresponds to a different difficulty level (with different structure and complexity) according to questions within it, and test the generalizability of the learned math operation representations. The results are detailed in Section 5.4.2. In practice, solution step data generated by real students is often limited. Therefore, we conduct two more experiments to test whether synthetically generated steps can help us learn math operation representations that generalize to real data. First, we repeat the experiments above using synthetically generated steps as the training set. This synthetic training set consists of $1,000$ steps for each math operation defined in Table 1 (adding up to a total of $7,000$ across different difficulty levels). The results are detailed in Section 5.4.3. Second, to study the impact of synthetically generated data when real data is limited, we pre-train the math operation representations with synthetic data, fine-tune on a small amount of real data from each difficulty level in the OK subset, and test on the rest. The results are detailed in Section 5.4.4.

To test the ability of our learned math operation representations on recognizing student errors, we use them to classify feedback types provided by CogTutor in the BUG data subset. Examples of such errors include when a student calculated the wrong simplification result, used the wrong sign in front of terms, and applied useless/unlogical steps to solve the problem, etc. The results are detailed in Section 5.4.5.

We use Adam optimizer [18] with learning rate 0.001, batch size 64 and run 10 training epochs for each experiment. The math expression encoder outputs length-512 embedding vectors for each math expression, which we adapt to length-32 embedding vectors dimensions using a trainable fully-connected neural network. All of our experiments were conducted on a server with a single Nvidia RTX8000 GPU.

5.4 Results and Discussion

5.4.1 Generalizing to incorrect steps

Table 2 shows the averages and standard deviations of math operation classification accuracy for every method we experimented with using the OK subset as the training set. As expected, testing on the ERROR and BUG subsets result in slightly lower (5-10%) math operation classification accuracy for all methods since the training set does not contain incorrect steps. However, even on steps that are incorrect, these methods can still effectively identify the math operation a student intended to apply (with up to 95% accuracy), suggesting that they may be applicable to fully open-ended question solving solutions that are not highly structured, unlike those in Cognitive Tutor, to provide feedback to teachers on students' solution approaches.

We observe that using GRUs and tree embeddings as representations for math expressions and applying a classification method on top of these representations result in similar performances; GRUs slightly outperform tree embeddings in cases where we use the ERROR and BUG subsets as the test set while tree embeddings slightly outperform GRUs in the case where we use a part of the OK subset as the test set. Using CNNs to encode math expressions as input to a classifier results in worse performance, suggesting that they do not capture the semantic and structural information in math expressions as well as GRUs and tree embeddings. As expected, using tree embeddings under the TransE and TransR frameworks leads to worse performance than the first two methods, with TransE achieving low performance (especially on the BUG subset) and TransR achieving comparable performance to the classification-based methods on the OK subset but lower performance on the ERROR and BUG subsets. This result can be explained by the additional structural restriction that math operations are represented as linear and additive in some embedding space in the TransE framework, which makes it less robust against incorrect student solution steps. Using the TransR framework mitigates this problem due to its use of different relation spaces for each math operation.

These methods perform similarly in the math operation classification task on real data largely due to the limited variation and complexity in the math expressions. The Cognitive Tutor system limits the degrees of freedom in a students' response by splitting an open-ended step into the separate actions of selecting a single math operation and entering the resulting math expression, which limits the variability in the data. In the next experiment, we see that when we control against different levels of complexity in these math expressions and forcing these methods to generalize across complexities, their performance vary significantly.

Figure 4 visualizes the confusion matrix for math operation classification on the OK subset and the pairwise euclidean distances between math operation embeddings learned via the TransE framework using tree embeddings for math expressions. Rows correspond to the true math operations applied in steps and columns correspond to predicted ones. Percentages in the confusion matrix (Figure 4a) are normalized w.r.t. the number of appearances of each math operation. We see that our math operation representation learning method captures some meaning of these operations (Figure 4b); the learned math operation embeddings capture the structural changes in math expression in ways that match our intuition. For instance, both COMBINE_ADD and COMBINE_MUL can be considered types of simplifications, so the Euclidean distance between the learned embeddings for these two operations is low. This observation is not surprising due to the similar nature of these operations. Moreover, COMBINE_ADD, COM-

(b) Euclidean distance between learned math operation embedding vectors.

Figure 4. Details of TE+TransE for the math operation classification task on the OK subset. These results match our intuition on how these math operations are related.

BINE_MUL, and DISTRIBUTE are often confused with one another. These results are also validated by a 2-D visualization (using t-SNE [42] as a dimensionality reduction method) of the learned math operation embeddings in Figure 5, where different math operations are mostly well separated except for COMBINE_ADD, COMBINE_MUL, and DISTRIBUTE. One possible explanation is that these operations are all applied to one side of the equation during a solution step, leaving one side of the equation unchanged, while the other operations, such as ADD_SIDE, SUB_SIDE, MUL_SIDE, and DIV_SIDE are all applied to both sides of the equation. Therefore, this result suggests that tree embeddings enable us to characterize a math operation by the *structural* change in math expressions before and after a solution step where it is applied. Furthermore, the classification accuracy for the DISTRIBUTE operation is significantly lower than that for other operations. This result is likely due to the fact that the number of steps with this operation is significantly lower than that for other operations.

5.4.2 *Generalizing to different difficulty levels*

In this experiment, we test the ability of our learned math operation representations to generalize to math expressions with different levels of complexity in questions at different levels of difficulty. Although they are all about equation solving, questions at different difficulty levels in Cognitive Tutor involve math expressions that look very different. For example, in the easiest level (ES_01), the equation that needs to be solved in a question looks like $x + 5 = 9$, with only a single variable and without numbers with decimals. In contrast, in the hardest level (ES_07), a question may contain coefficients with several decimal places and multiple variables, such as solve for m in the equation $m(k - n) = gs$. We only compare the GRU-based encoder and the tree embedding-based encoder in conjunction with a classifier since they are the best performing methods in the previous experiment. Table 3 lists the math operation classification accuracy for both methods after training on steps at different difficulty levels in the OK subset and testing on steps at other difficulty levels (including incorrect ones). We see that TE+C overall outperforms GRU+C in almost every case. This results suggest that tree embeddings are effective at capturing the structural property of a math expression. As a result, math operation representations based on tree embeddings excel at capturing the structural *change* in math expressions before and after applying a math operation, leading to better generalizability than GRU-based encoding that do not explicitly account for this change.

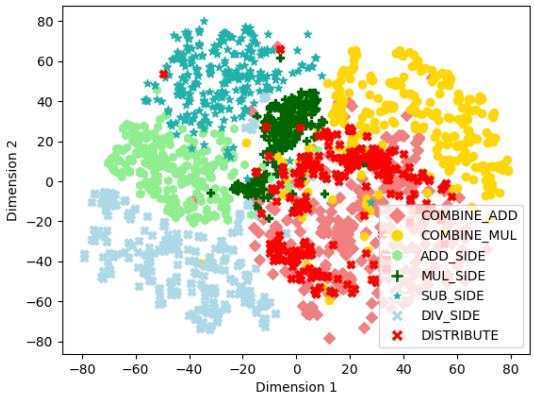

Figure 5. Visualization of learned math expression change for a randomly sampled subset of student solution steps in 2-D and corresponding operations (best viewed in color).

5.4.3 *Generalizing to different data distributions*

In this experiment, we test the ability of our methods to generalize from synthetically generated data to real student data. We train different math operation classification methods on the 2,000 synthetically generated steps and test them on steps generated by real students in the CogTutor dataset. Table 4 shows the mean and standard deviation for each method on each real data subset. We see that TE+C significantly outperforms GRU+C and CNN+C on all data subsets, which is in stark contrast to the previous experiment where the difference in performance across all methods is much smaller. This observation suggests that tree embeddings are more effective at capturing the semantic/structural effect of math operations on math expressions, thus generalizing better to different data distributions. Indeed, although the synthetically generated steps and the real steps have the same set of math operations, the distributions of numbers

Train on	Method	OK	ERROR	BUG
ES_01	GRU+C	58.82 ± 1.12	63.74 ± 1.13	66.02 ± 1.12

	TE+C	79.44 ± 0.62	79.29 ± 0.72	72.53 ± 2.26

Table 3. Math operation classification accuracy after training on steps with different difficulty levels and testing on the OK ERROR, and BUG subsets. Tree embedding-based encoding outperforms GRU-based encoding.

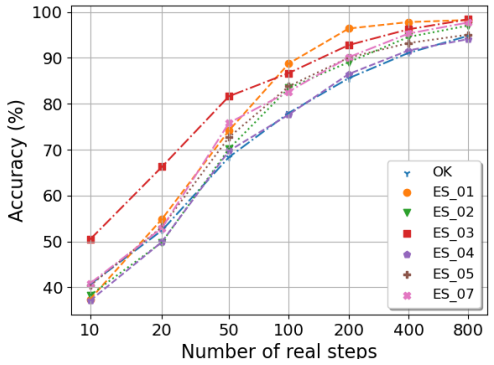

Figure 6. Math operation classification accuracy for the TE+C method when real data is limited. Using synthetically generated steps as a starting point, we already start with acceptable classification accuracy even with few real steps generated by students. The performance steadily improves after more real data becomes available.

$(1, 0.5, -7,$ etc.) and variables $(x, u, t,$ etc.), resulting in a mismatch between the data distributions. Tree embedding-based methods benefit from the tree-based representations of math expressions that can effectively capture structural information, making it easy for the learned embeddings of math expressions to generalize to unseen data.

5.4.4 *Generalizing from synthetic data*

Ideally, if there is a large amount of training data, i.e., steps generated by real students containing different types of math expressions and detailed labels on these steps such as the math operation(s) applied, the error(s) if a step is incorrect, and corresponding feedback, we can simply use that data to learn our math operation representations. However, in practice, the amount of real data is often limited. Figure 6 plots the performance of TE+C on all subsets of the CogTutor dataset, training on a portion of steps in the subset for training and testing on the rest. We see that the performance on math operation classification suffers considerably when we only have limited training data. Therefore, synthetically generated data can play a vital role in improving their performance under this circumstance; the strategy of fine-tuning models trained on synthetically generated data using a small amount of real data can be effective. Specifically, we start with a pre-trained math operation classification model on the 7000 synthetically generated steps and fine tune it on a small number of real steps by doing gradient descent on these steps for 10 epochs. Figure 7 plots the improvement in math operation classification accuracy for the fine-tuned model over the model that trains on only real data of various amounts on all data subsets. We see that the pre-trained models always performs better, with significant improvement when the real data is extremely limited. This result suggests that i) effectively leveraging synthetically generated data can mitigate the problem of limited real data and ii) our math operation representation learning methods are capable of generalizing across different data distributions (synthetic $\rightarrow$ real).

	OK	ERROR	BUG

Tree embedding-based methods significantly outperform other methods, showing better ability to generalize to different data distributions.

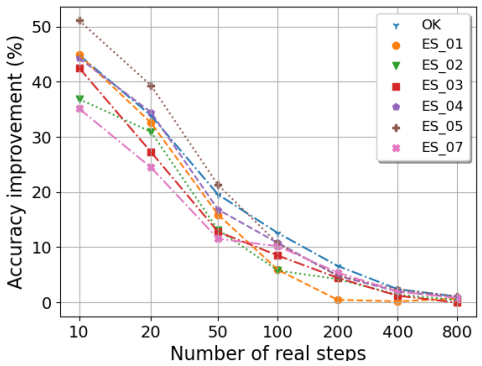

Figure 7. Math classification accuracy (difference in percentage) for TE+C, pre-training on synthetic data before fine-tuning on real data versus training only on real data. When real data is limited, pre-training on synthetic data results in significantly better performance.

5.4.5 *Feedback type classification*

In this experiment, we evaluate our math operation representation learning methods on the feedback type classification task. These feedback items were automatically deployed by Cognitive Tutor for incorrect steps in the BUG subset. We pre-processed these steps and grouped the detailed feedback items according to the students' errors that each

Method	Accuracy
GRU+C	75.35 ± 1.41
TE + C	78.71 ± 1.74
CNN+C	67.23 ± 1.54
TE + TransE	69.15 ± 1.13
TE + TransR	73.21 ± 1.63

Table 5. Feedback type classification accuracy for all methods on the BUG subset. Tree embedding-based encoding outperforms other encoding methods while TransE and TransR frameworks do not reach similar performance levels due to shortage of training data.

feedback item addresses and narrowed it down to a total of 24 types that occur multiple times. We perform 5-fold cross validation on this subset. Table 5 shows the averages and standard deviations of feedback classification accuracy for all methods on this task across the five folds. We see that due to the limited size of the BUG subset (only $5,744$ steps) and the high number of classes (24), all method perform worse than they do on the math operation classification task. Specifically, we see that the tree embedding-based encoder in conjunction with a classifier performs best while GRU-based encoding also performs well. This result shows that although tree embeddings are superior at capturing the meaning of math expressions, their advantage over simple encoding methods such as GRU-based encoding decreases due to increased noise in the data; some math expressions submitted by students in incorrect steps are ill-posed and do not make sense. Using the TransE and TransR frameworks result in slightly worse performance than classifiers since these methods explicitly learn a representation for each math operation, which limits their performance on this task due to the shortage of training data. However, since they capture the structural difference in math expressions before and after the step, they can cancel out some of the noise in erroneous steps, resulting in acceptable performance.

5.5 Discussions

Overall, we find that the GRU-based and tree embedding-based math expression encoders in conjunction with a classifier perform almost equally well in most situations, while the CNN-based encoder performs worse. The tree embedding-based encoder has stronger generalizability across different data distributions. We believe that as the math expressions and operations get more complicated, methods that leverage the tree structure of math expressions would be more advantageous. We also observe that TransR outperforms TransE most of the time, although in some experiments using TransE and TransR to explicitly learn math operation embeddings lead to slightly worse performance than classifiers using implicit representations of math expressions. However, TransE and TransR are much more powerful and enable us to study more tasks such as clustering solution steps and identifying typical student errors and learning solution *strategies*; See Section 6 for a detailed discussion.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we developed a series of methods to learn representations of math operations by observing how math expressions change as a result of these operations in step-by-step solutions to open-ended math questions. Our methods leverage math expression encoding methods that map tree-structured math expressions into a math embedding vector space. We demonstrated the effectiveness of our methods on a dataset containing detailed student solution steps to equation solving questions in the Cognitive Tutor system on two tasks: i) classifying the math operation applied in each step and ii) classifying the feedback the system deploys for each incorrect step. Results show that our learned math operation representations are meaningful and can often effectively generalize across different data distributions such as questions with different difficulty levels.

However, the success of our methods heavily depends on the availability of diverse large-scale training data. The Cognitive Tutor dataset that we used in this work represents a heavily restricted solution process since the list of math operations a student can apply in a step is pre-defined. Therefore, additional work has to be done to extend our method to truly open-ended step-by-step solution processes that are less structured. Moreover, our methods are restricted to a single solution step only and do not consider the relationship across multiple steps, which is related to another important aspect of solving open-ended math questions: the overall solution strategy, i.e., which math operation to apply next. Furthermore, in both classification tasks, using tree embeddings to encode math expressions in conjunction with a classifier outperforms explicitly learning vectorized representations of math operations in the TransE and TransR frameworks. However, these explicit representations may enable us to perform other tasks such as Nevertheless, our work provides a series of tools to analyze the math expressions students write down in their solutions by bridging the gap between symbolic math representations with continuous representations in vector spaces, enabling the use of state-of-the-art neural network-based methods. We believe that this work can potentially open up a new line of research that studies how to automatically analyze student solutions for grading and feedback purposes.

There are many avenues of future work. First, since most real-world open-ended solutions contain a mixture of math expressions and text, there is a need to learn a joint representation of math expressions and text in a shared embedding space. Second, this joint representation will enable us to train automated feedback generation methods in an end-to-end manner, using sequence-to-sequence learning methods [41]. Third, using learned math expression representations as the states and learned math operation representations from the TransE and TransR frameworks as the state transition model, we can apply reinforcement learning and inverse reinforcement learning methods to learn solution strategies, i.e., which math operation to apply in the next step. We can also study solution strategies employed by real students [33] and diagnose their errors and design corresponding feedback mechanisms to improve their learning outcomes. These future work directions will enable us to tap into the full potential of explicit math operation representations, which is not fully demonstrated in this paper: on the CogTutor dataset, the only relevant real-world dataset we found, we could only evaluate these explicit representations on the math operation and feedback prediction tasks, where they may not outperform tree embedding-based classification-based methods.

ABSTRACT

Classifying educational forum posts is a longstanding task in the research of Learning Analytics and Educational Data Mining. Though this task has been tackled by applying both traditional Machine Learning (ML) approaches (e.g., Logistics Regression and Random Forest) and up-to-date Deep Learning (DL) approaches, there lacks a systematic examination of these two types of approaches to portray their performance difference. To better guide researchers and practitioners to select a model that suits their needs the best, this study aimed to systematically compare the effectiveness of these two types of approaches for this specific task. Specifically, we selected a total of six representative models and explored their capabilities by equipping them with either extensive input features that were widely used in previous studies (traditional ML models) or the state-of-the-art pre-trained language model BERT (DL models). Through extensive experiments on two real-world datasets (one is open-sourced), we demonstrated that: (i) DL models uniformly achieved better classification results than traditional ML models and the performance difference ranges from 1.85% to 5.32% with respect to different evaluation metrics; (ii) when applying traditional ML models, different features should be explored and engineered to tackle different classification tasks; (iii) when applying DL models, it tends to be a promising approach to adapt BERT to the specific classification task by fine-tuning its model parameters. We have publicly released our code at `https://github.com/lsha49/LL_EDU_FORUM_CLASSIFIERS`

Educational Forum Posts, Text Classification, Deep Neural Network, Pre-trained Language Models

1. INTRODUCTION

In the past two decades, researchers have developed a number of online educational systems to support learning, e.g., Massive Open Online Courses, Moodle, and Google Classroom. Though being widely recognized as a more flexible option compared to campus-based education, these systems are often limited by their asynchronous mode of delivery that may hinder effective interaction between instructors and students and between students themselves [27, 20]. As a remedy, the discussion forum component is often included to support communication between instructors and classmates, so students can create posts for different purposes, e.g., to ask questions, express opinions, or seek technical help. Moreover, in certain cases, instructors rely heavily on the use of a discussion forum to promote peer-to-peer collaboration, e.g., specifying a topic to spur discussions among students.

In this context, the timeliness of an instructor's response to a student post becomes critical. A group of studies has demonstrated that students' learning performance and course ex-

EDM '21 June 29 - July 02 2021, Paris, France

perience were greatly affected by the timeliness of the responses they received from instructors [2, 24, 14]. It is, therefore, critical that instructors monitor the discussion forum to provide timely help to students who need it and ensure the discussion unfolds in a way that benefits all students. However, nowadays, up to tens of thousands of students can enroll in an online course and create a variety of posts that differ by importance, i.e., not all of them warrant instructors' immediate attention. Therefore, it becomes increasingly challenging for instructors to timely identify posts that require an urgent response or to understand how well students collaborate in the discussion space.

To tackle this challenge, various computational approaches have been developed across different courses and domains to classify educational forum posts, e.g., to distinguish between urgent and non-urgent posts [2, 24] or to label posts for different levels of cognitive presence [11, 52]. Typically, these approaches relied upon traditional Machine Learning (ML) models, such as Logistic Regression, Support Vector Machine (SVM), and Random Forest. These models yielded a high level of accuracy, most often due to the extensive efforts that domain experts made to engineer input features. For post classification tasks, such features are linguistic terms describing the post content (e.g., words that represent negative emotions) and the post metadata (e.g., a creation timestamp) [31, 38, 19].

In recent years, Deep Learning (DL) models have emerged as a powerful strand of modeling approaches to tackle data-intensive problems. Compared to traditional ML models, DL models no longer requires the input of expert-engineered features; instead, they are capable of implicitly extracting such features from data with a large number of computational units (i.e., artificial neurons). Particularly, DL models have achieved great success in solving various Natural Language Processing (NLP) problems, e.g., machine translation [48], semantic parsing [22], and named entity recognition [60]. Driven by this, a few studies have been conducted and demonstrated the superiority of DL models over traditional ML models in classifying educational forum posts [24, 10, 59]. For instance, Guo et al. [24] showed that DL models can outperform a decision tree based ML model proposed in [2] by 0.1 (measured by F1 score) in terms of identifying urgent post, while [59] demonstrated that, when determining whether a post contains a question or not, the performance difference between SVM and DL models was up to 0.68 (measured by Accuracy).

Though achieving high performance, DL models have not been justified as an always-more-preferable choice compared to traditional ML models. The reasons are threefold. Firstly, studies investigating the difference in performance between traditional ML and DL models have mostly harnessed a limited set of traditional ML models for comparison, without making extensive feature engineering efforts to empower those traditional ML models. As an example, [59] compared only SVM to a group of DL models, and the SVM model in this study incorporated only one type of features, i.e., the term frequency–inverse document frequency (TF-IDF) score of the words in a post. This implies that the potential of the traditional ML models used in existing studies was not fully explored and the actual performance difference between the two types of models might be smaller than the studies to date have reported on. Secondly, researchers and practitioners often need to deliberately trade off several relevant factors before determining which model they should use in practice, and classification performance is only one of these factors. Other important factors are the availability of human-annotated training data and computing resources [29]. For instance, compared to traditional ML models, DL models demand a much larger amount of human-annotated training data, whose creation can be a time-consuming and costly process. Besides, efficient training of DL models requires access to strong computing resources (e.g., a GPU server), which may be unaffordable to researchers and practitioners with a limited budget. Most traditional ML models, on the other hand, can be easily trained on a laptop. Thirdly, the feature engineering required by traditional ML models plays an important role in contributing to a theoretical understanding of constructs that are not only useful for classification of forum posts, but are also informative about students' discussion behaviors, offering instructors insights on whether their instructional approach works as expected [45, 12, 58].

To assist researchers and educators select relevant models for post classification, this study aims at providing a systematic evaluation of the mainstream ML and DL approaches commonly used to classify educational forum posts. Throughout this evaluation, we advance research in the field by ensuring that: (i) sufficient effort is allocated to design as many meaningful features as possible to empower traditional ML models; (ii) an adequate number of representative ML and DL models is included; (iii) the effectiveness of selected models is examined by using more than one dataset, thus adding to the robustness of our approach to different educational contexts; (iv) all models are compared in the same experimental setting, e.g., with same training/test data splits, and performance reported on widely-used evaluation metrics to provide common ground for model comparison; and (v) the coding schemes used labeling discussion posts are made publicly available to motivate the replication of our study. Formally, the evaluation was guided by the following two **R**esearch **Q**uestions:

RQ1 To what extent can traditional ML models accurately classify educational forum posts?

RQ2 What is the performance difference between traditional ML models and DL models in classifying educational forum posts?

To answer the RQs, we chose two human-annotated datasets collected at two educational institutions: Stanford University and `Monash University`. We further conducted the evaluation as per the following two classification tasks: (i) whether a post requires an urgent response or not; and (ii) whether the post content is related to knowledge and skills taught in a course. Specifically, to answer RQ1, we first surveyed relevant studies that reported on applying traditional ML models to classify educational forum posts. We hence selected four models that were commonly utilized, i.e., Logistics Regression, Naïve Bays, SVM, and Random Forest. In particular, we collected features frequently employed

in the reviewed studies and incorporated them as an input to empower the four traditional ML models in our experiment. Given that these features may play different roles in different classification tasks, we further conducted a feature selection analysis to shed light on the features that must be included in the future application of these models for similar classification tasks.

To answer RQ2, we selected the two widely-adopted DL models, Convolutional Neural Network coupled with Long Short-Term Memory (CNN-LSTM) and Bi-directional LSTM (Bi-LSTM), and compared them to the four selected traditional ML models. Recent studies in DL suggested that the performance of a model adopted for solving an NLP task (CNN-LSTM or Bi-LSTM in our case, denoted as the *task model* for simplicity) can be greatly improved with the aid of state-of-the-art pre-trained language models like BERT [16] in two ways. Firstly, BERT can be used to transform the raw text of a post into a set of semantically accurate vector-based representations (i.e., *word embedding*), which comprise the input information for the task model and enable the model to distinguish among multiple characteristics of a post. Secondly, BERT can adapt itself to capture the unique data characteristics of the task at hand. To this end, BERT couples with the task model and learns the model parameters. In particular, such flexibility has been demonstrated as extremely helpful in the contexts where training data was not sufficient. Therefore, we explored the effectiveness of BERT in empowering the two DL models selected for the experiment. We provide details in Section 3.

Performance of the four traditional ML and two DL models were examined by four evaluation metrics commonly used in classification tasks, i.e., Accuracy, Cohen's κ, Area Under the ROC Curve (AUC), and F1 score. In summary, this study contributed to the literature of the classification of educational forum posts with the following main findings:

- Compared to other traditional ML models, Random Forest is more robust in classifying educational forum posts;
- Both textual and metadata features should be engineered to empower traditional ML models;
- Different features should be designed when applying traditional ML models for different classification tasks;
- DL models tend to outperform traditional ML models and the performance difference ranges from 1.85% to 5.32% with respect to different evaluation metrics;
- Using the pre-trained language model BERT benefits the performance of DL models.

2. RELATED WORK

2.1 Content Analysis of Forum Posts

Across disciplines, educators widely utilize online discussion forums to accomplish different instructional goals. For instance, instructors often provide an online discussion board as a platform for students to ask questions and get answers about course content [12, 57], argue for/against a particular issue and, in that way, engage deeply with course topics [43, 42] or work collaboratively on a course project [49, 13]. In this process, instructors monitor student involvement by reading their posts. At the same time, instructors judge student contributions in the discussion task, e.g., whether students asked a question that relates to course content vs. a question about semester tuition; described their feelings about the discussed problem vs. just rephrased the problem; or clearly communicated their ideas to classmates in a collaborative learning task. Upon identifying posts that do not contribute to the forum at the expected level, the instructor may intervene accordingly. Sometimes, such an intervention needs to be provided immediately (e.g., in a case of a post pointing out the error in the practice exam key).

With the increasing popularity of online discussion forums in the instructional context, educational researchers have become interested in conducting content analysis of students' posts to find evidence and extent of learning processes that instructors aimed to elicit in online discussion. To this end, researchers utilize coding scheme, a predefined protocol that categorizes and describes participants' behaviors representative of the observed educational construct [47, 37], e.g., knowledge building [23, 35], critical thinking [39, 35], argumentative knowledge construction [55], interaction [26, 43], social cues, cognitive/meta-cognitive skills and knowledge, depth of cognitive processing [26, 25], and self-regulated learning in collaborative learning settings [50]. As per the analytical procedure, researchers read student postings and apply a code over a unit of analysis that can be determined physically (e.g., entire post), syntactically (e.g., paragraph, sentence) or semantically (e.g., meaningful unit of text) [15, 47]. Content analysis clearly demonstrated a potential to capture relevant, fine-grained discussion behaviors and provide researchers and educators with warranted inferences made from coding data [46, 47, 28].

Manual content analysis is time-consuming [25], especially in high-enrollment courses with thousands of discussion posts that students create. To automate the process of content analysis and support monitoring of student discussion activity, various computational approaches have been developed for post classification. These approaches relied upon traditional ML models and DL models and handled four common types of post classification tasks: content, confusion, sentiment, and urgency. Below, we expand upon the studies that reported on these tasks.

2.2 Traditional Machine Learning Models

Educational researchers have applied traditional ML models to automate content analysis of online discussion posts for different instructional needs. The ML models we identified in this review are predominantly based on supervised learning paradigm and can be categorized into four general methodological approaches: regression-based (e.g., Logistics Regression [1, 61, 57, 2, 62, 36]), Bayes-based (e.g., Naive Bayes, [5, 4, 36]), kernel-based (e.g., SVM [45, 12, 5, 18, 36, 58, 40, 30]), and tree-based (e.g., Random Forest [5, 2, 36, 31, 19, 38]). These models were designed to predict an outcome variable that represented the meaning of discussion posts across different categories such as confusion, sentiment or urgency. For instance, [12] created an SVM classifier to differentiate between content-related and non-

content-related questions in a discussion thread to help instructors more easily detect content-related discourse across an extensive number of student posts in MOOC, while [1] implemented a Logistic Regression classifier to detect confusion in students' posts and automatically recommend task-relevant learning resources to students who need it. [58] applied SVM to detect student achievement emotions [41] in MOOC forums and studied the effects of those emotions on student course engagement.

In recent years, researchers became increasingly interested in analyzing the expression of urgency (e.g., regarding course content, organization, policy) in a discussion post [2]. For example, [2] developed multiple ML classifiers to identify posts that need prompt attention from course instructors. While researchers mostly implemented supervised ML models, here we also note a small group of studies that reported on using unsupervised methods to classify forum posts, e.g., a lexicographical database of sentiments [36] and minimizing entropy [8].

Traditional ML models built upon textual and non-textual features extracted from students' posts. Textual features characterize content of the discussion post, e.g., presence of domain specific words [61, 44], presence of words reflective of psychological processes [31, 38, 19], term frequency [2, 5], emotional and cognitive tone [12, 57, 40, 58, 7, 34, 1], presence of predefined hashtags [21], text readability index [62], text cohesion metrics [31, 38, 19], and measures of similarity between message text [31, 38, 19]. Non-textual features, on the other hand, include post metadata, e.g., popularity views, votes and responses [12, 45, 36], number of unique social network users [45, 1, 18], timestamp [45, 36], type (post vs. response) [36], variable that signals whether the issue has been resolved or not [61], the relative position of the most similar post [51], variable that signals whether the author of the post is also the initiator of the thread [51], page rank value of the author of current post [51], indicator if a message is the first or last in a thread [38, 31, 19], and structure of the discussion thread [53, 31, 19, 38].

Researchers computed a variety of evaluation metrics to assess performance of these models. Classification accuracy was commonly applied in studies that we reviewed (e.g., [12, 61, 36]). Generally, models achieved classification accuracy of 70% to 90% in classifying forum posts across different levels of content identification, urgency, confusion, and sentiment. We also note that some authors opted for different or additional evaluation metrics, e.g., precision/recall [12, 1, 62], AUC [12, 18], F1 [1, 2], kappa [1, 61, 57]. Across the models, authors utilized a wide range of different validation strategies (e.g., cross validation, train/test split).

We identified two major challenges researchers should be aware of when using traditional machine learning approaches to detect relevant content, confusion, sentiment and/or urgency in a discussion forum. First, traditional machine learning approaches usually involve extensive feature engineering. In the context of post classification, a huge number of textual and non-textual features of a post is practically available to researchers. Features can be generated using different text mining approaches (e.g., dictionary-based, rule-based) and can be even produced using other classifiers (e.g.,[1]). Researchers thus often face a challenge to decide which feature subset to choose to best capture educational problems (e.g., off-topic posting, misinterpreting the discussion task, unproductive interaction with peers) and/or learning process of interest (e.g., knowledge building, critical thinking, argumentation). For this reason, domain and learning experts, including course instructors, learning scientists, and educational psychologists are often needed to define a feature space that aligns with the purpose of an online discussion. Second, works in [12, 57, 4, 2] took a variety of different approaches to validate the classifiers they developed in terms of metrics, datasets, and training parameters which makes it hardly possible to directly compare the performance of these ML models.

2.3 Deep Learning Approaches

To our knowledge, relatively fewer studies attempted to explore the effectiveness of DL approaches in classifying educational forum posts [54, 59, 10, 24, 8, 3, 6]. The DL models adopted by these studies, typically, relied on the use of CNN, LSTM, or a combination of them. For instance, [54] developed a DL model called ConvL, which first used CNN to capture the contextual features that are important to discern the type of a post, and then applied LSTM to further utilize the sequential relationships between these features to assign a label to the post. Through extensive experiments, ConvL was demonstrated to achieve about 81%∼87% Accuracy in classifying discussion posts of different levels of urgency, confusion, and sentiments. In a similar vein, [59] proposed to use Bi-LSTM to better make use of the sequential relationships between different terms contained in a post (i.e., from both of the forward and backward directions). By comparing with SVM and a few DL models, this study showed that Bi-LSTM performed the best in determining whether a post contained a question or not (72%∼75% Accuracy).

It is worth noting that the success of DL models often depends on the availability of a large-amount human-annotated data for model training (typically tens of thousands at least). This, undoubtedly, limits the applicability of DL models in tackling tasks with only a small amount of training data (e.g., a few thousand). Fortunately, with the aid of pre-trained language models like BERT [16], we can still exploit the power of DL models [10]. Pre-trained language models aim to produce semantically meaningful vector-based representations of different words (i.e., word embeddings) by training on a large collection of corpora. For instance, BERT was trained on English Wikipedia articles and Book Corpus, which contain about 2,500 million and 800 million words, respectively. Two distinct benefits were brought by such pre-trained language models: (i) the word embeddings produced by them encode a rich contextual and semantic information of the text and can be well utilized by a task model (e.g., ConvL described above) to distinguish different types of input data; and (ii) a pre-trained language model can be adapted to a specific task by concatenating itself to the task model and further fine-tuning/learning their parameters as a whole with a small amount of training data. For example, [10] showed that BERT was able to boost classification Accuracy up to 83%∼92% when distinguishing posts of different levels of confusion, sentiment, and urgency.

Though gaining some impressive progress, the studies de-

Table 1: The features used as input for traditional ML models. The features used to train models are denoted as *Yes* under the column *Included*

Category	Feature	Description	# features	Studies used this feature	Included
Textual	# unigrams and bigrams	Only the top 1000 most frequent unigram/bigrams are included.	2000	[12, 57, 40, 2, 56, 62, 51]	Yes
	Post length	# words contained in a post.	1	[58, 45, 36, 62]	
	TF-IDF	The term frequency-inverse document frequency (TF-IDF) of the top 1000 most frequent unigrams.	1000	[2, 5]	
	Automated readability index	A score $\in [0, 100]$ specifying the post readability.	1	[62]	
	LIWC	A set of features denoted as scores $\in [0, 100]$ indicating the characteristics of a post from various textual categories including: *language summary*, *affect*, *function words*, *relativity*, *cognitive process*, *time orientation*, *punctuation*, *personal concerns*, *perceptual process*, *grammar*, *social* and *drives*.	84	[2, 58, 7, 34, 31, 38, 19]	
	Word overlap	The fraction of words that appeared previously in the same post thread.	-	[7]	No
	# domain-specific words	Words selected by expert to characterize a specific subject, e.g., "*equation*" and "*formula*" for Math.	-	[61, 44]	
	LDA-identified words	Words that are specific to topics discovered by applying the topic modeling method Latent Dirichlet allocation.	-	[62, 4, 44]	
	Coh-Metrix	A set of features indicating text coherence (i.e., co-reference, referential, causal, spatial, temporal, and structural cohesion) linguistic complexity, text readability, and lexical category.	-	[31, 38]	
	LSA similarity	A score indicating the average sentence similarity within a message.	-	[31]	
	Hashtags	Hashtags pre-defined by instructors to characterize the type of a post, e.g., #help and #question for confusion detection.	-	[21]	
Metadata	# views	The number of views that a post received.	1	[45, 12, 36, 62, 18]	Yes
	Anonymous post	A binary label to indicate whether a post is anonymous to other students.	1	[45, 1, 18]	
	Creation time	The day and the time when a post was made.	2	[45, 36, 18]	
	# votes	The number of votes that a post received.	1	[45, 12, 36, 62, 18]	
	Post type	A binary label to indicate whether a post is a response to another post.	1	[36, 2]	
	Response time	The amount of time before a post was responded.	-	[18]	No
	# responses	The number of responses that a post received.	-	[45, 12, 36, 18]	
	Discussion status	A binary label to indicate whether the issue has been resolved or not.	-	[61]	
	Comment Depth	A number assigned to a post to indicate its chronological position within a discussion thread.	-	[53]	
	First and Last Post	A binary label to indicate whether the post is the first or the last in a discussion thread respectively.	-	[51, 53]	

scribed above were often limited in providing a systematic comparison between the proposed DL models and existing traditional ML models. In other words, these studies either did not include traditional ML models for comparison [10, 54] or only compared DL models with only one or two traditional ML models and the potential of these traditional ML models might be suppressed due to a limited amount of efforts spent in feature engineering [59]. This necessitates a systematic evaluation of the two strands of approaches so as to better guide researchers and practitioners in selecting models for classifying educational forum posts.

3. METHODS

We open this section by describing the datasets used in our study. Then, we introduce the representative traditional ML models, including the set of features we engineered to empower those models (RQ1), and then describe the two DL models we chose to compare to the four traditional ML models (RQ2).

3.1 Datasets

To ensure a robust comparison between traditional ML and DL models in classifying educational forum posts, we adopted two datasets in the evaluation, briefly describe below.

Stanford-Urgency consists of 29,604 forum posts collected from eleven online courses at Stanford University. These courses mainly cover subjects like medicine, education, humanities, and sciences. To our knowledge, this dataset is one of the few open-sourced datasets for classifying educational forum posts and was widely used in previous studies [57, 2, 5, 10, 56, 24, 21]. In particular, Stanford-Urgency contains three types of human-annotated labels, including the degree of urgency of a post to be handled by an instructor, the degree of confusion expressed by a student in a post, and the sentiment polarity of a post. In line with the increasing research interest in detecting urgent posts [2, 10, 24, 3], we used Stanford-Urgency and focused on determining the levels of urgency of posts in this study. The count of urgent and non-urgent posts is 6,418 (22%) and 23,186 (78%), respectively. Originally, the urgency label was assigned on a Likert scale of $[1, 7]$, with 1 denoting being not urgent at all and 7 denoting being extremely urgent, respectively. Similar to previous studies [2], we pre-processed the data by treating those of value larger than or equal to 4 as urgent posts and those less than 4 as non-urgent posts, and the classification task became a binary classification problem. It is worth pointing out two notable benefits of including Stanford-Urgency: (i) the large number of posts contained in Stanford-Urgency provided sufficient training data for DL models; and (ii) in addition to the text contained in a post, Stanford-Urgency contains rich metadata information about the post, e.g., the creation time of a post, whether the creator of a post was anonymous to other students, the number of up-votes a post received, which enabled us to explore the predictive utility of different types of data.

Moodle-Content was collected by `Monash University`, the dataset contains 3,703 forum posts that students generated in the Learning Management System `Moodle` during their coursework in courses like arts, design, business, economics, computer science, and engineering. The posts were first manually labelled by a junior teaching staff and then independently reviewed (and corrected if necessary) by two additional senior teaching staff to ensure the correctness of the assigned labels. In contrast to Stanford-Urgency, this dataset contains labels to indicate whether a post was related to the knowledge and skills taught in a course or not, e.g., "*What is poly-nominal regression?*" (relevant to course content) vs. "*When is the due date to submit the second assignment?*" (irrelevant). The count of content-relevant and content-irrelevant posts is 2,339 (63%) and 1,364 (37%), respectively. Therefore, similar to the adoption of Stanford-Urgency, we also tackled a binary classification problem here. However, it should be noted that, compared to Stanford-Urgency, the metadata of posts were not available in Moodle-Content.

3.2 Traditional Machine Learning Models

Model Selection. To ensure our evaluation is systematic, we included representative models that emerged in previous studies. As summarized in Section 2.2, the traditional ML models commonly investigated to date can be roughly grouped into four categories, i.e., *regression-based*, *Bayes-based*, *kernel-based*, and *tree-based*. Therefore, we selected one model from each group and explored their capabilities in classifying educational forum posts, namely Logistics Regression, Naïve Bayes, SVM, and Random Forest.

Feature Engineering. Different from previous studies [59, 5], we argued that traditional ML models should involve an extensive set of meaningful features to fully unleash their predictive potential before being compared to DL models, specifically, we expected that ML models demonstrate improved performance when utilising more features. Therefore, we surveyed studies that reported on applying traditional ML models to classify educational forum posts, engineered features following previous studies and incorporated those features into the four traditional ML models, as summarized in Table 1. These features can be classified into two broad categories: (i) *textual* features that are extracted from the raw text of a post with the aid of NLP techniques; and (ii) *metadata* features about a post. As the metadata of posts was not available in Moodle-Content, only textual features were engineered for this dataset, while both textual and metadata features were engineered for Stanford-Urgency. We excluded several types of features from the evaluation, mainly due to the unavailability of the data required to engineer those features, e.g., *# domain-specific words*, and *Hashtags*. As for *LDA-identified words*, *Coh-Metrix*, and *LSA similarity*, we have left these features to be explored in our future work.

Feature Importance Analysis. Previous studies [12, 57, 56] have demonstrated the benefits of feature importance analysis in providing a theoretical understanding of the underlying constructs that are useful to classify educational forum posts, e.g., identifying features that are useful across different classification tasks. Therefore, we adopted the following approach to identify the top k most important features of an ML model:

1. the Chi-squared statistics between engineered features and the target classification labels were computed;
2. each time, the feature of the highest Chi-squared statistic was fed into the model and the feature was kept in the set of input features only if the classification performance had increased;
3. we repeated (2) until k most important features were identified.

3.3 Deep Learning Models

Existing studies on developing DL models to characterize different types of forum posts, typically, involved the use of CNN or LSTM, which motivated us to include the following two DL models to our evaluation:

- **CNN-LSTM** [54, 24, 59]. This model consists of: (i) an input layer, which learns an embedding representation for each word contained in the input test; (ii) a CNN layer, which performs a one-dimensional convolution operation on the embedding representation produced by the input layer and captures the contextual

information related to each word; (iii) an LSTM layer, which takes the output of the CNN layer to make use of the sequential information of the words; and (iv) a classification layer, which is fully-connected layer taking the output of the LSTM layer as input to assign a label to the input text.

- **Bi-LSTM** [59, 24, 6]. Though LSTM has been demonstrated as somewhat effective in utilizing the sequential information of long input text, they are limited in only using the previous words to predict the later words in the input text. Therefore, Bi-directional LSTM was proposed, which consists of two LSTM layers, one representing text information in the forward direction and the other in the backward direction to better capture the sequential information between different words. Formally, this model consists of: (i) an input layer (same as CNN-LSTM); (ii) a Bi-LSTM layer; and (iii) a classification layer (same as CNN-LSTM).

Both CNN-LSTM and Bi-LSTM use an input layer to learn the representation of the input text, i.e., embeddings of the words in a post. Instead of learning word embeddings during training, previous studies [17, 33, 32] suggested that pre-trained language models like BERT can be used to initialize embeddings. Such embedding initialization has been demonstrated as an effective way to facilitate a task model to acquire better performance. Therefore, we adopted BERT to initialize the input layer of both CNN-LSTM and Bi-LSTM and, correspondingly, the implemented models are denoted as Emb-CNN-LSTM, and Emb-Bi-LSTM, respectively.

In addition to word embeddings initialization, as suggested in recent studies in the field of NLP [17, 33], we can further couple BERT with a task model (i.e., CNN-LSTM or Bi-LSTM) and adapt BERT to suit the unique characteristics of a task by training BERT and the task model as a whole. In other words, the task model is often concatenated on top of BERT's output for the `[CLS]`, which is a special token used in BERT to encodes the information of the whole input text. The co-training of BERT and the task model enables BERT to fine-tune its parameters to produce task-specific word embeddings for the input text, which further facilitates the task model to determine a suitable label for the input. In fact, this fine-tuning strategy, compared to being used for embedding initialization, has been demonstrated as a more promising approach to make use of BERT. For instance, [10] showed that, even by simply coupling with a classification layer (i.e., the last layer of CNN-LSTM and Bi-LSTM), BERT was capable of accurately classifying 92% forum posts. Most importantly, it should be noted that the parameters of the coupled model can be well fine-tuned/learned with only a few thousand data samples. That means, this fine-tuning strategy enables CNN-LSTM and Bi-LSTM to be also applicable to tasks that deal with only a small amount of data, e.g., Moodle-Content in our case. In summary, we fine-tuned BERT after coupling it with CNN-LSTM (CNN-LSTM-Tuned) and Bi-LSTM (Bi-LSTM-Tuned), respectively. Besides, to gain a clear understanding of the effectiveness of this fine-tuning strategy, we coupled BERT with only a single classification layer (denoted as SCL-Tuned) and compared it with CNN-LSTM-Tuned and Bi-LSTM-Tuned. Table 2 provides a summary of the DL models implemented in this study.

Table 2: The DL models used in this study. Here, SCL denotes Single Classification Layer.

Models	Usage of BERT		Task Model		
	Embedding Initialization	Fine-tuning	CNN-LSTM	Bi-LSTM	SCL
Emb-CNN-LSTM	√		√		
Emb-Bi-LSTM	√			√	
CNN-LSTM-Tuned		√	√		
Bi-LSTM-Tuned		√		√	
SCL-Tuned		√			√

3.4 Experiment Setup

Data pre-processing. Training and testing data were randomly split in the ratio of 8:2. The Python package `NLTK` was applied to perform lower casing and stemming on the raw text of a post after removing the stop words.

Evaluation metrics. In line with previous works in classifying educational forum posts, we adopted the following four metrics, i.e., Accuracy, Cohen's κ, AUC, and F1 score, to examine model performance. We ran each model three times and reported the averaged results.

Model implementation and training. The traditional ML models (i.e., Logistics Regression, Naïve Bays, SVM, and Random Forest) were implemented with the aid of the Python package `scikit-learn` and their parameters were determined by applying grid search and fit the grid to the training data. Note all model hyper-parameters will be documented in the released GitHub repository. The ML models were trained with textual and metadata features for the Stanford-Urgency dataset, and trained with textual features for the Moodle-Content dataset. When applying the method detailed in 3.2 to perform feature importance analysis, we used F1 score as the metric to measure the changed model performance. For both CNN-LSTM and Bi-LSTM, the model parameters are selected to be comparable with similar previous works in [54, 24, 59, 10]. To this purpose, the size of the BERT embeddings used in the input layer was 768 and the number of hidden units used in the final classification layer was 1. We used the activation function sigmoid and L2 regularizer. In CNN-LSTM, the CNN layer was set to have 128 convolution filters with filter width of 5, while the LSTM layer was set to have 128 hidden states and 128 cell states. In Bi-LSTM, the number of the hidden states and cell states in the LSTM cells was both set to 128. For all DL models, (i) 10% of the training data was randomly selected as the validation data; (ii) the batch size was set to 32 and the maximum length of the input text was set to 512; (iii) the optimization algorithm Adam was used; (iv) the learning rate was set by applying the one cycle policy with maximum learning rate of 2e-05; (v) the dropout probability was set to 0.5; and (vi) the maximum number of training epochs was 50 and early stopping mechanisms were used when the model performance on the validation data starts to decrease, and data shuffling was performed at the end of each epoch. The best model is selected based on validation error. For BERT, we used the service provided by `Bert-as-service`[1].

Stanford-Urgency				Moodle-Content			
Accuracy	**Cohen's κ**	**AUC**	**F1**	**Accuracy**	**Cohen's κ**	**AUC**	**F1**
0.8610 (-3.42%)	0.7315 (-7.31%)	0.8617 (-3.35%)	0.8628 (-3.25%)	0.7175 (-4.89%)	0.5577 (-5.91%)	0.7186 (-4.83%)	0.7358 (-3.96%)

4. RESULTS

Results on RQ1. The performance of the four traditional ML models is presented in Table 3. Across both classification tasks, Random Forest achieved the best performance, as per the calculated evaluation metrics, followed by SVM and Logistics Regression. Naïve Bayes, on the other hand, achieved the lowest performance. Specifically, Random Forest was capable of accurately classifying almost 90% of the forum posts in Stanford-Urgency, and reached an AUC and F1 score of 0.8916 and 0.8918, respectively. Besides, Cohen's κ score achieved by Random Forest for the same dataset was 0.7892, which indicates a substantial (and almost perfect) classification performance. In terms of classifying Moodle-Content, we noticed the overall performance of all models was lower than in Stanford-Urgency. This may be attributed to the lack of metadata features and significantly fewer posts in Moodle-Content than in Stanford-Urgency, making it harder for the models to reveal characteristics of different types of posts in Moodle-Content. Still, Random Forest achieved an overall accuracy, AUC, and F1 score of 0.7544, 0.7551, and 0.7661, respectively, and Cohen's κ score was very close to 0.6, which indicates an almost substantial classification performance.

Before delving into the identification of the most predictive features, we submitted each group of the textual and metadata features to the best-performing ML model (i.e., Random Forest) to depict their overall predictive power. The results are given in Table 4, derived only from Stanford-Urgency due to the unavailability of the metadata features in Moodle-Content. We observe that both textual and metadata features were useful in boosting classification performance, and textual features seem to have had a stronger capacity in distinguishing urgent from non-urgent posts. For instance, when only taking textual features into consideration, the AUC score was 0.8462, which is about 6% higher than that of metadata features (0.8152) and only 5% lower than that when considering both textual features and metadata features.

To gain a deeper understanding of the predictive power of different features, we further applied the method described in Section 3.2 to select the top 10 most important features in both Stanford-Urgency and Moodle-Content, described in Table 6. Here, several interesting observations can be made.

Firstly, almost all of the identified features were textual features, with only one exception observed in Stanford-Urgency, i.e., the metadata feature *# views*. This is in line with the findings we observed in Table 4, i.e., compared to metadata features, textual features tended to make a larger contribution in classifying forum posts. Among those textual features, we should also notice that most of them were extracted with the aid of LIWC. This corroborates with the findings presented in previous studies [31, 38, 19], i.e., LIWC is a useful tool in identifying meaningful features for characterizing educational forum posts.

Secondly, there is little overlap regarding the top ten most important features in the two tasks (only two shared feature, i.e., *LIWC: pronoun* and *LIWC: posemo*). In particular, we note that the number of features was highly related to the context of a classification task. In the Stanford-Urgency case, a number of top features were associated with a sense of stimulation (e.g., *anxiety*, *affect*, *drive*), which represents a subjective representation of urgency. In the Moodle-Content case, features were more associated with a sense of investigation (e.g., *Analytic* and *Understand*). This shows that different classification tasks (i.e., Urgency vs. Content-related) require task-specific features to best capture the task-specific information (i.e., whether the post expressed a sense of ur-

Table 6: The top 10 most important features used in Random Forest. Features shared by the two tasks are in bold.

Stanford-Urgency		Moodle-Content	
Features	**Description**	**Features**	**Description**
Metadata: # views	The number of views that a post received.	Post length	# words contained in a post.
LIWC: pronoun	# of the occurrence of all pronouns (e.g., personal and impersonal pronouns)	LIWC: Analytic	A score indicating the formal, logical, and hierarchical thinking patterns in a post
Unigram: they	# of the occurrence of the word "*they*"	LIWC: Tone	A score indicating the emotional tone conveyed in a post
LIWC: number	# of the occurrence of the digital numbers	**LIWC: pronoun**	# of the occurrence of all pronouns (e.g., personal and impersonal pronouns)
LIWC: affect	A score indicating the overal emotion (positive and negative) of a post	LIWC: ppron	# of the occurrence of all personal pronoun (e.g., he, she, me) in a post
LIWC: posemo	A score indicating the positive emotion of a post	Unigram: I	# of the occurrence of the word "*I*"
LIWC: drives	A score indicating the needs, motives, and drives of a post (e.g., references to success and failure)	**LIWC: posemo**	A score indicating the positive emotion of a post
LIWC: power	A score indicating the power of a post (e.g., reference to dominance)	TF-IDF: understand	The TF-IDF score of the word "*understand*"
LIWC: anx	A score indicating the anxiety conveyed in a post	LIWC: affiliation	A score indicating the capacity for enjoying close, harmonious relationships conveyed in a post
LIWC: QMark	# of the occurrence of question mark	LIWC: Exclam	# of the occurrence of exclamation mark

Table 7: The performance of DL models. The results in bold represent the best performance in each task. The fractions within brackets indicate the increased performance compared to the best performance achieved by Random Forest (Table 3).

	Models	**Accuracy**	**Cohen's κ**	**AUC**	**F1**
Stanford-Urgency	1. Emb-CNN-LSTM	0.9203 (3.23%)	0.8192 (3.80%)	0.9201 (3.20%)	0.9203 (3.20%)
	2. Emb-Bi-LSTM	0.9159 (2.73%)	0.8051 (2.01%)	0.9153 (2.66%)	0.9159 (2.71%)
	3. CNN-LSTM-Tuned	**0.9211** (3.32%)	**0.8210** (4.02%)	**0.9221** (3.42%)	**0.9221** (3.40%)
	4. Bi-LSTM-Tuned	0.9210 (3.30%)	0.8196 (3.85%)	0.9208 (3.28%)	0.9210 (3.27%)
	5. SCL-Tuned	0.9210 (3.31%)	0.8206 (3.98%)	0.9215 (3.35%)	0.9219 (3.38%)
Moodle-Content	6. CNN-LSTM-Tuned	**0.7934** (5.17%)	**0.6230** (5.11%)	**0.7952** (5.32%)	**0.7993** (4.33%)
	7. Bi-LSTM-Tuned	0.7854 (4.11%)	0.6220 (4.93%)	0.7901 (4.64%)	0.7913 (3.29%)
	8. SCL-Tuned	0.7716 (2.29%)	0.6092 (2.77%)	0.7733 (2.42%)	0.7803 (1.85%)

gency).

Moreover, when solely using the top 10 features as an input, the performance of Random Forest was 3.25%∼7.31% lower than the performance obtained after incorporating all available features (Table 5). This finding hence confirms that while the traditional ML models can achieve good classification performance using only the top 10 best features, there is still potential for improvement when using more features. Hence, researchers should attempt to apply more features to fully unleash traditional ML models' capability.

Results on RQ2. The performance of the implemented DL models is presented in Table 7. As Moodle-Content contained only 3,703 labeled posts, that was likely to be insufficient to support the training of CNN-LSTM or Bi-LSTM from scratch. Therefore, we only implemented the fine-tuned models, i.e., CNN-LSTM-Tuned, Bi-LSTM-Tuned, and SCL-Tuned on Moodle-Content. Several observation can be derived based on the results in Table 7.

Firstly and unsurprisingly, DL models uniformly achieved a better performance than traditional ML models. This corroborates findings reported in [59, 54, 33, 24]. DL models are, therefore, superior to traditional ML models in terms of capturing the characteristics of a dataset and obtaining better classification results. However, we should note that the performance difference between traditional ML models and DL models was not that large. Specifically, the best-performing model CNN-LSTM-Tuned achieved an improvement of only 3.32% in Accuracy, 4.02% in Cohen's κ, 3.42% in AUC, and 3.40% in F1 score. In particular, the Cohen's κ score was 0.8210, which suggests an almost perfect classification performance.

Secondly, contrasting findings reported in [59], we found that CNN-LSTM slightly outperform Bi-LSTM in most cases (i.e., Row 1 vs. Row 2, Row 3 vs. Row 4, and Row 6 vs. Row 7 in Table 7). Thirdly, instead of using BERT for embedding initialization, the classification model would achieve better performance by fine-tuning BERT by coupling it with the task model and training the coupled model as a whole (i.e., Row 1-2 vs. Row 3-4 in Table 7), though the improvement was rather limited, e.g., less than 1% when comparing to that of Emb-CNN-LSTM and CNN-LSTM-Tuned on Stanford-Urgency. Fourthly, we showed that in Stanford-Urgency, by simply coupling BERT with a single classification layer (SCL-Tuned, Row 5 in Table 7), the classification perfor-

mance was almost as good as those derived by coupling BERT with more complex DL models like CNN-LSTM and Bi-LSTM (Row 3-4 in Table 7). This implies that, BERT can capture the rich semantic information hidden behind a post, which can be used to deliver adequate classification performance even by employing a single classification layer.

5. DISCUSSION AND CONCLUSION

The classification of educational forum posts has been a longstanding task in the research of Learning Analytics and Educational Data Mining. Though quite some previous studies have been conducted to explore the applicability and effectiveness of traditional ML models and DL models in solving this task, a systematic comparison between these two types of approaches has not been conducted to date. Therefore, this study set out to provide such an evaluation with aiming at paving the road to researchers and practitioners to select appropriate predictive models when tackling this task. Specifically, we compared the performance of four representative traditional ML models (i.e., Logistics Regression, Naïve Bays, SVM, and Random Forest) and two commonly-applied DL models (i.e., CNN-LSTM and Bi-LSTM) on two datasets. We further elaborate on several implications that our work may have on the development of classifiers for educational forum posts. We also list limitations to be addressed in future studies.

Implications. Firstly, the performance difference between traditional ML models and DL models was not as large as reported by previous studies (e.g., [59]). More specifically, we showed that traditional ML models were often inferior to DL models in terms of only 1.85% to 5.32% decrease in classification performance measured by Accuracy, Cohen's κ, AUC, and F1 score. This finding implies that, when researchers and practitioners have no access to strong computing resources and, for this reason, cannot utilize DL models, they can still achieve acceptable classification performance by using traditional ML models, as long as those ML models incorporate carefully-crafted features.

Secondly, our results demonstrate that the performance of Random Forest classifier is more robust compared to other traditional ML models. This implies that other more advanced tree-based ML models (e.g., Gradient Tree Boosting [9]) might be worth exploring to achieve even higher classification performance. Besides, given that the most important feature in Stanford-Urgency was *# views* (Table 6) and the models' performance in Moodle-Content might be suppressed due to the unavailability of metadata features, it may be worth paying special attention to acquiring and using metadata features when applying traditional ML models. Another finding suggests that little overlap was detected between the top 10 most important features selected in each of the two classification tasks (Table 6). This implies when tackling a classification task, features should be designed to suit the unique characteristics of the task and fit the theoretical model utilized to annotate data (e.g., with predefined coding scheme). This aligns with findings presented in [31, 38, 19], in different phases of cognitive presence, different importance scores were obtained for the same features. Lastly, researchers and practitioners may wish to take advantage of pre-trained language models like BERT when developing DL models. Our experiment showed that BERT can be effectively used in two ways, i.e., (i) to initialize the word embeddings of the post text as the input for a task model; or (ii) to suit the needs of the specific classification task by coupling itself with the task model and then fine-tuning model parameters. Particularly, the second way enables DL models to be applicable to tasks that deal with only a small amount of human-annotated data, like in Moodle-Content).

Limitations. Firstly, the evaluation presented in this study focused only two classification tasks, i.e., Stanford-Urgency and Moodle-Content. To further increase the reliability of the presented findings, more tasks should be included and investigated, e.g., determining the level of confusion that a student expressed in a forum post or whether the sentiment contained in the post is positive or negative [10, 54]. Secondly, a few types of features were not included when exploring the capabilities of traditional ML models in our evaluation, e.g., *# domain-specific words* and *LDA-identified words*. To accurately depict the upper bound of the performance of traditional ML models in classifying educational forum posts, it would be worthy to recruit domain experts to further engineer and make use of these features. Thirdly, we should notice that the DL models used in our evaluation (i.e., CNN-LSTM and Bi-LSTM) only utilized the raw text of a post as input and left the metadata features untapped. Given that metadata features have been demonstrated of great importance in the application of traditional ML models, future research efforts should also be allocated to design more advanced DL models that are capable of using both the raw text of a post and the metadata of the post for classification.

Lastly, we acknowledge that, due to the scope of this study, we did not attempt to investigate the reasons causing the performance difference between traditional ML models and DL models, e.g., whether the two categories of models misclassified the same types of messages. In the future, we will further investigate whether the performance difference between traditional ML models and DL models can be attributed to their model structures and explore potential methods to boost their classification performance, e.g., collecting additional forum posts to continue the pre-training of BERT before coupling it with a downstream classification model.

ABSTRACT

Engaged and disengaged behaviors have been studied across a variety of educational contexts. However, tools to analyze engagement typically require custom-coding and calibration for a system. This limits engagement detection to systems where experts are available to study patterns and build detectors. This work studies a new approach to classify engagement patterns without expert input, by using a play persona methodology where labeled archetype data is generated by novice testers acting out different engagement patterns in a system. Domain-agnostic task features (e.g., response time to an activity, scores/correctness, task difficulty) are extracted from standardized data logs for both archetype and authentic user sessions. A semi-supervised methodology was used to label engagement; bottom-up clusters were combined with archetype data to build a classifier. This approach was analyzed with a focus on cold-start performance on small samples, using two metrics: consistency with larger full-sample cluster assignments and stability of points staying in the same cluster once assigned. These were compared against a baseline of clustering without an incrementally trained classifier. Findings on a data set from a branching multiple-choice scenario-based tutoring system indicated that approximately 52 unlabeled samples and 51 play-test labeled samples were sufficient to classify holdout sessions at 85% consistency with a full set of 145 unsupervised samples. Additionally, alignment to play persona samples for the full set matched expert labels for clusters. Use-cases and limitations of this approach are discussed.

1. INTRODUCTION

Engagement represents a necessary (though not sufficient) condition for learning. Engagement has been shown to impact learning [4] and persistence [9]. Research has also found that engagement is actionable and can be increased [25]. This is a particularly important topic for computer-based learning: unlike in a classroom, where engagement can be assessed and acted on by an instructor in real-time, patterns of engagement are often not visible [10].

However, building engagement analytics for a new system is time consuming. Custom metrics are typically developed and then require substantial data to identify patterns (i.e., the cold-start problem). Worse, the extensive effort to design such analytics is buried in application-specific code. While heuristics are available to infer disengagement, such as response times under 3 seconds [6], applying these to different systems requires benchmarking and calibrating detectors for the content and system. Efforts to analyze engagement often start almost from scratch. This is unfortunate, since research on behavioral engagement has identified patterns which appear to generalize across systems [3, 4, 6, 14, 15].

To address this gap, we are researching a service for analyzing and classifying engagement that relies on a standards-based learning record store [1]. This effort is called the Service for Measurement and Adaptation to Real-Time Engagement (SMART-E). Rather than being optimized to analyze a specific system or data set, SMART-E targets three high-level goals: 1) *Cold-Start Calibration*: ability to identify and benchmark engagement behaviors, which does not require large data sets or in-depth expert analysis; 2) *Re-Usability*: reliance on standards and data available from most learning environments; and 3) *Actionability*: generation of actionable insights, which an instructor or adaptive system could leverage or investigate further.

SMART-E is influenced by two techniques: 1) *semi-supervised learning*, which trains with a small set of labeled data and

a larger set of unlabeled data and 2) *play persona*, behavioral archetypes commonly used for testing and analysis of video games [7, 32]. Our paper describes the process and findings from applying this approach to a data set from a scenario-based tutoring system for training counseling skills. Contributions from this work include a) reviewing features that generalized engagement analytics should consider, b) developing a pipeline for analyzing engagement which does not require expert labeling or application-specific feature engineering, and c) demonstrating the effectiveness of a semi-supervised approach with reasonable data requirements (e.g., about 50 samples each of labeled and unlabeled data) to approximate inferences that experts might make given similar data. As such, this research represents a step toward a generalized framework for diagnosing learner engagement that does not require an expert researcher analyzing data or observing subjects.

2. BACKGROUND AND THEORY

Across the learning science community, engagement is defined and measured in vastly different ways, ranging from split-second physiological responses (e.g., eye tracking, facial affect) to long-term trends lasting months or years (e.g., returning to a system, building social ties) [2, 13]. The research in this paper targets behavioral engagement at the task level (e.g., time spent working through a problem) and session level (e.g., sustained effort to improve performance and learning).

A key reason for this focus is data availability and data interpretability. Most systems collect data logs at these levels and, as described next, substantial research has also identified common behavioral patterns. Research on lower-level affective cues (e.g., facial affect) has found certain actionable events that generalize (e.g., gaze inattention [15]), but other patterns are not trivial to generalize due to differences between individuals or across contexts [28]. Moreover, facial data is often unavailable due to the privacy issues involved with recording learning. Larger time scales are not the focus of this work because engagement levels over those time scales would require longitudinal data and also are more likely to be visible to instructors (e.g., absences).

2.1 Patterns of Behavioral Engagement

Behavioral engagement analysis from log files has shown repeated evidence of useful, actionable patterns, such as response time, response time vs. accuracy/correctness interactions, approach vs. avoidance behaviors relative to problem difficulty (e.g., skipping hard problems), and noisiness of answer quality (e.g., carelessness) [5]. Response time, particularly very fast response time, is one of the most obvious features linked to behaviors associated with disengagement (e.g., guessing, skipping, straight-lining). For scored tasks, the interaction between response time and correctness has been extensively researched in the study of basic cognition as well as authentic learning tasks [6]. The relationship between correctness and time is frequently a logistic relationship (assuming that time does not directly impact scoring): with very fast responses, correctness is approximately random, increasing rapidly to better than chance for more ordinary response time, and approaching an individual skill-level asymptote as time increases. At very large times, answer quality may once again decrease, either due to distraction (e.g., multi-tasking) or difficulty selecting a final answer [27].

More complex interactions often require understanding the relative problem difficulty. Research indicates that students with poor learning outcomes tend to avoid or abuse hints on problems that they find difficult [5]. Conversely, self-regulated learners may be more likely to skip or "game" through problems that that are easier relative to their skill level but dedicate more time to harder problems [33]. While not yet investigated, this might also imply that more self-regulated learners may be less likely to demonstrate wheel-spinning [18] since they are more actively monitoring the usefulness of tasks.

Estimates of answer correctness versus expected correctness have also been used, though these are likely most clear when the learner is close to mastery. Of these, carelessness and "slips" are the most well-established mechanisms [12]. More generally, there may be value in investigating any situation where correctness appears decoupled from traditional factors (e.g., little correlation between time and answer quality, little correlation between expect mastery and later performance). However, such decoupling could be due to poor task design (e.g., item response issues [20]) or problems unrelated to engagement (e.g., attention or memory problems), so additional context may be needed to interpret this.

2.2 Archetypes for Behavioral Engagement

When considering these different patterns of behavioral engagement and disengagement, we posit that engagement has at least two dimensions: a) passiveness vs. activeness and b) avoidance vs. approach. For example, passive avoidance represents disengagement commonly associated with boredom such as distraction or skipping through material. By comparison, other learners employ short-cut strategies to cheat or cherry-pick tasks to minimize effort while still providing acceptable performance (active avoidance). A similar division exists for engaged learners, in that some study almost exclusively on assigned content (passive approach) while others monitor and self-regulate their effort to focus their learning (active approach).

These latent engagement factors may be evident through different observed patterns. For example, while distraction and racing through material both represent disengagement, their data patterns will look very different. In considering these patterns, we developed the following candidates which may be evident across a variety of systems:

- Diligent (Active Engagement): Spends somewhat more time on tasks and shows correspondingly better performance, and more likely to complete optional tasks.
- Self-Regulated (Active Engagement): Seeks out and spends greater time on harder tasks, but may skip or disengage on easier tasks. [22, 33].
- Cherry Picking (Active Disengagement): Seeks out easier tasks or abuses features to make tasks easier (e.g., hint abuse), and avoids harder tasks [3].
- Nominal Engagement (Passive Engagement): Completes tasks as recommended or assigned, with ordinary time-on-task and performance.

- Expert/Recall (Passive Engagement): Regardless of difficulty level, completes tasks very rapidly and with high performance. Possibly an expert on the content, but might also be shallow recall or lookup.

- Racing/Guessing (Passive Disengagement): Rapidly answers (potentially multiple times) despite relatively poor performance [26].

- Distracted/Slow (Passive Disengagement): Uncommonly delayed or irregular answers, particularly when extra time does not appear to improve performance [27].

As with prior research on engagement, we do not assume that these archetypes are necessarily stable for a specific user across all content, but that they represent modes of interaction during learning. Additionally, these candidate patterns are not exhaustive and the specific evidence for each pattern may not be identical: while racing through material might involve rapid guessing in one system, in another it might involve skipping material entirely. Historically, this has meant that detectors are tuned using expert-labeled observations and/or expert feature engineering.

2.3 Play Persona as a Labeling Methodology

This work applies a new approach to generating engagement labels for user sessions. While substantial research has been conducted on engagement, existing methods for determining engagement during computer-based learning are challenging to scale. Our research is intended to complement three methods currently in-use: expert observers, sensor-based affect detection, and self-report [13].

Expert observers can be trained on a specific coding manual until they reach high levels of agreement. Using techniques such as BROMP [29], a trained observer can monitor and label engagement events for multiple students. The primary barriers to collecting this data are the number of trained observers required and issues of privacy and technology (e.g., observing students in online courses). Automated affect detection (e.g, automated facial affect detection) has also been used to analyze engagement [28, 19]. While in principle facial affect scales to a large number of learners, engagement is hard to interpret without also analyzing behavioral patterns (e.g., screen recordings, log files). As with human observers, privacy issues may prevent the necessary recording of data. Moreover, for both human and automated labeling, while learner states may be recorded, they do not include any interpretation about what strategies a learner is using (e.g., focusing on hard vs. easy problems). Self-report offers a different type of engagement label. Users can report their overall engagement and may also be able to describe the learning strategies that they are using [13]. However, self-reported engagement can be affected by reporting bias (e.g., claiming to be more engaged) or subjectivity of engagement ratings.

To address these limitations, we identified play persona as a way to generate labeled engagement data. Play persona are behavioral archetypes often used for testing and analysis of video games, that reflect different goals and behavior patterns [35, 32]. For example, in a strategy game there are recognized archetypes such as the Builder (invest in long-term expansion) versus Greedy-Optimizer (take quick wins) [34]. Likewise, research on Massive Multiplayer Games (e.g., [36]) has identified behavior archetypes such as competitors who focus on head-to-head tasks and explorers who focus on exploring the world. Artificial game players can be crafted to mimic these play persona for procedural play-testing [21].

We hypothesize that play persona methods can also be useful to identify and label engagement patterns with the modification that human testers will act out these roles (e.g., diligent) which would be difficult to simulate artificially. If this approach is useful, it has at least three advantages over existing methods. First, it ensures rapid data collection of labels, since rather than having unbalanced labels (i.e., 80% of real users might be in one bin), testers can be directed to act out a variety of roles. Second, play-test labels should be interpretable since the intent of the learner is known, as opposed to purely bottom-up patterns or self-reported labels, which require experts to infer underlying strategies. Finally, despite some constraints (e.g., difficulty in faking more or less knowledge), dedicated testers may be able to play out multiple archetypes and do so repeatedly, reducing the need to recruit new testers.

3. RESEARCH QUESTIONS

This work investigates techniques to leverage play-testing data for detecting engagement patterns. However, this approach will only be feasible if testers reasonably approximate the behavior of real users. It also relies on the assumption that while systems may differ, the main engagement archetypes will be fairly predictable (e.g., some users will be highly invested in learning every piece of content, others will be trying to get through as fast as possible). In this work, we examine the feasibility of play-testing to help classify engagement patterns, and in particular investigate the following questions:

- Q1 (Distinctiveness): Are the data patterns for a set of play-tester archetypes distinct (different testers act similarly, given similar instructions)?

- Q2 (Alignment): Will play-test archetypes align with unsupervised clusters producing labeled clusters similar to how experts would label them?

- Q3 (Semi-Supervised Comparison): Will a semi-supervised approach that builds a classifier from play-test and aligned data label individual learners more consistently than relying only on bottom-up clusters?

- Q4 (Basic Features): Will average response time and scores, in simple systems, be sufficient for reasonable engagement labels?

- Q5 (Expanding Features): Will increasing the number of features to include task difficulty and feature interactions lead to greater consistency in fewer samples?

These questions investigate the strengths and limitations of the approach. Specifically, Q1 and Q2 focus on the reliability of play-test labels to label unsupervised data, as compared to human ratings. Q3 examines if building a semi-supervised

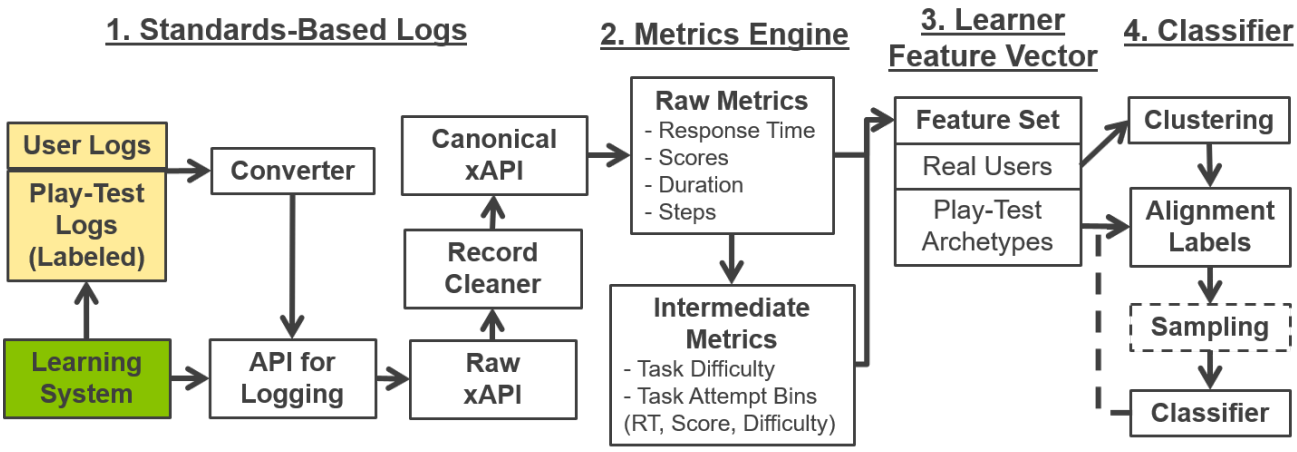

Figure 1: SMART-E Analytics Pipeline Phases

classifier is useful as opposed to simply using archetypes to label bottom-up clusters. Q4 and Q5 query the effectiveness of feature sets identified in the literature for classifying engagement, starting with a very minimal set (response time and scores) and then analyzing an expanded set of features for their impact on cold-start performance.

4. METHODS

To examine these questions, an analytics pipeline was developed and then applied to a data set from a scenario-based intelligent tutoring system. This section will briefly describe the pipeline, then the learning system that produced the data set, and finally the techniques used to investigate each research question.

4.1 Engagement Analytics Pipeline

While this paper focuses on a specific data set, the techniques applied here are designed to be generalizable and reusable as part of the SMART-E pipeline, shown in Fig. 1. This pipeline starts by standardizing the data available, recording data from an arbitrary learning system as learning records that meet the xAPI standard [1]. This "Raw xAPI" data may either be sent directly by the system (e.g., through an API for logging) or generated by running a converter on system logs after-the-fact. Raw xAPI data logs are then cleaned by a script (partially system-specific) which corrects common data problems, such as sessions that terminated improperly or missing data fields that can be inferred from other data. This ensures that the Canonical xAPI data store does not have missing data.

All xAPI records contain metadata which allow them to be structured into an activity tree, representing both sequential and parallel tasks. While the tree can be nested arbitrarily, four levels are analyzed to generate raw metrics tables: steps, tasks, lessons, and sessions. Raw metrics primarily record time-based information (e.g., duration of a task, response time for first step), score-based information (e.g., numerical score and/or correctness), and support used (e.g., hint counts, retrying a problem).

Metrics related to task skills are not calculated, since the majority of systems do not tag their tasks with a consistent ontology of knowledge components. Intermediate metrics are generated using feature construction calculations based on raw metrics, without analyzing the xAPI logs. For this work, the most important intermediate metrics are averages across attempts (e.g., average scores, average task duration), the average difficulty for each task (inferred from first-attempt scores), z-scores for task metrics (e.g., time-on-task for the learner relative to other users) and a Laplace-smoothed logarithm of each task duration (i.e., $ln(t+1)$). Additional metrics can be added fairly rapidly, if they rely on raw metrics.

Based on these metrics, feature vectors are generated that represent each learner's performance in the system. In the current work, these vectors rely on all of the learner task data for a session, though one could generate similar features for specific tasks, across multiple sessions, or for recent tasks in a session (i.e., any collection of tasks). First, two simple features were calculated: average response time across tasks (Avg. RT) and average task performance (Avg. Score). These were considered the minimal information to potentially infer engagement.

Next, a more complex feature set was developed to model interactions between task response time (RT), task scores, and task difficulty. Based on z-score cutoffs, the value of each variable was placed into one of three categories (low, medium or high) when possible, and into the most categories available when not (i.e., only medium if all values equal; only low and high if only two types of values). This was done based on a one-dimensional Gaussian distribution, with cutoff values at <33% (low), 33-66% (medium), and >66% (high). Further we ensured that each variable had at least 4 corresponding data-points in order to arrive at robust cutoffs (i.e., each unique task had been attempted by at least 4 different learners, to judge its difficulty, score and time distribution). Each scored task increments a bin associated with its three variables (e.g., RT=fast, score=high, difficulty=high will increment exactly one out of 27 possible bins). This binning approach is fairly general, and can be inferred using only standard logging data.

Since 27 bins will often be fairly sparse for an individual

learner, these were aggregated to form 7 bins which align to behavioral engagement patterns from the literature: Expert, Cherry Picking, Engagement/Diligent, Self-Regulated, Distracted, Racing, and Careless. These bins roughly correspond to the patterns we introduced earlier except we omitted Nominal Engagement, roughly equivalent to average, and we added a Careless bin focused on errors on easier tasks. The Expert bin was increased whenever high scores were obtained for difficult problems with only a normal or low delay or for high scores on ordinary problems done quickly. The Cherry Picking bin incremented for high scores with a low delay (regardless of problem difficulty). Engagement/Diligent was incremented when difficult problems were completed after a high delay. Self-Regulated was incremented when the amount of time spent on the problem was at least as high as the difficulty level, even if the score was not high. Distracted was triggered in the opposite case, where the time to respond was overly long for the difficulty of the problem. Racing was incremented for fast responses, either with low scores or with medium / high scores on easier problems. The Careless bin included only low scores on easy problems or low scores on medium difficulty problems when completing them quickly.

These bins were not mutually exclusive, since more than one behavior might explain a given interaction. Additionally, they are not validated and should be thought of as noisy constructs to bin low-level features, rather than necessarily predictive of their given labels. However, since these aggregation patterns are derived from the literature, these features are candidates that may be relevant across different systems, users, or data sets.

4.2 User Data: ELITE Scenarios

We use data from the system, ELITE Lite Counseling, designed for U.S. Army officers in training to learn leadership counseling skills, such as active listening, checking for underlying causes, and responding with a course of action [11]. Learners select what to say to virtual subordinates from a menu leading to different points in a branching graph representing the possible conversations. The virtual subordinates speak using pre-recorded audio and act via 3D animations.

Each learner choice can have both positive and negative annotations. Positive annotations correspond to correctly applying a skill such as active listening, and negative annotations correspond to omissions or misconceptions. Based on these annotations, a choice can be fully correct (only positive annotations) or two forms of incorrect: fully incorrect (only negative annotations) or mixed (both positive and negative annotations). For the pipeline, this was converted to two forms: a correctness category and a numerical score in which mixed answers were given partial credit (0.5) compared to correct answers (1.0) and incorrect answers (0.0).

Each simulated conversation is also followed by an After Action Review (AAR) in which learners are asked multiple-choice questions about all of their dialogue choices that were mixed or incorrect. For these AAR questions, if the first attempt to answer was successful the learner earned a score of 1; otherwise, the learner earned a score of 0 but had to keep trying until they selected the correct response.

The ELITE data set for this research included a corpus of 145 subjects from experiments described here [17] which we consider user data. Each "user" completed three scenarios: Scenario 1, Scenario 1 (Repeated), and Scenario 2. Due to the dialog trees, users did not all see the same decision tasks when completing the same scenarios. However, substantial overlap was observed for tasks and a majority of tasks were attempted by a significant number of users. For the purpose of estimating task difficulty, a threshold of 5 attempts was used, below which the difficulty and metrics relying on difficulty (e.g., binning) could not be calculated.

4.3 Play Persona Data

Play-testers were students and employees of the lab who volunteered their time, and generally were not familiar with the scenario content. For the ELITE system, only 5 play-test archetypes were reasonable to classify: Expert, Diligent, Nominal Engagement, Racing, and Distracted. Play-testers followed the same protocol (i.e., scenario 1, scenario 1 repeated, scenario 2) used to collect the user data. Thus, they had no direct control over the tasks they encountered, and so some patterns were unlikely to be observed (e.g., Self-Regulated and Cherry Picking).

Each play-tester was able to generate data for up to three archetypes, by attempting them in a specific sequence. First, they could play as either Diligent or Distracted. These roles could only be played at the beginning of testing to simulate a novice seeing the system for the first time. Next, a Racing run was completed; fast response times meant testers would still make errors despite their previous practice. Expert runs were collected in two ways: either an actual expert generated the data (2 sessions), or a tester carefully reviewed the correct answers (e.g., in the AAR) and/or was coached by an expert (13 sessions). These different methods for "expert" data produced similar results, though actual experts were slightly faster. In the unlabeled data, an archetype for Nominal Engagement was generated by extracting five clusters and assigning Nominal Engagement to the cluster not aligning with the other four archetypes.

Instructions for each play-test archetype were as follows. **Diligent:** spend as much time as you need on each choice to try to get the best answer, including reading carefully, and double-checking answers. **Distracted:** engage in one or more competing activities, including checking email and responding when relevant, browsing social media, engaging in a conversation, and eating. **Racing:** pretend you don't care much about the content, so you are doing the bare minimum and are fine with a so-so score to get done quickly. **Expert:** review content in-depth immediately ahead of time, and approach it with as many answers memorized or quickly-available as possible (e.g., in notes, from an expert) so you can answer well quickly. Of these, all except Distracted were easily understood by testers. Due to the lack of standardization for Distracted, some testers struggled to find a competing distraction task (e.g., did not use much social media, did not have high email volume, already ate lunch). In this case, a member of the research team asked the user questions or other requests to distract them. A total of 51 archetype sessions were collected, which may be more than necessary, since preliminary analyses found similar results with about 25 points balanced across classes.

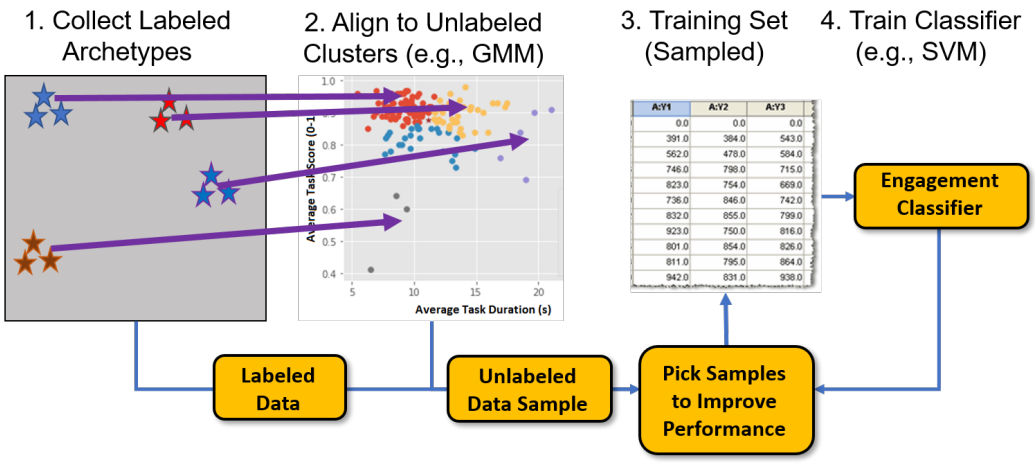

Figure 2: Semi-Supervised Classifier Training

4.4 Cluster Alignment Testing

As shown earlier in Fig. 1, both the real user data and the play-tester archetype data were processed by SMART-E to generate feature vectors that represent each individual. A number of techniques were then applied to generate labeled clusters. This cluster-labelling process allowed us to classify a learners' engagement coarsely on the basis of the cluster that they were assigned to.

First, user feature data was clustered bottom-up into five distinct clusters using k-means and Gaussian mixture models (GMM) methodologies as implemented in the scikit-learn package [30]. The number of clusters was verified through an elbow-curve analysis of variance explained (elbow at k=5). Exploration of k=4 and k=6 found both to be less stable; cluster assignments were often very different for subsamples of data points, with k=4 being particularly unstable.

For this analysis of the full sample, we associated each user cluster with a unique archetype (i.e., alignment of the smaller archetype clusters with the user clusters). The alignment was determined using the Hungarian Method (Kuhn-Munkres algorithm)[24], which is a global, optimal-matching algorithm which minimized the sum of the Euclidean distances between these user cluster centroids and archetype centroids. As noted previously, the Nominal cluster was determined as the cluster remaining after all archetype groups were matched. As a result, each of the user clusters (and consequently the points within that cluster) had an associated unique archetype which additionally served as its label. When this cluster alignment process is used as the only technique to label points, it will be referred to as *Clustering Alone*.

4.5 Semi-Supervised Classification

This technique of clustering alignment was compared against a semi-supervised approach that built a classifier using the play-test and user clusters. The high level concept of this semi-supervised classifier is shown in Fig. 2. The first two steps of the semi-supervised approach are the same as Clustering Alone. This generates a pool of weakly-labeled candidate labeled points. The points in this pool can be either taken as a full set to train a classifier model such as SVM or they can be sampled to incrementally train a classifier using active learning techniques until a stopping rule is hit (e.g., entropy sampling).

To compare the classifier against cluster-level labels based on archetype alignment alone, we calculated two quality metrics for the labels given to user sessions, which we will term *consistency* and *stickiness*. Consistency refers to the fraction of sessions that are labeled with the same engagement archetype which they would receive when the full data set is available. This is important because as data gets larger, unsupervised clusters are more likely to reflect the true distributions.

Stickiness refers to the likelihood that a user session retains the same engagement label after a batch of new data is added (similar to intra-rater reliability). This is important for actionable engagement metrics: if Student A is classified as Diligent, it will be confusing if Student B who completes an identical run is classified differently due to data that arrived in between. While this cannot be fully avoided, approaches that tend to keep the same label for an identical session will appear more fair and reliable, so that an instructor could be more confident in using the classifications.

That said, neither consistency or stickiness alone are sufficient for useful classification. For example, always assigning all users to the same category maximizes both metrics. However, assuming clusters for the full data set are reliable, then these measures help to identify how quickly and reliably labels approximate the final labels. This is important for addressing the cold start problem, so that engagement patterns can be quickly identified in a new system.

To calculate the number of samples to reach a given level of cold start performance, random splits were made of the user data set into train-test subsets (115 train, 30 test). For each random split, the classifier was trained using the archetype data set (51 samples) and increasingly larger subsets of the user training data in increments of 5. When evaluating cold-

start performance, a consistency of 85% was considered a reasonable target threshold for reliability against the full sample. While the actual consistency required will depend on the specific application, this cutoff should give some insight into how quickly different approaches converge toward their larger-sample performance.

Since the pipeline parameterizes the specific algorithms, follow-up exploratory analyses were conducted with different types of clustering algorithms (e.g., k-means, GMM), classification algorithms (e.g., logistic regression, support vector machines), and semi-supervised sampling algorithms (e.g., full sampling, margin sampling with stopping rules to exclude certain unsupervised samples). Different combinations of these algorithms did not show qualitatively different end-results on these metrics, and any differences were not conclusive (e.g., GMM clusters appeared slightly more stable than k-means as data was added, but within random variation). As a result, this paper presents results for the GMM clustering with a Support Vector Classifier, where these results are representative for the different approaches explored.

5. RESULTS

Focusing on GMM clustering, we revisit the alignment of the five user clusters with the play-tester archetype groups. The clusters were generated using the average of the logarithms for task response time (Log-RT) and average of task scores (Scores). Fig. 3 plots the real user data with unsupervised clusters. Table 1 shows feature means and standard deviations for each archetype, above its most closely-aligned bottom-up cluster. Note that while Log-RT was used for clustering, the actual time in seconds is given in the table and figure for easier interpretation.

Despite being generated independently, the play-test data closely resembles the real bottom-up clusters. As a trend, the play-tester archetypes tend to be more extreme (i.e., farther from the average user) than the clusters they align to. This is likely due to play-testers acting out more exaggerated or consistent patterns than real users. However, this may actually be an advantage, since play-test archetype data points may be more likely to be outliers in the vector space and good anchors for distinct clusters. The results from Table 1 support research question Q1, in that play-testers were able to act out similar patterns as real users and that the play-tester data showed fairly distinct groupings (as evident in the standard deviation values). One exception was the Distracted archetype, which had a very high variance for time compared to real users in the corresponding cluster. However, despite the high variance, the Distracted archetype data remained distinct from other archetypes' data.

5.1 Reliability vs. Expert Labels

The validity of this alignment on the full data set was evaluated by surveying a set of external engagement experts (N=5) to label the same bottom-up clusters obtained from the user feature data, based on the descriptions of the engagement archetypes. Selection criteria for experts required a Ph.D. in a relevant area, publishing at least one substantial paper researching learner engagement, and having no prior experience with the data set.

Experts labeled cluster graphs (e.g., Fig. 3) generated by both k-means and GMM, and maintained quite similar labels across each (76% agreement). Since the clusters and labels for both GMM and k-means were very similar, all labels were treated as examples from the same task. Inter-rater reliability metrics were moderate between experts: 55% Agreement; Fleiss' kappa = 0.44; Krippendorff's alpha = 0.45. Expert raters had very high reliability for Expert and Racing labels, but approximately half of experts demonstrated a consistently different interpretation for Diligent, Nominal (phrased as "Average" in the survey), and Distracted. Based on open response comments, this may have been the result of interpreting minor wording differences in the prompts (e.g., "novice learners" for Diligent vs. "learners" in Distracted).

The human labels for clusters were then compared pairwise against the automated alignments, resulting in Agreement, Fleiss' Kappa and Krippendorff's alpha metrics which were higher than within-experts though still in the moderate range: 66% Agreement; Fleiss' kappa = 0.57; Krippendorff's alpha = 0.58. Given these results and expert sensitivity to the wording of archetype descriptions, we conclude that the automatic alignment appears to be at least as useful as expert consensus ratings for labeling engagement clusters. We anticipate automatic alignment to be even more advantageous when the feature space expands beyond 3 dimensions, making it difficult for human experts to visualize or evaluate.

Group	N	Avg. RT (s)	Avg. Score
Expert (Arch)	15	8.53 ± 2.43	0.95 ± 0.04
Cluster 1	25	8.10 ± 1.00	0.93 ± 0.03
Diligent (Arch)	14	13.15 ± 3.83	0.89 ± 0.07
Cluster 2	75	11.06 ± 1.61	0.90 ± 0.03
Nominal (Arch)	-	-	-
Cluster 3	13	8.63 ± 1.11	0.82 ± 0.02
Distracted (Arch)	12	22.27 ± 13.80	0.77 ± 0.17
Cluster 4	28	15.81 ± 3.43	0.83 ± 0.07
Racing (Arch)	10	7.18 ± 2.47	0.56 ± 0.17
Cluster 5	4	7.98 ± 1.08	0.55 ± 0.09

Figure 4: Consistency and Stickiness for Semi-Supervised vs. Clustering Alone

5.2 Consistency of Semi-Supervised vs. Clustering Alone

To evaluate how play-test data can be used to classify new user sessions, a semi-supervised approach was explored which trained a Support Vector Machine (SVM) classifier using both the play-test archetype data and the data from the bottom-up cluster that best aligned to each archetype, with test-set labels determined by the classifier. For the clustering alone comparison case, bottom-up clusters were directly aligned against archetype data to determine their labels and test-set labels were determined based on their closest cluster. 20 random splits were made of the user data set into train-test subsets (115 train, 30 test). For each random split, the classifier was trained using the archetype data set (51 samples) and increasingly larger subsets of the training data set in increments of 5, and then evaluated.

Consistency was calculated against the test set of 30 samples. Stickiness of labels was calculated for each set of labels against the prior set (e.g., model trained on N samples vs. N-5 samples). Due to the higher level of noise for clustering alignment alone, 100 runs were conducted instead of 20 for a smoother average. These results indicated that training a classifier which combined both types of data produced higher consistency and less variation. Specifically, on the basic features (avg. RT and performance only), the semi-supervised SVM reached 85% average consistency at 52 samples (Fig. 4a), while aligned clusters alone required 95 samples to reach this level (Fig. 4c). Clustering alone was more consistent with the full-data cluster labels until approximately 25 samples (i.e., when the user data reached approximately half of the archetype data).

Likewise, the stickiness of labels as data increased reached an average of 85% by 45 samples for the semi-supervised classifier (Fig. 4b). Clustering alone never reached 85% and remained less than 70% on average (Fig. 4d). For both metrics, the variance (blue bars) were larger for clustering alone. One reason for greater variability for clustering alone

is that sparse data for certain cluster regions (e.g., Racing, with only 4 real users), so alignment alone may try to align a non-existent cluster given limited data. However, the semi-supervised classifier appears to mitigate this issue since training is anchored by play-test data points.

These analyses were performed using both the basic features and the expanded feature set (e.g., bins that count instances of engagement behavior patterns based on response time, score, and difficulty categories). Both feature sets required a similar number of samples to reach the same level of consistency (e.g., about 85% consistency after 50 samples). While it is possible that the expanded feature set might produce more valid labels for an instructor (e.g., better reflecting the categories of users who an instructor might follow-up with), this will not be due to improved cold-start performance.

5.3 Semi-Supervised Class-wise Consistency

An analysis of the consistency for labels in individual clusters (Fig. 5) shows similar insights to the overall clustering label consistency. Points in larger clusters (e.g., Diligent, Expert) are consistent fairly quickly. However, small clusters (Racing) may have few/zero examples even when considering as many as 40 data points, and even with 100 data points have poor consistency. As such, classes with few examples might only be useful for a smaller set of use-cases (e.g., sufficient to share with an instructor, but possibly not reliable enough to take an automated action confidently). We also note that based upon the stickiness analysis (Fig. 4d), performance may be limited by the instability of clustering (points moving between clusters even with nearly full data).

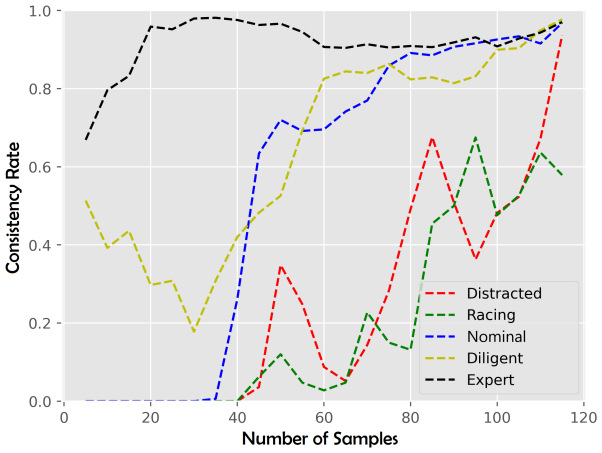

Figure 5: Class-wise Consistency for Semi-Supervised SVM

5.4 Semi-Supervised vs. Final Clusters

The semi-supervised results were compared for their agreement with the labels obtained via alignment with the final clusters generated using the full data set. This final-clusters reference point (see Fig. 3) was used to calculate average accuracy, precision, recall and F-scores (Fig. 6), as a function of the increasing dataset size. While final clusters are not a perfect reference, it shows that accuracy versus final clusters increases fairly rapidly, but that precision, recall and F-scores are consistently lower.

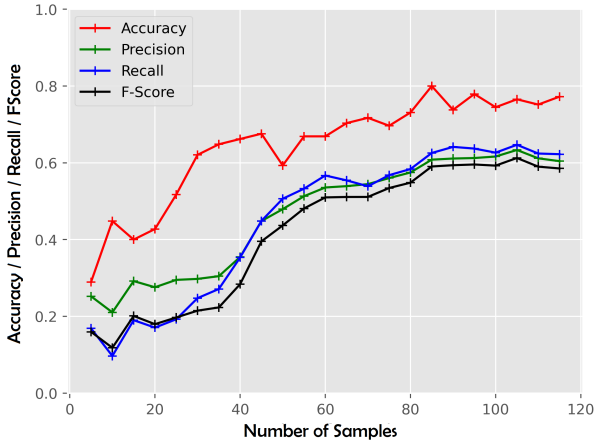

Figure 6: Agreement of Semi-Supervised SVM vs. Final Cluster Labels

6. DISCUSSION

Based on the results presented, this work demonstrates the feasibility of using a play-testing methodology for detecting behavioral patterns of engagement. Moreover, this work also found that a classifier could be developed using this approach without engineering application-specific features. The classifier also offered reasonable cold-start performance and labeled engagement data fairly consistently for 5 categories after 52 unlabeled samples and 51 archetype samples.

Of the five research questions investigated, there was positive support for four answers, with one left indeterminate. For Q1, play-tester data was distinctive and archetype data followed coherent patterns on features (e.g., response time, correctness). Archetype data did not show substantial overlap between archetypes, even though play-testers received only limited instructions. This may be due to the limited degrees of freedom for the task. In a more complex or open-ended system, increased variation might lead to less coherent archetype data. With that said, many systems have similar characteristics to the ELITE scenarios studied here (i.e., sequential linear or branching choice tasks, mixed with passive content such as videos or animations). Moreover, these kinds of systems are often problematic for engagement, such as mandatory corporate training modules.

For Q2, it was demonstrated that automated matching of play-test archetypes against pre-defined clusters performed comparably to expert labels for the same clusters. While refining instructions might improve inter-rater reliability on this specific task, the features presented to experts were already chosen to be simple and visualizable so this represented an optimistic scenario for expert cluster labeling. On more complex feature sets or systems, expert analysis might not even be possible. The broader question not explored in this work is the machine vs. human play-test agreement if they were not given pre-defined clusters (i.e., a data exploration task). However, this would be challenging to conduct: it requires a deep analysis by each expert researcher and the types of engagement categories might be highly uneven. Alternatively, archetypes might be determined from already-analyzed data sets (e.g., such as for hint-abuse), to

see how effectively traces of play-test disengagement might match authentic disengagement patterns.

For Q3, it was established that training a classifier with both play-test data and unsupervised cluster data showed advantages over simply re-clustering with new unsupervised data and then aligning clusters to archetype data. In some respects, this is not surprising: while the consistency metric used for evaluation is based on the unsupervised results from the full data set, the classifier is able to train with more data up-front (as much as double initially). More importantly, since all key archetypes are present in the play-test data, no category will start unrepresented. This particularly helps for classifying points from relatively rare but distinctive categories (e.g., Racing). However, despite this advantage, points in small classes remained substantially less consistent than those in larger classes.

As a long term issue, it is an open question about the best way to mix this data. Neither data source represents ground truth. The archetype data demonstrates coherent engagement patterns, but these patterns might not reflect the ways real users experience the system (e.g., in the current research, they were exaggerated/overly extreme). The real user data is authentic, but may slowly wash out the classifier with unremarkable samples (e.g., overly ordinary). Exploratory work was conducted where stopping rules were applied to balance the number of archetype vs. authentic samples (derived from active learning techniques, such as margin sampling and entropy sampling), but this has not yet produced obvious improvements. Similarly, techniques for weighting samples might be applied. However, the ideal balance between these data sources probably depends on the target use-case for the classifier. A recommender system may want a classifier that acts on labels regardless of their confidence scores. By comparison, a human instructor might prefer a narrowly-scoped but highly-actionable classifier, which might detect clear outliers but allow the majority of user sessions to be in a non-descript "Nominal" category or not confidently classified.

On questions about the features required to classify engagement, we found that basic features for the log of response times and scores were sufficient in this case (Q4) but did not show improvement with the expanded feature set including task difficulty and feature interactions improved classification (Q5). These features helped to detect engagement behavior that matched patterns observed from play-testing: Expert/Recall, Diligent, Racing, and Distracted as well as Nominal (i.e., matched by exclusion). However, both k-means and GMM tended to split up the mass of points in the region of Expert, Diligent, and Nominal despite these clusters being adjacent to each other. The cluster-alignment approach used in this work was selected primarily for the ability to interpret cold-start trends, while more advanced methods should further improve performance. It might be preferred to investigate techniques such as anomaly detection, which would favor a larger central cluster and smaller outliers which could correspond to atypical behavior which is actionable. Alternatively, alternate semi-supervised techniques are available, such as applying specialized semi-supervised support vector machines (which optimize margins for both labeled and unlabeled data) [8, 31] or more advanced techniques for integrating cluster data [16]. While expanded features did not improve consistency or stickiness metrics (Q5), other systems may still benefit from expanded features. However, additional features also increase the required data and may result in overfitting, need attenuating/filtering features during clustering, or other trade-offs. As such, further research is needed on this problem.

7. CONCLUSIONS AND FUTURE WORK

Based on these findings, this work contributes a number of novel approaches to analyzing engagement. First, this research demonstrates the utility of play persona data gathered during professional or quality assurance testing for training useful data mining algorithms. Since there is no definitive metric for engagement, play-test data offers an additional distinct data source to help recognize engagement and disengagement. To our knowledge, this approach has not been applied to analyzing engagement in learning.

Second, this approach offers advantages over current approaches for cold-start labels. Since the behavioral intentions of the play-test users is known with confidence, these labels offer a good data set to help overcome cold start problems. As compared to traditional approaches such as training observers or collecting in-the-moment self-reported engagement [13, 29], play persona data can be collected prior to real system users. This approach also allows balanced sampling for important but lower-frequency engagement behaviors (such as racing, in this analysis).

Third, we have demonstrated that semi-supervised classifiers trained based on a combination of play-test labels and unlabeled data offer more consistent labels than relying on clustering alone, which has been used to analyze engagement behaviors [23]. Moreover, as shown by agreement with expert labels at the cluster level, the alignment approach can provide similar insights without manually interpreting clusters. While expert interpretation is still ideal, this allows immediate insights without waiting for an expert analysis.

This approach is also pragmatic: System developers should already test and perform quality assurance on their software and content [35]. Behavioral archetype data can be collected during this process, by having testers play out engagement styles in a prescribed order based on their expected learning. Moreover, this work is not unique to specific archetypes: if learners are expected to engage in different patterns, play-testers may be able to produce those patterns instead. However, not all archetypes may be realistically playable by testers. For example, experts cannot typically generate novice answers. As such, this approach may be most effective when testers are similar to authentic users. As such, future work will explore how expert observer labels and self-report data might complement this play persona data.

ABSTRACT

Improving the pedagogical effectiveness of programming training platforms is a hot topic that requires the construction of fine and exploitable representations of learners' programs. This article presents a new approach for learning program embeddings. Starting from the hypothesis that the function of a program, but also its "style", can be captured by analyzing its execution traces, the *code*2*aes*2*vec* method proceeds in two steps. A first step generates abstract execution sequences (AES) from both predefined test cases and abstract syntax trees (AST) of the submitted programs. The *doc*2*vec* method is then used to learn condensed vector representations (embeddings) of the programs from these AESs. Experiments performed on real data sets shows that the embeddings generated by *code*2*aes*2*vec* efficiently capture both the semantics and the style of the programs. Finally, we show the relevance of the program embeddings thus generated on the task of automatic feedback propagation as a proof of concept.

1. INTRODUCTION

Increasingly, programming is being learned through the use of online training platforms. Typically, learners submit their code(s) and the platform returns any syntax errors or functional errors (typically based on test cases defined by the teacher). The exploitation of these data opens up new perspectives to monitor and help beginners in learning programming. They can be used, for example, to identify students who are dropping out, to target bad practices or to propagate teacher feedbacks. These functionalities would allow the learner to be more autonomous during his learning, and the teacher to be more reactive and efficient in his interventions. However, this exploitation requires a detailed analysis of the submitted programs. These training platforms must go beyond a simple syntactic analysis of the script, and allow the associated semantics to be considered. For this purpose, learning program embedding has recently emerged as a promising area of research [15, 13, 17, 7, 2, 3]. A natural way to generate such vectorial and condensed representations is to consider a computer program as a text and to exploit methodologies inspired by Text Mining.

Text mining has attracted a lot of interest in recent years. The representation of texts as vectors of real numbers, also called "embedding", has been at the heart of many recent works. These representations make it possible to project (or 'embed') a whole vocabulary into a low-dimensional space. Moreover, such a representation of words allows to exploit a wide variety of numerical processing methods (neural networks, SVM, clustering, etc.). At that stage, one of the challenges is to capture in these representations the underlying semantic relationships (e.g. similarities, analogies). The work of [11] based on the use of neural networks has been a precursor in this area. Their *word*2*vec* method is one of the most referenced in the field. Its principle is based on the relation between a word and its context (words appearing before and after). To do this, they propose some simple and efficient architectures to learn word embeddings from a corpus of texts. For example, the *CBOW* (Continuous Bag-Of-Words) architecture trains a neural network to predict each word in a text given its context. Their results show the ability of this approach to extract complex semantic relations (analogies) from simple operations on $v()$ projections, s.t. $v(\text{"}king\text{"}) - v(\text{"}man\text{"}) + v(\text{"}woman\text{"}) \approx v(\text{"}queen\text{"})$ or $v(\text{"}Paris\text{"}) - v(\text{"}France\text{"}) + v(\text{"}Italy\text{"}) \approx v(\text{"}Rome\text{"})$.

The transposition of these approaches to computer programs is not straightforward. The code has certain specificities that need to be integrated to have such rich representations [1]. Unlike texts, codes are runnable, and small modifications can have significant impacts on their executions. A program can also call other programs that can themselves call other programs. The context in which an instruction is used is also particularly important in deducing its role. Finally, unlike texts, program syntax trees are usually deeper and composed of repeating substructures (loops). Existing approaches for building program embeddings only partially integrate these specificities. They independently exploit the instructions [3], the inputs/outputs [15], part of the execution traces [17] or the abstract syntax tree (AST) [2]. They

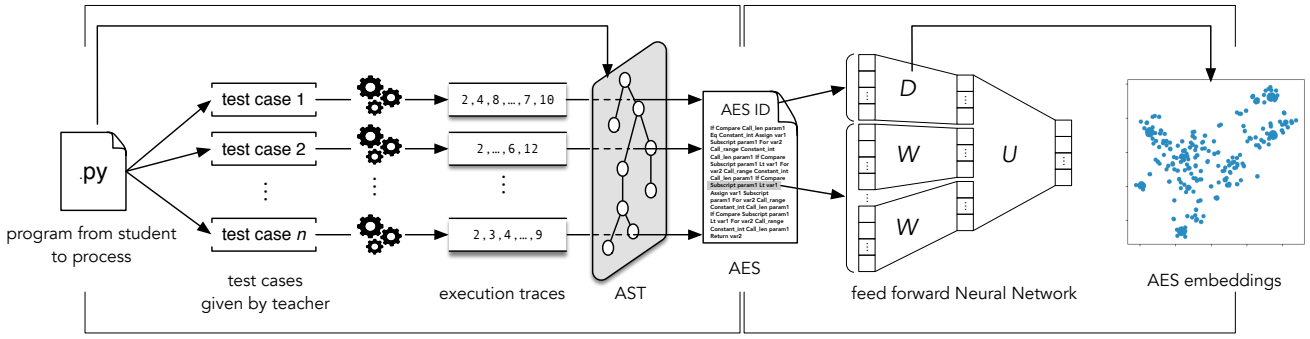

Figure 1: General scheme of the *code2aes2vec* method for learning program embeddings.

focus more on the function of the program (what it does) than on its style (how it does). Moreover, most of these approaches are supervised and build embeddings for a specific task (e.g. predict errors, predict functionality, etc.).

In view of these limitations, we propose the *code2aes2vec* method, exploiting instructions, code structure and execution traces of programs, in order to build finer program embeddings. Figure 1 schematizes the overall approach *code2aes2vec* we propose. The first step of this method consists in generating Abstract Execution Sequences (AES) from traces obtained on test cases executions and program ASTs. The second step uses the *doc2vec*[1] neural network [8] to learn program embeddings from AESs. Contrary to existing approaches, we therefore propose a generic and unsupervised method that learns program embeddings by using functional, stylistic and execution elements. This aspect is crucial in our application to be able to differentiate programs answering to the same exercise (i.e. implementing the same functionality) but in different ways (in terms of strategy or efficiency). Our approach is validated on two real data sets, composed of several thousands of Python programs from educational platforms. On these datasets, we show that embeddings generated with *code2aes2vec* allow to efficiently detect the function and the style of a program. In addition, we present a proof of concept of the use of such embeddings to propagate teacher feedbacks.

To summarize, the main contributions of this paper are :

1. the definition of a new (intermediate) program representation, called Abstract Execution Sequences (AES), allowing to capture more semantics,
2. exploiting these (intermediate) representations with *doc2vec* to build program embeddings in an unsupervised way,
3. the diffusion to the community of two enhanced datasets from educational platforms in computer science,
4. a proof of concept on the use of such program embeddings for feedback propagation for educational purposes.

The next section details existing works in the field and the originality of our approach in relation to it. Section 3 presents our two-steps method: the construction of abstract execution sequences (AES) and the learning of embeddings from them. Section 4 is devoted to the qualitative and quantitative evaluations of the learned representations before drawing up the many perspectives of this work (section 5).

2. RELATED WORKS

Learning representations from programs is at the heart of many recent works. They aim to embed this data in a semantic space from which further analysis can be conducted, because the generated representations (vectors of real values) are directly exploitable by a large part of the learning algorithms. To do this, recent work relies heavily on methods developed to build word embeddings in texts, while trying to integrate the specificities of the code.

These program embeddings are then used for prediction or analysis tasks related to the software development (debugging, API discovery, etc.) and teaching (learning programming). Two types of embeddings are more particularly studied: embeddings of the elements composing a program (words, tokens, instructions, or function calls) [12, 6, 7] and embeddings of the programs themselves [15, 17, 3, 4].

Nguyen et al. [12] study API call sequences to derive an API embedding that is independent of the programming language (thus allowing translation from one language to another). This embedding is learned by *word2vec* [11] from call sequences from several million methods. This method allows to build a word embedding from words appearing nearby in each text (i.e. its context). Two datasets derived from the Java JDK and from more than 7000 recognized C# projects from GitHub (more than 10 stars) are used for learning.

De Freez et al. [6] have a close objective, namely to build an embedding of functions used in a code in order to find

[1]a method derived from *word2vec* that allows to learn a document embedding from its words.

synonymous functions. However, the function calls made in each program are extracted in the form of a graph depending on the control structures. Random walks are then performed in this graph for each function, and the extracted paths are used as input to *word2vec* [11] to derive an embedding of functions. An extract of two million lines of the Linux kernel is used to learn the embedding.

In [7], the authors propose a relatively similar approach but replace function calls with abstract instructions. Each instruction sequence represents a path in the code depending on conditional instructions. In this way, it is similar to a trace even if the code is never executed. All possible paths are extracted but loop repetitions are ignored and only the most frequent instructions are considered (a threshold of 1000 occurrences is used in the experiments). Moreover, only certain constant values are considered to limit the size of the vocabulary. An embedding of these program instructions is then learned by the GloVe method [14] based on the co-occurrence matrix of the words. The authors also use a corpus of 311,670 procedures (in C language) from the Linux kernel, and evaluate it on a data set of 19,000 pre-identified analogies.

In many applications, it is not just a matter of considering the program's components but the program as a whole. Recent work has therefore focused on the construction of program embeddings.

Following a 'teaching' motivation, Piech et al. [15] construct student program embeddings and use them to automatically propagate teacher feedbacks (using the *k-means* algorithm). The embedding space is built from a neural network trained to predict the output of a program using its input. It thus captures the *functional* aspect of the code. The authors also try to capture the *style* of programs, using a recursive neural network based on the program's AST. Contrary to other approaches, the generated embeddings are matrices, not vectors, thus limiting their exploitation as inputs for next data analyses. They also don't consider learner-defined variables. The obtained representations actually capture quite well the code *function*, but fail in capturing the *style* of codes. The analyzed programs (from the Hour of Code site and a course at Stanford) are written in a language similar to Scratch and allow operations in a labyrinthine world.

In [17], the authors highlight the limitations of syntax-based approaches to capture the semantics of a program. Instead, they propose to consider the trace resulting from the code execution, and more precisely the values of the most frequent variables. Different representations are proposed and used to train a recurrent neural network whose objective is to predict errors made by students in a programming course. The embeddings of the programs corresponds to one of the neural network's layers. The authors put forward one representation more particularly, considering the trace of each variable independently and integrating the dependencies between variables in the structure of the neural network. However, the obtained embeddings are specific to one task, and this method requires to redefine the neural network architecture, with re-training, for each exercise.

Finally, Alon et al. [2] propose a neural network to predict the name of a method (i.e. the functionality) from its code. To do this, the program is first decomposed into a collection of paths (from one leaf to another) in the AST. Only the most frequent paths in the dataset are used as features (size constraints are also integrated). Then, the network learns which one is important for predicting the method name using the attention principle. The parameters of the trained neural network correspond partly to the final embeddings and partly to the weights supposed to quantify the importance of each (feature) path for the prediction task (attention principle). Training is performed on a corpus of more than 13 million Java programs from GitHub's 10,072 most popular projects. As mentioned by the authors, this approach requires a large number of input programs. Furthermore, it is not possible to predict the function (and embedding) of a program whose paths do not appear in the training set. The embeddings produced capture information and semantic relationships about the function of the code, but ignore style variants. Thus, two programs with the same function will be similar, regardless of how they have been coded. The quality of the analyzed code also has an impact on learning. The names given to the variables are particularly important for prediction.

3. THE *code2aes2vec* METHOD

Two main strategies emerge for learning program embeddings : by observing the results of program execution [15, 17] or by analyzing the script [3] and/or its AST [2]. Our approach is at the intersection of these two strategies and thus aims to take advantage of the functional and syntactic descriptions of the programs to induce relevant embeddings. We thus propose the *code2aes2vec* method which proceeds in two steps :

1. the *code2aes* step represents a program as an Abstract Execution Sequence (AES), corresponding to the AST paths used by the program during its execution on predefined test cases;

2. the *aes2vec* step uses a neural network to construct the embedding of the programs based on their AES (using the *doc2vec* approach [8]).

3.1 *code2aes*: construction of Abstract Execution Sequences (AES)

Translating a program into an AES requires providing, in addition to the program itself, a collection of test cases on which the program will be run in order to exploit its traces. In our educational context, the preparation of such a collection of test cases is not an additional effort since test cases are generally integrated into training platforms to evaluate submitted contributions. Moreover, this approach offers teachers the possibility of introducing verification choices and thus to drive the interpretation of his/her learners' programs according to his/her own pedagogical choices. For example, let's consider an exercise whose objective is to find a value in a table/list. A teacher wishing to emphasize algorithmic efficiency may choose to integrate a few unit tests for which the desired value appears early in the table. In such case, an efficient program stops the loop as soon as the desired value appears. These test cases will thus make it

possible to distinguish two (valid) programs based on their execution trace.

In practice the number of test cases provided by the teacher is quite small. We generally observe that less than ten test cases are enough to evaluate whether a program is correct or not.

Figure 2 illustrates the process of translating a program into an AES. This example considers as input the code submitted by a learner in response to the exercise "*write a Python function that returns the minimum value in an input list*". First, the AST is constructed. It describes the syntactic structure of the program in terms of control structures (`if-else`, `for`, `while`), function calls (`call`), assignments (`assign`), etc. Second, the code is executed on an example (here the input `[12, 1, 25]`) and its execution trace is kept, indicating the program lines successively executed. Finally, the AES is constructed by mapping these two levels of information: syntactic and functional. The sequence resulting from the trace is translated into a sequence of "words" extracted from the nodes of the AST.

Three levels of translation (or abstraction) are proposed according to the depth considered in the AST:

- AES level 0 : each program line is represented by a single word corresponding to the head symbol of the associated sub-tree in the AST (in red in Figure 2),
- AES level 1 : each program line is represented by one or more words corresponding to the head symbols of the associated sub-tree and its main sub-trees (in red and blue in Figure 2),
- AES level 2 : each program line is translated in a sequence of words corresponding to all the nodes appearing in the associated sub-tree (in red, blue and black in Figure 2).

For the last two levels, the names of the variables and parameters, as well as the values of the constants, have been normalized so as not to artificially extend the considered "vocabulary". Thus, the variable `res` is renamed `var1` and the variable `i` is renamed `var2`.

Note that each execution of a program on one test case generates a partial AES. A program will finally be represented by the concatenation of the partial AES obtained on each test case. An AES can thus be considered as a representative text of the program. Each partial AES corresponds to a sentence of this text.

3.2 *aes2vec* : learning program embeddings from AES

The *word2vec* method [11] is based on the distributional hypothesis of words in natural language [16] : a word can be inferred from its context. For example, the CBOW (Continuous Bag Of Words) version of *word2vec* allows to train an feed-forward Neural Network to predict a (central) word from its context. In *word2vec* a *context* is defined by the preceding and following words in the text. The structure of the neural network is reduced to a single hidden layer (encoding) ; the matrix W of the weights connecting the input layer to the hidden layer contains the word embeddings.

word2vec has already been used to learn token embeddings from a computer program [6, 3]. However the distributional hypothesis seems less satisfied on the tokens from a program than on the natural language, in particular because of the very limited size of the vocabulary and especially a little constrained compositionality (almost all combinations are observed).

[8] have proposed a variant of *word2vec*, aiming to learn simultaneously the embeddings of the words and the documents from which they are extracted. The *doc2vec* method is still based on the distributional hypothesis allowing to predict a word knowing its context, but this time the context integrates (in addition to the preceding and following words) the identifier of the document from which the word sequence comes from. In doing so, the authors introduce the idea that there are document specific variations in the natural/universal distribution of words in the language.

We exploit precisely this hypothesis of *document-based distributional variations* for the processing of AES built from the programs. We consider that each program, during its execution, generates different sequences of tokens (AES). We then use the DM (Distibutive Memory) version of the *doc2vec* algorithm to train a feed-forward Neural Network (with one hidden layer) to maximize the following log probability :

$$\mathcal{L} = \sum_{s=1}^{S} \sum_{i=k}^{T_s - k} \log p(w_i^s | w_{i-k}^s, \ldots, w_{i+k}^s, d_s) \qquad (1)$$

with S the total number of documents (or AESs), T_s the total number of words (or tokens) in document s, d_s the s^{th} document, w_i^s the i^{th} word in document d_s and k the size of the context on either side of the target word.

Figure 3 presents the architecture of the neural network used for *doc2vec* as we use it for learning program embeddings via their AES. The forward pass consists in first calculating the values of the hidden layer by aggregating the encodings of each word of the context and of the document : $h(w_{i-k}^s, \ldots, w_{i+k}^s; W, D)$ where $h()$ denotes an aggregation function to be defined (typically a sum, average or concatenation), W and D denoting the word embedding matrix (weight matrix between word inputs and hidden layer) and the document embedding matrix (weight matrix between document input and hidden layer) respectively. The output of the neural network can be interpreted as a probability distribution on the words of the vocabulary by applying an activation function (*softmax*) on the output $y_{w_i^s} = b + Uh(w_{i-k}^s, \ldots, w_{i+k}^s; W, D)$ where b is a bias term and U the weight matrix between hidden and output layer:

$$p(w_i^s | w_{i-k}^s, \ldots, w_{i+k}^s, d_s) = \frac{e^{y_{w_i^s}}}{\sum_j e^{y_j}} \qquad (2)$$

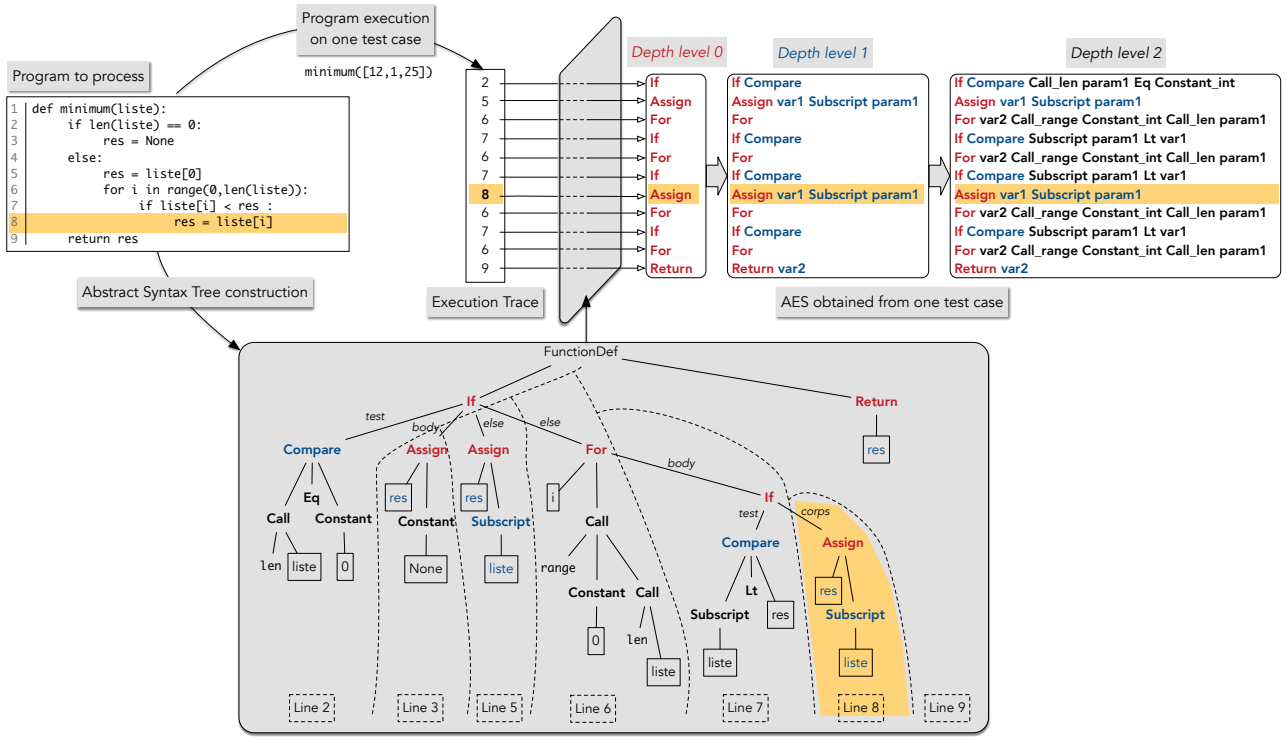

Figure 2: Construction of an AES from a Python program and a given test case.

Finally, the network weights are updated by stochastic gradient descent on the error, defined by the difference between the obtained output and the one-hot vector encoding the target word.

We consider programs as textual documents whose word sequence is given by an AES obtained by the previous step (*code2aes*). Indeed, as for text, the choice and the order of the "words" in an AES capture the semantic of the program, i.e. what the program does (its function) and how it operates (its style).

In this learning model, each AES vector (in D) is used only for predictions of the tokens from this AES, while token vectors (in W) are common to all AESs. The size of the vectors (for AES and tokens) is fixed and actually corresponds to the size of the desired representation space (embeddings).

Once the model is trained, the D matrix contains the embeddings of the programs. The positioning of a new program in this embedding space consists in inferring[2] a new column vector in D using the tokens from the new AES. The other parameters of the model remaining fixed (W as well as the *softmax* parameters).

Finally, let us mention that the choice of the aggregation strategy used in the hidden layer can be decisive. Indeed, a *sum* or *average* will consider each context as a bag-of-words (without taking into account the order), whereas a *concatenation* strategy offers the opportunity to exploit the order of words within the context. If the sequentiality (inside the context) is not a determining factor in the construction of embeddings for natural language, we will confirm in future experiments that the order of tokens is of high importance for learning program embeddings using AESs.

[2]Inference is made by purshasing the learning on the Neural Network.

4. EVALUATION OF THE APPROACH

4.1 Dataset presentation

Educational data are complex since programs may contain errors, be small in size, may not fully meet the intended functions and may be relatively redundant. These data have very different characteristics from the datasets used in software development. For our experiments, we thus built and use several real educational datasets (see Table 1). They consist of Python programs submitted by students on two training platforms in introductory programming courses. In addition to our (documented) *code2aes2vec* code for learning program embeddings, we also make available[3] these three "corpora" of Python programs, the associated test cases, and the AESs built on each program. All of the results presented in the rest of this section can thus be fully and easily reproduced.

The **NewCaledonia-5690** dataset (or NC-5690) includes the programs created in 2020 by a group of 60 students from the University of New-Caledonia, on a programming training platform[4]. The **NewCaledonia-1014** dataset (or NC-1014)

[3]*https://github.com/GCleuziou/code2aes2vec.git*

[4]Platform developed and made available by the CS department of the Orléans University Institute of Technology.

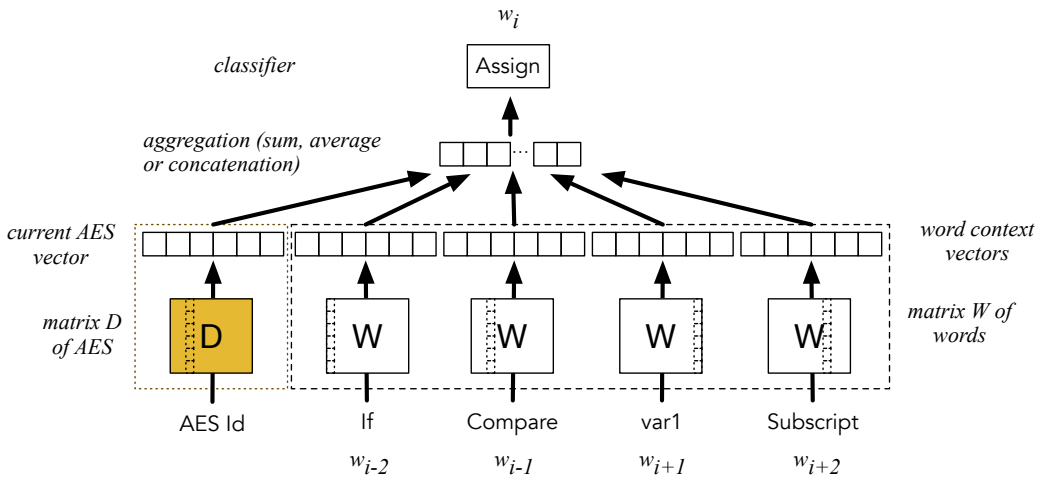

Figure 3: The neural network $aes2vec$ used to predict a word w_i from its original AES identifier and its context (here, two previous and two following words).

Table 1: Characteristics of the three Python datasets collected on programming training platforms. The 'Nb. of words' reported is the total size of the AES corpus; the number in parentheses indicates the size of the 'vocabulary'.

Datasets	NC-1014	NC-5690	Dublin-42487
Nb. programs	1,014	5,690	42,487
Avg nb. test cases per program	13.1	10.4	3.7
Nb. correct programs	189	1,304	19,961
Nb. exercises	8	66	65
Nb. 'words' AES-0	113,223 (20)	761,726 (44)	7,4 M (38)
Nb. 'words' AES-1	226,682 (42)	1,7 M (57)	15,2 M (83)
Nb. 'words' AES-2	690,019 (71)	3,9 M (113)	40,4 M (209)

Table 2: Exercises in the NewCaledonia-1014 dataset.

Exercice	Statement	#test cases
swapping	swap items in a list	4
minimum	look for the minimum in a list	8
compareStrings	compare two strings	11
fourMore100	return the first four values greater than 100 from an input list	7
indexOccurrence	return the index of the first occurrence of an item in a list	7
compareDates	compare two dates from their day, month and year	30
polynomial	return the roots of a polynomial of degree 2	6
dayNight	display information about the period of a day given a time	32

includes a sub-part of **NewCaledonia-5690** composed of contributions associated with 8 exercises selected for their algorithmic diversity (see Table 2) and their balanced volumetry (100 to 150 programs per exercise). We will use it as a 'toy' dataset facilitating qualitative analyzes. The **Dublin-42487** dataset includes student programs from the University of Dublin, carried out between 2016 and 2019. Although the original corpus [3] contains nearly 600,000 programs (Python and Bash), we propose here a subset enriched semi-automatically with test cases (not provided initially).

4.2 Embedding analysis

In the following experiments, each dataset has been divided into three sub-parts: training (90%), validation (5%) and test (5%); the validation set being used to select the best model among those learned during the different iterations ($aes2vec$). Unless otherwise stated, the $aes2vec$ algorithm has been set up to learn embeddings of dimension 100, the size of the context is set to 2, concatenation is used as aggregation stage and the training is performed over 500 iterations.

In a first step, we evaluate our approach in a qualitative way on the dataset **NewCaledonia-1014** constituted for this purpose. Figure 4 (left) shows a visualization of the 912 programs of the training set, obtained by a non-linear projection using the t-SNE dimension reduction algorithm [9]. It can be seen that, although embeddings are learned in an unsupervised manner, the $code2aes2vec$ method learns, from a relatively limited number of training data, a representation space in which the areas identify distinct program functionalities. Thus, the program vectors are organized quite naturally into 8 clusters that are highly correlated with the original 8 exercises. Moreover, the topological organization of the clusters matches well with the algorithm inherent to the programs. Exercises 'swapping' and 'minimum' are close in the embedding space and correspond to the only two exercises that iterate over all values of an input list. Exercises 'compareStrings', 'fourMore100' and 'indexOccurrence', in

the upper part of the space, require to partially iterate over a list. Finally, the last three exercises do not require loops and rely only on the use of conditional instructions. The exercise 'dayNight' is distinguished by the expected use of a display function (`print`) while all the other exercises return a result (`return`). This feature may explain the 'isolation' of the programs from this exercise from other programs.

Stylistic differentiation of programs is difficult to assess quantitatively. This task would require either objective criteria that can be extracted automatically or expensive expert labeling. Given the absence of such stylistic knowledge in datasets, we choose to illustrate on an example how the *code2aes2vec* method distinguishes different styles in the writing of a same function. Figure 4 (right) presents in detail the embedding space learned for the exercise 'minimum'. It's interesting to notice that program styles are clearly distinguished, notably the two ways to program a Python `for` loop (using indexes vs. elements directly). In a very detailed way, programs are also grouped according to whether their loop starts with the first element of the list (`range(0,...)`) or with the second one (`range(1,...)`), after initialization of the minimum to the first element in any cases.

Word order is important in our *aes2vec* method. For example, our approach distinguishes programs having a similar boolean condition but expressed in a different order (`if liste[i]<res:` vs. `if res>liste[i]:`). This distinction may seem artificial since these two expressions are strictly equivalent from the evaluation point of view. However, the first syntax appears more 'natural' than the second. It would be easy to get rid of this phenomenon by normalizing the expressions at the *code2aes* step; this option can be left at teacher's discretion.

Finally, we draw the reader's attention on some valid but atypical programs. In particular a program using the native Python function `min`, or the one using the `sort` function. Their separation from the rest of the programs is crucial since it offers a way to detect programs (a priori valid) that a teacher would like to reject or at least moderate considering that they deviate from his/her pedagogical objective. More generally, this analysis seems to confirm that the embedding spaces learned by the *code2aes2vec* method correctly captures not only the function of the programs but also their style. Their intrinsic quality paves the way for many practical uses that could significantly improve the efficiency of learning platforms (detection of atypical solutions, automation/propagation of feedbacks, student 'trajectory' analysis, study of error typologies, etc.).

In a second step, we evaluate the *code2aes2vec* approach from a quantitative point of view on the three datasets (Table 3). We consider an usual task for program embedding evaluation, namely the prediction of its function (i.e. exercise identification). For each considered configuration (AES level), the training data are used first to learn (without supervision) a representation space. Then, these embeddings are used to learn (with supervision) a SVM classifier (with polynomial kernel) [5]. Finally, the embeddings are (indirectly) assessed according to their ability to predict the function of the code (i.e. the exercise) for test data.

As baselines, *random classifier* informs about the difficulty of this task *a priori*, while *doc2vec* corresponds to the (naive) use of the algorithm *doc2vec* [8] to learn embeddings from the codes directly (without any intermediate representation). We also report the results obtained by the (supervised) *code2vec* approach[5] [2] executed with default parameters.

	NC-1014	NC-5690	Dublin-42487
random classifier	*0.125*	*0.015*	*0.009*
code2vec [2]	0.230	0.098	0.037
doc2vec [8]+SVM	0.412	0.495	0.380
code2aes2vec+SVM			
(AES-0)	0.882	0.460	0.391
(AES-1)	**1.0**	0.698	0.544
(AES-2)	**1.0**	**0.832**	**0.651**

Table 3: Quantitative and comparative evaluation of the produced embeddings, on the task of retrieving the function of a program (accuracy).

It can be seen that the *code2vec* model recently proposed by [2] cannot be trained satisfactorily on any of the three datasets. This is due to the numerous parameters to learn and the large number of examples this method requires. In the largest dataset (Dublin-42487), *code2vec* "only" has 42,487 programs as inputs. To the opposite, our *code2aes2vec* method as several million entries thanks to our AES intermediate representation.

The comparative results obtained with three different levels of AES (denoted by AES-0, AES-1 and AES-2 in Table 3) confirm that the quality of the embeddings is improved when the level of detail of the AES increases. Level 2 AES (AES-2) are undeniably leading to the best vector representations of programs.

In order to take into account the word/token order, *code2aes2vec* and *doc2vec* have been set up so far with concatenation as aggregation step. In order to confirm the importance of the order, we compare in Figure 5 embeddings obtained by the *code2aes2vec* algorithm with both types of aggregation (sum vs. concatenation). Unlike for concatenation, we observe a very rapid degradation in the quality of the embeddings obtained with a sum type aggregation when the size of the context increases. Indeed, the vocabulary on which AESs are based is very limited (only a few dozen or even hundreds of tokens) and the distribution of these words in AESs is not uniform. Thus it quickly becomes difficult to differentiate contexts as their size increases without taking into account the word order.

4.3 Application to feedback propagation

In order to confirm that the learned embeddings are fine enough to be usefully exploited in an educational context, we have implemented a first proof of concept on the task of propagating feedbacks.

We have considered the exercise *'mean'* from the dataset **NewCaledonia-5690** whose instruction was to write a Python

[5]The other methods presented in the state of the art could not be compared because of the lack of available operational implementations.

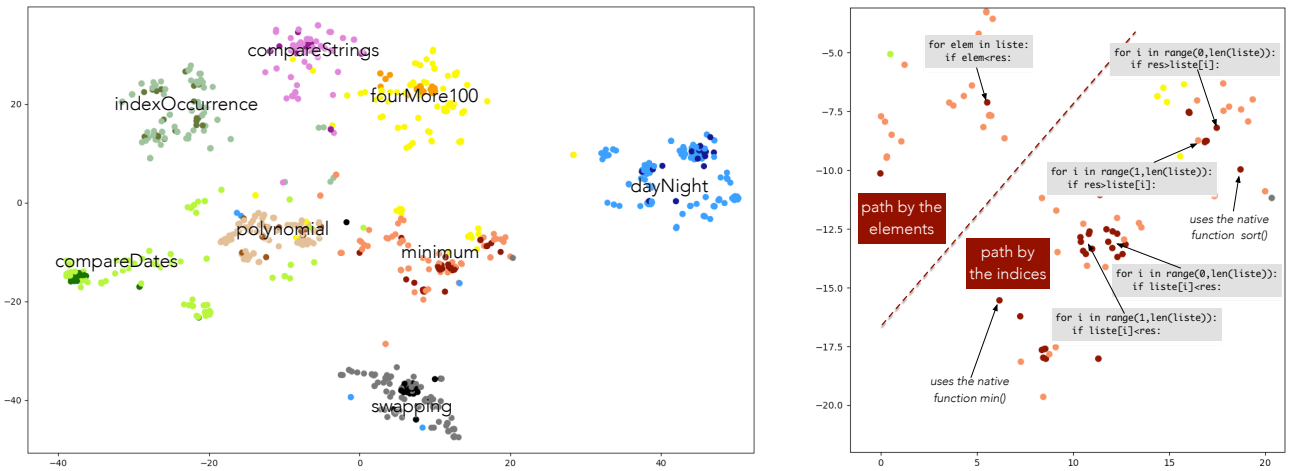

Figure 4: Visualization of program embeddings obtained by the method *code2aes2vec* for the 8 exercises of the dataset *NewCaledonia-1014*. The colors identify the exercises, with incorrect programs in light and correct ones in dark. The figure on the left represents all the embeddings and the one on the right details the area associated with the 'minimum' exercise.

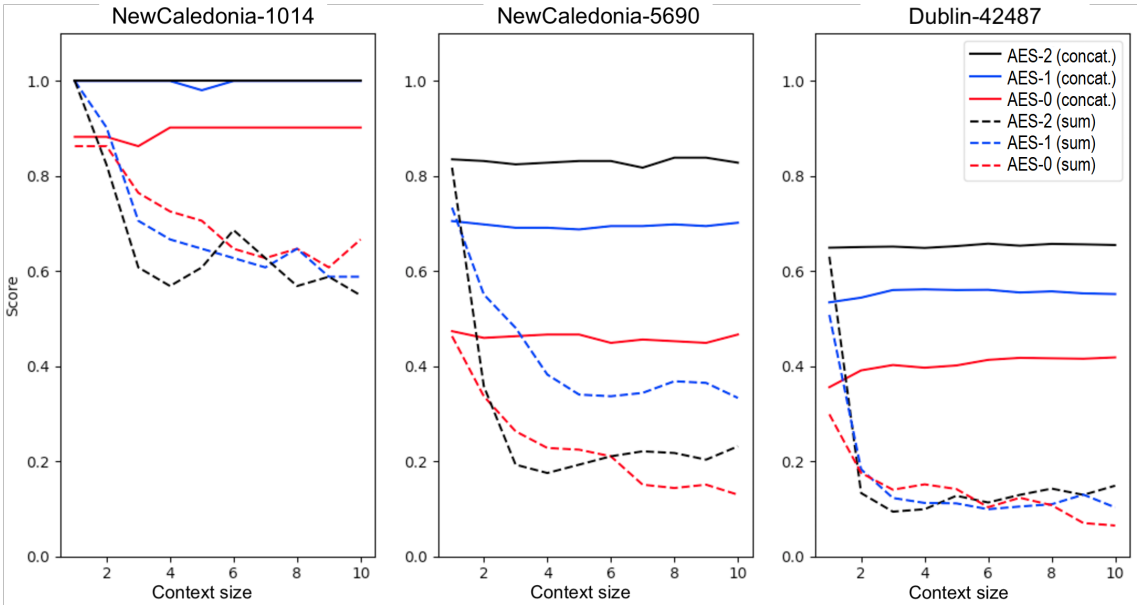

Figure 5: Evaluation of the embeddings on each of the three datasets according to the type of AES, the aggregation method and the context size (nb. words before/after).

function returning the mean of the values contained in a list passed as a parameter (and returning None if this list is empty). For this exercise, 157 programs were submitted to the platform by 24 different students ; among these submissions 122 programs were evaluated as incorrect by the platform and on which we sought to propagate teacher feedbacks based on their embeddings.

For this purpose, we performed a clustering (k-means [10]) on the 122 incorrect programs. We then presented to a teacher the most representative program (cluster medoid) of each cluster obtained, asking him to provide one feedback to help the student correct his proposal[6]. Once the k feedbacks were compiled (one per cluster/medoid), we went through each cluster and asked the teacher, for each program (other than the medoid), to indicate whether the feedback defined for the medoid could be applied to that other program. The objective is thus to assess the extent to which feedback from one medoid can propagate to all other programs in the same cluster.

Operationally, clustering is performed on the 122 incorrect

[6]If more than one error is found, the teacher must choose the one he/she feels needs to be corrected first. Each feedback is thus limited to the resolution of a single error.

programs, defined by their embeddings in $\mathbb{R}^{100}$. For a fixed number of k clusters, the partition selected to be analyzed is the one minimizing the MSE (Mean Square Error) among 100 runs (random initializations) of the k-means.

Table 4 presents the partition obtained for 5 clusters ($k = 5$). For each cluster we indicate its size, the program associated with its medoid as well as the feedback provided by the teacher for this medoid.

Let us first observe that the feedbacks provided by the teacher may relate to errors different in nature. It can be either an error in the design of the algorithm (clusters 1 and 3) or an error in the writing of the Python program (clusters 2, 4 and 5).

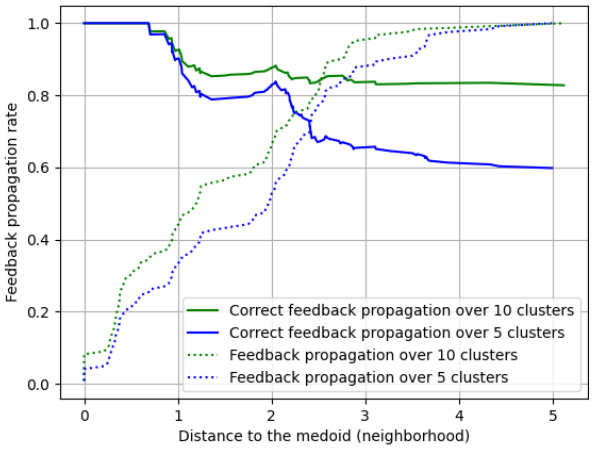

Figure 6: Propagation of teacher feedback to neighboring programs in each cluster. Illustration on the exercise *mean*.

We repeated this work with a partition into 10 clusters, this time asking the teacher to provide 10 feedbacks. Finally, we measured the rate of correct feedback when propagating the feedback from each medoid to its neighboring programs in the same cluster. Figure 6 shows the evolution of the correct feedback rate as a function of the neighborhood size considered for propagation. It can be seen that the further away from the medoids, the more errors in the automatically determined feedbacks.

Of course, a small number of feedbacks (5 or 10) is not enough to cover all the errors present in the 122 incorrect programs. In practice, it will therefore not be envisaged to propagate to all the programs in the cluster but only to the neighboring programs of the medoid. The dashed curves in Figure 6 indicate the proportion of programs covered as a function of the size of the neighborhood under consideration. We can see that with a neighborhood radius corresponding to a distance of 1.0, a propagation over 5 clusters allows to cover 33% of the programs with a precision of 90%; similarly such a propagation on 10 clusters allows to cover significantly more programs (43%) with a higher precision (93%).

The use of embeddings allows in this example to assist the teacher in his task of accompanying the students. For each feedback requested, 4 to 5 additional neighboring programs are automatically processed. Moreover, it is reasonable to think that over time a sufficiently large collection of feedbacks will be defined by the teacher to cover almost the entire embedding space so as to systematically identify one relevant feedback each time a new incorrect program is submitted and its embedding will position it in a pre-identified neighborhood.

5. CONCLUSION AND PERSPECTIVES

This paper studies the problem of learning vector representations, or embeddings, of programs in an educational context where the function is just as important as the style. Faced with this problem, we propose the method *code2aes2vec* transforming the code into abstract execution sequences (AES), and then into embeddings. This approach adapts the *doc2vec* method for program application and is based on the *document-based distributional variations* hypothesis.

The publication of the source code of the approach is accompanied by the availability to the community of a new enriched 'corpus' composed of more than 5,000 student programs (Python). Experiments conducted on these new data and on a public data set validate the quality of the learned embeddings, capturing in a fine way the function and the style of the programs. In addition a promising proof of concept was carried out on a classical task in the field, namely the propagation of teacher feedbacks.

The perspectives of this work are numerous. First, our experimentation focus on programs done in introductory courses, i.e. pretty simple codes. It would be interesting to analyze more elaborated ones (from more advanced courses) and to evaluate the impact of code complexity on performance.

Then, it seems necessary to complete the results observed on the stylistic differentiation of programs, by formalizing the notion of *style* of a program, in order to quantitatively evaluate our program embeddings. In the same way, a more precise analysis of the test cases used will have to be carried out in order to determine to what extent the constructed embeddings are sensitive to them.

Finally, to have more exploitable corpora, we plan to extend our implementation to handle any type of language (the current implementation only processes the Python language).

From a more methodological perspective, all the words in the program have the same weight during the embedding construction in our approach. Thus, a correct program and one returning a wrong value (or throwing an error) may have very similar embeddings, although functionally very different. This aspect could be integrated in the construction of our AES or in the architecture of the neural network used to generate embeddings. For that, it could also be interesting to add to our AES the values taken by the variables, in the same way that [17] but in a generic multimodal approach. Another perspective would be to allow the expert to integrate part of his knowledge on the language. As discussed previously, some instruction sequences can be equivalent

The division step must be performed once the sum calculation is completed (put this instruction out of the `for` loop).	*The `//` operator corresponds in Python to the integer division. For the computation of a mean a simple division is required (operator `/`).*	*In the case of an empty list, your function does not return None (as requested).*	*The null value in Python is written 'None' (instead of 'none').*	*The `%` operator corresponds in Python to the modulus. For the computation of a mean a simple division is required (operator `/`).*

Table 4: Description of the 5 cluster partition generated by k-means on the embeddings of the incorrect programs from the *mean* exercise. For each cluster (table column): (1) the number of programs, (2) the program associated with the medoid of the cluster and (3) the feedback defined by the teacher for this program. Instructions in red are the ones that are questioned in the feedback.

(e.g., `if liste[i] <res:` vs. `if res> liste[i]:`). Semantic relations between words can also be known (e.g., the relation between `for` and `while` statements). This knowledge could be used to constrain the neural network and guide embedding construction. Finally, these program embeddings open up a large number of perspectives for teaching aid, in addition to the task of feedback propagation. For example, they could be used to identify error typologies, alternative solutions, or even predict dropout students through the analysis of their 'trajectories'.

ABSTRACT

With the increasing adoption of Learning Management Systems (LMS) in colleges and universities, research in exploring the interaction data captured by these systems is promising in developing a better learning environment and improving teaching practice. Most of these research efforts focused on course-level variables to predict student performance in specific courses. However, these research findings for individual courses are limited to develop beneficial pedagogical interventions at the student level because students often have multiple courses simultaneously. This paper argues that student-centric models will provide systematic insights into students' learning behavior to develop effective teaching practice. This study analyzed 1651 undergraduate student's data collected in Fall 2019 from computer science and information systems departments at a US university that actively uses Blackboard as an LMS. The experimental results demonstrated the prediction performance of student-centric models and explained the influence of various predictors related to login volumes, login regularity, login chronotypes, and demographics on predictive models. Our findings show that student prior performance and normalized student login volume across courses significantly impact student performance models. We also observe that regularity in student logins has a significant influence on low performing students and students from minority races. Based on these findings, the implications were discussed to develop potential teaching practices for these students.

1. INTRODUCTION

Teaching and learning changed a lot in recent years with the increasing adoption of new computer-based teaching and learning technologies in educational institutions worldwide. As education and learning technology evolves with time, leveraging the technical advances to improve teaching practice and student learning will be a prominent research area. The most common technologies used by instructors to deliver course content include Learning Management System (LMS), Course Management Systems (CMS), and Learning Content Management Systems (LCMS) [1]. Even though these systems seem to be synonymous, they have their specific use in the education domain. LMS tools focus on communication, collaboration, content delivery, and assessment, whereas LCMS is similar to LMS with fewer administrative functions. CMS, on the other hand, will focus on the enrollment and performance of students. Of these three systems, LMS is the one that is best suitable for delivering learning strategy to students and is the primary focus of this study.

LMS systems provide a unique opportunity to administrators, and researchers to evaluate student data related to time spent on an activity, access times and day, grades, interactions, and many other useful student learning variables. The data logs collected by LMS systems are analyzed with scientific techniques published in the Educational Data Mining (EDM) domain. In their study, Romero and Ventura [2] described that current EDM methods rely on clustering and pattern recognition techniques to categorize students into various groups based on their interaction patterns. Categorization of students using clustering and pattern recognition supports instructors in making changes for a set of students. Teaching practices that impact the entire classroom can be evaluated using predictive analytics that tracks student learning and achievement from the vast amount of interaction data collected by LMS.

Existing research in Learning Analytics (LA) and EDM focused on developing highly accurate predictive models that can estimate student learning outcomes related to assignment scores, course grades, and drop-out probability [3,4]. These course-based predictive models provide early warning to student counselors or instructors associated with a specific course [5,6]. Even with considerable success in this area, many of the student performance prediction models have several shortcomings. One significant issue with course-based models is the bias introduced by teaching style and the type of course (descriptive, programming, mathematical etc.). This bias impacts these models' scalability across different courses and makes it difficult to understand the student level factors on their achievement. For example, if a student enrolls in five courses, developing models to study students' progress in these five courses independently is not realistic and gives different insights based on varying features and performances. Therefore, these modeling efforts are limited to reduce different biases introduced by instructor and the diverse amount of content made available in LMS.

Course level predictions are suitable for supporting instructor level decision making; however, if intervention is on student level behaviors such as study habits or self-regulation skills, it is beneficial to look at student-centered indicators so that interventions may be more targeted and cost-effective [7,8]. Developing student-centric models that analyze student LMS interactions across courses in a college/university setting will help

Varun Mandalapu, Lujie Chen, Zhiyuan Chen and Jiaqi Gong "Student-centric Model of Login Patterns: A Case Study with Learning Management Systems". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 263-274. https://educationaldatamining.org/edm2021/

address the issues with course specific models. This study is the first step in developing models that supports the identification of student level indicators.

For colleges that have a high penetration of LMS, LMS activity may give a holistic indicator of students' engagement level (behavior engagement specifically). We ask the question to what extent those holistic indicators predict student term Grade Point Average (GPA) performance in the future. To explore this, we specifically focus on student login related features as they can be generalized across courses and act as proxy variables for time management [51, 52]. It is also challenging to aggregate other features like discussions, readings, and assessments across courses compared to access related LMS variables. This study's data is drawn from Blackboard Learn, a commercial LMS software available for colleges and universities to deliver course content and assessments through internet-enabled computer systems. Most importantly, the data is drawn from all students in computer science and information systems at a large public university in the US during the Fall 2019 semester. In addition to student interactions from LMS, we also access demographic and prior student performance data from the university's student administration system to build and interpret downstream predictive models. The university's Institutional Review Board (IRB) approved this study, and all the student specific demographic and personal information are anonymized by following General Data Protection Regulation (GDPR) standards.

In this work, we focus on model predictions and explanations to understand student learning behaviors. First, we apply new methods to process student interaction data collected across different courses enrolled in a semester to build student-centric performance models based on machine learning principles. Secondly, we utilize a novel approach in local model explanations, correlation and regression to understand the impact of various features captured by LMS on student performance. One primary reason for using Locally Interpretable Model Explanations (LIME) is its ability to explain the relationship between predictor variables and predictions, especially the input variable's impact on the outcome. On the other hand, statistical correlation analysis will provide the relation between input predictors and the observed target variable. As correlation analysis does not consider the interaction effect between input variables, we also use a linear regression model to study the output variable's feature importance's based on the model coefficients. To address the research gap discussed earlier, we explore the below three research questions.

RQ 1 How different student-centric machine learning models perform in predicting student end-of-term GPA?

RQ 2 How do student login and time interval pattern across courses influence student learning outcomes?

RQ 3 Is there a significant variability in feature importance for students coming from diverse demographics?

2. RELATED WORK

Universities and colleges around the world adopted LMS systems, such as Moodle and Blackboard, to provide onsite, hybrid, and online courses based on their capabilities to support communication, content creation, administration, and assessment [9, 10]. Besides the automation and centralization of various administrative tasks like creating and managing student accounts, creating syllabus, assignments, assessments, grading, etc., LMS systems assemble and deliver personalized learning materials and content quickly [11]. These systems also support the reusability of materials created by instructors. The systems also enable instructors to create content structures, deliver them in a sequence, maintain control access, organize group activities, track student activities, load and replace learning materials and provide feedback on assessments. With advanced database software developed by Oracle, IBM, and Microsoft that emphasize interconnectedness, data independence, and security, LMS systems employ various login roles based on user classification. These roles will permit instructors to create new content or privately address student issues and create discussion boards to capture student knowledge on specific topics.

LMS platforms enable students to access learning material in various formats, such as pdf, PowerPoint presentations, video lectures, and audio files. The systems also track student activity related to content downloads, access timestamps to display student progress in learning to instructors [12]. LMS also provides both asynchronous and synchronous communication for students to interact with instructors and encourages group activities. Combining the tools provided by LMS with innovative learning strategies like self-directed learning, small group instructions, and collaborative learning with instructor interventions, a wide variety of activities can be developed for individual, small groups, or larger classes [12,13]. Given the simplicity and convenience of accessing online materials through LMS systems, it is not surprising to see high student satisfaction scores for courses delivered through LMS.

In recent years, the data sets related to student learning activities have drawn significant attention from researchers in academic communities to develop possible solutions to address student retention and academic success issues. This type of work has been called learning analytics and focuses on student activities such as navigating lecture materials, what information is accessed, how long it takes to complete an activity, and how students transform the information in learning materials into measurable learning [14, 15]. Multiple commercial resources like SPSS, google analytics, Stata and Nvivo can build predictive models on data captured by LMS to assess student drop-out probabilities to develop targeted learning courses or model collective learning behaviors. Since most instructors deliver course assessments and material through LMS, they can track student activity by processing a digital footprint during every online interaction captured by system log files.

2.1 Learning Analytics Research

LMS systems have the ability to capture large data streams related to user interactions through which administrators and instructors can develop methods to improve the learning experience. The collection, analysis, and reporting of data about learning activities on web-enabled learning platforms to assess student academic progress, predict performance, and identify potential issues that need attention is the central proposition of emerging fields like learning analytics and educational data mining [16, 17]. Outcomes derived from learning analytics aim to gain insights about student learning behaviors, real-time information about institutional practices and support the designing of personalized courses in CMS. Although there are huge data stores in universities and colleges that can be used to make data-driven decisions to support optimal use of both pedagogical and economic resources, to date there has been minimal application of this data in higher education [18].

2.1.1 Student Engagement and Frequency of LMS Use

An LMS system records student interaction details related to logins, number of posts written on discussion threads, time spent on lecture materials, total downloads, etc., in their log files. These logs can be analyzed to generate reports that help teachers to observe student progress at a granular level. Once there are enough student records collected in LMS, they can be used to develop computational models to predict future student performances. Multiple works in EDM and LA studied the relation between the usage of LMS and student academic achievements. Vengroff and Bourbeau's [19] study showed evidence that providing additional material in LMS benefited students at the undergraduate level. They also conclude that students who used LMS regularly did better in exams than their peers who have minimal interactions. In their research, Dutt and Ismail [20] observed that tracking resources students interact with on LMS supports developing new strategies that make learning easier and enhance learner progress. Their work also focused on analyzing thresholds related to student interaction features like self-assessment tests, time spent on exercises, discussion forums, and performance outcomes. Another study by Lust et al. [21] explored the usage variations in different tools used by students on LMS, such as time on web-link, time on web-lectures, time on a quiz, time on feedback, postings on discussion board, and messages read. The results from this study heavily contributed to the development of adaptive and innovative recommendation systems. In their work, Hung and Zhang [22] also found patterns based on six indices that represent student effort: Frequency of accessing the course material, number of LMS logins, total interactions in discussion threads, number of synchronous discussions, number of posts read, and final grades in a course.

While exploring a link between student online activity on LMS and their grades, Dawson et al. [23] observed a significant difference in the number of online sessions accessed, total time spent, and the number of posts in discussion forums between high and low performing students. Another study by Damainov et al. [24] developed a multinomial logistic regression model based on time spent in LMS. This study found a significant relationship between student time spent and grades, especially in students who attained lower grades between D and B. Instead of using time spent online, other works focused on the frequency of course material access within LMS. A study by Baugher et al. [25] found that regularity in student hits is a reliable predictor of student performance compared to the total number of hits. In their study, Chancery and Haque analyzed student interaction logs of 112 undergraduate students and found students with low LMS access rates obtained lower grades than their peers with higher access rates. This study was complemented by Biktimirovan and Klassen [26] that reported a strong relationship between student hit consistency and success. Their study counted access to various LMS activities and found that homework solution access is the only strong predictor of student performance. However, these studies are primarily descriptive rather than predictive.

2.1.2 Instructional Design and Student Participation

Online teaching strategies are primarily dependent on instruction design as each mode of interaction - student/instructor, student/student, and student/content have their own positive impacts on student progress. A study by Coldwell et al. [27] focused on the relationship between student participation in a fully online course and their final grades. They found a positive relationship between student participation and final grade. Dawson et al. [23] examined the impact of various LMS tools and found a highly positive correlation between discussion forum activity and student success. They observed more than 80% of interactions occurred in the discussion forum, which is the primary interaction tool in LMS. Another study by Greenland [28] found that asynchronous communication is the primary form of all online course interactions. Nandi et al. [29] found an increasing number of posts in discussion forums close to assignment and exam deadlines. They also found a high correlation between exam scores and online class participation throughout the semester, especially in high-achieving students.

All the studies discussed above adopted log files from LMS systems to extract unbiased details from activity and performance to identify a relationship between independent interaction variables and student grades. Most of the discussed studies are based on univariate analysis focusing on a single variable or a set of highly impactful variables of a single course or similar courses on student outcomes. However, student performance is a highly complex area in education to measure or understand, especially across various courses offered on-campus in a university setting. Most of the authors discussed above noted the need for more in-depth works to investigate student performance across courses and based on multiple variables. These studies also lack an explanation about variables used in their studies to track student performance, and it is evident that the authors selected LMS variables based on their belief that these variables are highly correlated with student scores.

2.1.3 Social Factors in Analytics

Factors that influence student academic performance have been the focus of researchers in LA and EDM domains for many years. It still remains an active area of education research, indicating the complex problem in measuring and modeling learner processes, especially in tertiary education. Positive learning characteristics have a significant positive impact on learner engagement improvement in multiple ways. The dispositional language specifies learning as a combination of self-regulation, learning inclinations, motivation, behavioral patterns, interactions, and cognitive ability. In their study, Buckingham et al. [30] proposed a combination of self-reported data gathered in surveys with student interaction data generated by LMS to study individual student performance, learning processes, and group interactions. These social analytics depend primarily on student self-reported data to develop toolkits that support a specific learning type, especially in courses with high diversity [31]. However, our study focuses on objective identification of student success based on data that LMS captures. We will also identify the crucial variables from predictive model output for various student groups based on their diverse backgrounds (race, gender, and student status).

2.1.4 Multivariate Analysis to Predict Student Success

Even though there is a common agreement about the purpose of learning analytics, there are still several varying opinions on what data needs to be collected and analyzed to improve teaching and learning processes. A study by Agudo-Peregrina et al. [32] argued that it is highly complex to identify the net contribution of various interactions to the learning processes. Their findings show that peer interaction between students has a lower influence than student-teacher interaction, which contradicts earlier studies that showed high importance for student peer interactions. A study by Dominquez et al. [33] utilized multiple variables like LMS logins, time stamps, and content access flags captured in a biology course

to predict student grade at the end of course completion. The results show that the algorithm predictive accuracy is at 50% in subsequent semesters. Lerche and Keil's [34] recent study utilized Moodle log data from 369 students enrolled in three online courses across three semesters to predict their scores at the end of the term for each course. Their regression results related to predicting student scores in a course at the end of the semester varied from 0.17 to 0.6 for all three courses. This broad range of performance across courses is due to varying variables utilized in each course based on the course structures. Studying the difference in instructional design, variables in extracted data, statistical inferences, predictive modeling used, interpreting model outcomes and pattern observations, etc., might explain the inconsistencies in results shown in earlier studies.

Data captured by LMS systems became prominent in LA and EDM circles as they capture student interactions in non-intrusive and ready-to-use settings. Several studies were discussed earlier in this research that utilized the LMS data to develop models that track student progress. However, it is still challenging to build highly accurate models that predict student learning outcomes across courses and understand the impact of different variables captured by LMS. Another significant gap in earlier research is their inability to predict student performance across courses in a given semester. One primary issue in predicting student performance across a semester is to find methods that aggregate student LMS variables across courses. This research shows methods to address the research gap found in earlier studies.

In this study, we approach the problem of tracking student achievement by developing student-centric models that build on aggregated LMS interaction variables collected across a semester irrespective of student year and course. One unique aspect of our work is related to the study of model performance on longitudinal student data. We develop models that predict student end-of-term GPA based on four cumulative periods in a semester. This work also focuses on explaining the impact of different aggregated LMS variables on various student groups categorized based on performance, race, gender, and student type. The importance of features is explained by adopting correlation statistics for univariate importance, a regression model for interaction effect, and LIME for model-based yet model agnostic explanations.

3. DATA & FEATURE SET

3.1 Dataset

For this study, we chose undergraduate student data captured by LMS in Fall 2019 from a large public university in the United States. These students were part of either Information Systems (IS) or Computer Science (CS) departments. The students from these departments were chosen as the instruction format and courses are closely aligned in both of them. Blackboard system is predominantly used as an LMS to deliver course material, assessment, and grading. The student demographic data captured by a standalone Student Information System (SIS) is used to categorize students based on different demographic variables. A total of 1651 students were enrolled in these two departments in the Fall 2019 semester. Based on student distribution, we categorized students into three ethnicities: White, Asian, and Minority. This study also researches student performance based on their admit types, such as four-year regular student or transfer student. The demographics of student data are provided in the below table 1. This study was approved by IRB and sensitive student data was de-identified based on GDPR standards.

Table 1. Student demographics

Demographic	Student Count
Total Students (N)	1651
No of unique courses	440
No of unique course instructor combinations	638
Male : Female	1302 (79%) : 369 (21%)
White : Asian : Minority	630 (38%) : 495 (30%) : 526 (32%)
4 – Year : Transfer	976 (59%) : 675 (41%)
Full Time : Part Time	1446 (88%) : 205 (12%)
IS : CS	934 (57%) : 717 (43%)
1st Yr : 2nd Yr : 3rd Yr : 4th Yr	115 (7%) : 329 (20%) : 515 (31%) : 692 (42%)
<= 3 : 4-5 : >5 (Courses enrolled)	298 (18%) : 1035 (63%) : 318 (19%)

3.2 Feature Extraction

We explored various LMS features related to student logins, content accesses, time spent, discussion posts, assignment submissions, and time intervals based on earlier literature. While exploring these features, we identified that only three features could be commonly extracted from different courses: Student Login Counts, Time intervals & prior knowledge.

One of the significant challenges while building a student-centric model on LMS data is to extract aggregated features that are least biased. As Blackboard's content is dependent on instructor and course, it is crucial to mitigate the variations caused by these factors on aggregate student variables. This work employs multiple statistical measures to mitigate these issues. The details are explained in the below sub-sections.

3.2.1 Normalized Login Volume

Earlier studies identified that student performance prediction is strongly dependent on the volume of student logins. One challenge with counting the student logins in Blackboard is its inability to find which course they accessed during each login. Also, calculating the total login count introduces a hidden bias as courses with more content on Blackboard prompt students to login more often than other courses with less content and flexible deadlines. To mitigate this issue, our work followed the below steps to extract student login features.

1. Extract all courses enrolled by all students in IS and CS.
2. Count the total number of logins for all students irrespective of their department in these extracted courses.
3. Calculate the Z-scores of student logins in each course. The reason for doing this is to mitigate the bias introduced by variations in the absolute count of logins as course logins vary a lot between students. Z-scores provide a value that helps understand if student logins are higher or less than average logins in a specific course.

4. Once the z-scores are calculated for all courses, we extract a vector of login z-scores for each student based on their enrolled courses.

5. As predictive models do not take vectors of variable length as input, this work extracts seven significant statistics from the login vector: mean, median, minimum, maximum, standard deviation, skewness, and kurtosis.

3.2.2 Login Regularity

Apart from student login volumes, the regularity between logins also provides valuable insights into student achievement as regularity is related to self-regulation capabilities. In this work, we utilize an entropy-based method to extract features that define student login regularity in each course. In information theory, entropy is used to define uncertainty or randomness [48]. Entropy measure will explain if student's logins are regular (less random) or irregular (more random). Based on this concept, if the entropy value is high, then a student has an irregular login pattern, and if the entropy value is low, the student has a regular login pattern. The steps to calculate student regularity features are given below.

1. Extract all course accesses with timestamps for every student in IS and CS.

2. Calculate the difference between timestamps. This difference will give a vector of time intervals for each course enrolled by a student.

3. Calculate entropy using the KL estimator with the k-nearest neighbor method proposed by Kozachenko and Leonenko [45]. KL estimator uses k-nearest neighbor distances to compute the entropy of distributions. The reason for adopting this method instead of Shannon entropy is based on the time interval vector's continuous characteristic [46].

4. Once the entropies are calculated, we get a vector of entropies for each student based on the number of enrolled courses. We then calculate the seven statistics similar to student logins: mean, median, minimum, maximum, standard deviation, skewness, and kurtosis.

3.2.3 Login Chronotypes

Studies in chronobiology and chronopsychology showed variation in different individual active periods at different times of the day [41, 42]. These studies classify an individual into either morning type or evening type based on their high activity time. For example, if an individual is highly active in the morning compared to the evening, they are considered morning type and vice versa. Inspired by this work in human psychology, this work divides a day into four-time bands T1 (12 AM to 6 AM), T2 (6 AM to 12 PM), T3 (12 PM to 6 PM), and T4 (6 PM to 12 AM) and extract student logins based on these four time bands. In addition to this, this work also extracts the logins on weekdays and weekends to study their influence on student performance.

1. Count the number of logins during each time band and on weekdays and weekends for each course.

2. Calculate the mean of login count vector for each of these time bands and weekday/weekend.

3. Normalize the login count with the number of courses enrolled by an individual student. This normalization will mitigate the bias introduced by the number of courses enrolled across the student cohort.

This work also utilizes the demographic and prior performance measured by GPA features captured by the SIS system. These features were listed in below table 2.

Table 2. Student demographic features

Demographic	Values
Start GPA (Prior Performance)	Cumulative GPA available till the start of semester
Gender	Male & Female
Ethnicity	White, Asian & Minority
Student Year	Freshman, Sophomore, Junior & Senior
Admit Type	Regular & Transfer
Enrollment Type	Full time & Part time
Student Age	Continuous variable

4. METHODOLOGY

The methodology section details the predictive modeling approach to predict student end-of-term GPA in fall 2019. In addition to this, we also describe the correlation-based LIME method to explain the features that contribute to model predictions. The workflow of developing student-centric models is depicted in figure 1.

4.1 Predictive Modeling

This work studied five of the most common regression models for comparison purposes. The selected models include Generalized Linear Model (GLM), Decision Tree (DT), Support Vector Regressor (SVR), Random Forest (RF), and Gradient Boosted Regressor (GBR). As model hyperparameter influences their predictive performance, we utilized a grid search mechanism to select multiple parameters to predict with high accuracy. We also adopted a feature selection method based on a multi-objective evolutionary algorithm in addition to hyperparameter search. This feature selection algorithm evaluates each feature set based on pareto-optimal that balances model complexity and accuracy. The details of models and hyperparameter search criteria are discussed below.

Generalized Linear Model: GLM is an extension of traditional linear models that fits input data by maximizing the log-likelihood. The regularization parameter is set so that the hyperparameter search space looks for an alpha value that fits between ridge and lasso regression. An alpha value of 1 represents lasso regression, and an alpha value of 0 represents ridge regression. This study searched for the best alpha value using a grid search between 0 and 1 in increments of 0.1.

Decision Tree: The decision tree algorithm is a collection of linked nodes intended to estimate the numerical target variable. Each node in the tree represents a rule used to split on an attribute value. The node uses a least-squares criterion to minimize the squared distance between the average value in a node when compared to the actual value. The hyperparameter search space for this algorithm evaluates both maximal depth and pruning. The maximal depth value varies between 1 and 100 in increments of 10. Pruning will make the DT algorithm use multiple criteria like

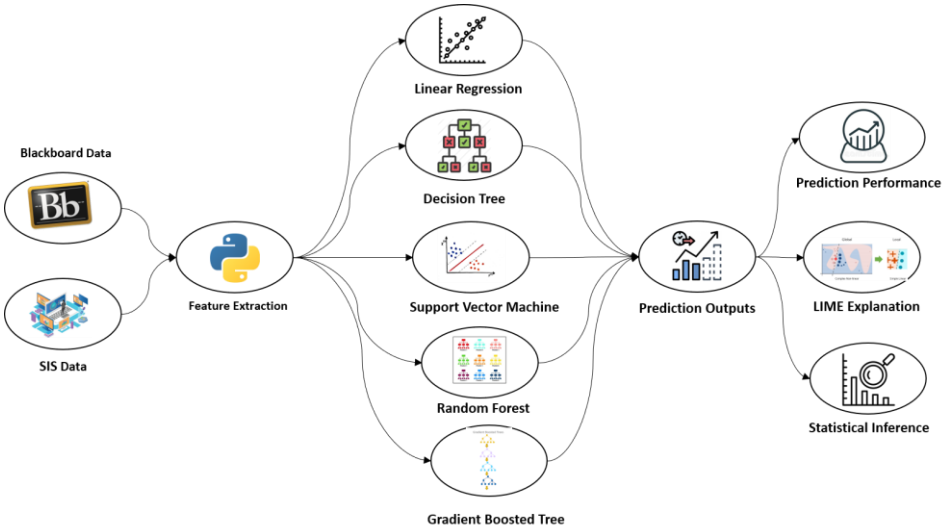

Figure 1: Student-centric Model Workflow

minimal gain, minimal leaf size, and pruning alternatives to decide the stopping criterion.

Support Vector Machines: The SVM used in this study is built based on Stefan Reupping's mySVM [47]. This algorithm will construct a set of hyperplanes in a high dimensional space for regression tasks. A good hyperplane is decided based on the functional margin. The hyperparameter search space focused on both dot and radial kernel functions with a C (SVM complexity) value range between 10 and 200. The kernel gamma function is set for a radial kernel with a range of 0.005 and 5 with three logarithmic increments.

Random Forest: A RF model builds an ensemble of decision trees on bootstrapped datasets. The splitting criteria are similar to a decision tree. The regression outcome is the average of the observed train data GPA present at that end node. We only tuned the number of trees hyperparameter to reduce the time complexity of the execution. The number of tree searches varied between 10 and 1000 trees in 10 linear steps.

Gradient Boosted Tree: The GBT model builds multiple regression trees in a sequence by employing boosting method. By sequentially applying weak learners on incrementally changed data, the algorithm builds a series of decision trees that produce and an ensemble of weak regression models. As GBT is a non-linear model, we search hyperparameters related to the number of trees, learning rate, and maximal depth. The number of tree values varies between 1 and 1000 in five quadratic increments, the learning rate varies between 0.001 and 0.01 in five logarithmic increments, and the maximal depth parameter varies between 3 and 15 in three logarithmic increments.

4.2 LIME Explanation

The concept of Locally Interpretable Model Explanations (LIME) was introduced to explain the predictions made by black-box models that deal with classification problems. LIME explains each prediction made by a complex model by training a surrogate model locally [35]. However, this earlier methodology is not scalable to deal with categorical variables, tabular data, and regression problems. In this work, we adopt the correlation-based LIME method available in RapidMiner to explain machine learning models' predictions [36, 37, 38].

1. Perturb data in the neighborhood of each sample in the dataset. The number of simulated samples can be user-defined. A higher number of simulated samples will provide higher accuracy of explanations but at the cost of more run times.
2. Make predictions using the ML model for all the simulated samples around each original sample in the dataset.
3. Calculate the correlation between each feature in the dataset and the target variable.
4. The features that have a positive correlation are considered supporting features, and features with negative correlation with predicted outputs are referred to as contradicting features.

As LIME provides feature importance value for each feature at each sample, we aggregate the importance value for all samples to build global importance for each variable. The significant advantage of this method compared to traditional global importance methods is its flexibility. As model global importance's are calculated across all samples in the data, the LIME based feature importance's can be calculated for subsets of data. This flexibility provides users with a deeper understanding of each feature's role for different sets of populations present in a dataset.

In addition to applying the LIME methodology, this work also studies univariate and multivariate feature importance on student performances by applying correlation and linear regression methods. The student dataset used in this study is divided into multiple subsets containing different student groups based on various demographics. A correlation value is calculated between input features and student end-of-term GPA. This value provides us with an intuition about the impact of various features on student performances related to different demographics. As correlation only provides independent variable importance on student performance, we also adopt a linear regression model to explore the variation of feature importance based on coefficient values. Applying a linear regression model will also consider the interaction effect between input features to fit the outcome variable.

5. RESULTS

This results section is divided into three subsections based on the three research questions we are focusing on in this study. The first subsection will detail various predictive models' performance on longitudinal student interaction data collected during the fall 2019 semester. The second subsection will detail the importance of student logins and regularity on performance predictions based on LIME methodology. The final subsection will discuss the importance of input features based on correlation and regression methods.

5.1 How different student-centric machine learning models perform in predicting student end-of-term GPA?

The five machine learning models adopted in this study were evaluated using a five-fold cross-validation method. In this method, the student data is divided into five equal folds at a student level. In every iteration, four of the five folds are used for model training, and one fold is used for model testing. The machine learning models are evaluated based on two performance metrics: R squared (R^2) and Root Mean Squared Error (RMSE). The output performance metrics are the average of five test fold performances.

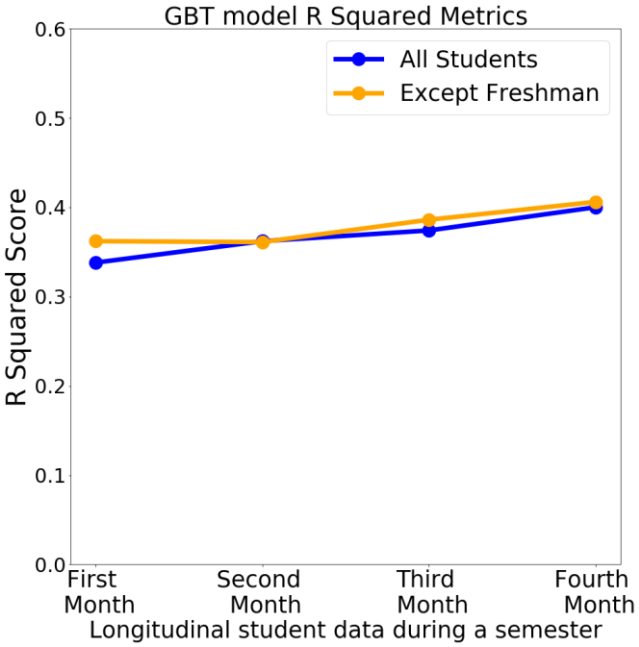

Figure 2. Compare performances of GBT model on different longitudinal datasets

In this study, we divided a semester into four parts to understand the impact of longitudinal interaction data across the semester on predictive model performances. This analysis will support the amount of data needed to balance predictive performance and early detection for interventions. The performance metrics evaluated on these four cumulative datasets will help understand the amount of student data needed to make accurate predictions. Tables 3, 4, 5, and 6 present the machine learning models' results evaluated on four cumulative datasets. While differentiating student performance based on multiple longitudinal datasets, we also study algorithms' performance without Freshman student data. This differentiation is to study the impact of missing start GPA feature values for first-year students as most of the full-time regular students in US universities start in the Fall semester.

Table 3. Student features from start to end of first month

Model	R^2		RMSE	
	All Students	Except Freshman	All Students	Except Freshman
GLM	0.213	0.249	0.657	0.633
DT	0.266	0.270	0.638	0.633
SVM	0.216	0.324	0.666	0.607
RF	0.332	0.353	0.607	0.588
GBT	**0.338**	**0.362**	**0.602**	**0.581**

Table 4. Student features from start to middle of semester

Model	R^2		RMSE	
	All Students	Except Freshman	All Students	Except Freshman
GLM	0.257	0.266	0.67	0.628
DT	0.263	0.295	0.67	0.618
SVM	0.195	0.315	0.705	0.609
RF	0.360	0.352	0.621	0.591
GBT	**0.362**	**0.361**	**0.622**	**0.586**

Table 5. Student features from start to end of third month

Model	R^2		RMSE	
	All Students	Except Freshman	All Students	Except Freshman
GLM	0.25	0.266	0.644	0.626
DT	0.255	0.255	0.658	0.650
SVM	0.335	0.344	0.612	0.597
RF	0.371	0.386	0.589	0.575
GBT	**0.374**	**0.386**	**0.588**	**0.572**

Table 6. Student features from start to end of semester

Model	R^2		RMSE	
	All Students	Except Freshman	All Students	Except Freshman
GLM	0.251	0.269	0.644	0.625
DT	0.246	0.274	0.657	0.641
SVM	0.320	0.289	0.616	0.627
RF	0.387	0.410	0.585	0.564
GBT	**0.400**	**0.406**	**0.575**	**0.562**

From the above tables, we observe that the GBT model performed better than the other four models based on the tradeoff between R squared and RMSE values. We also observe that there is no significant difference in student end-of-term GPA prediction with and without freshman details. This might be due to less sample

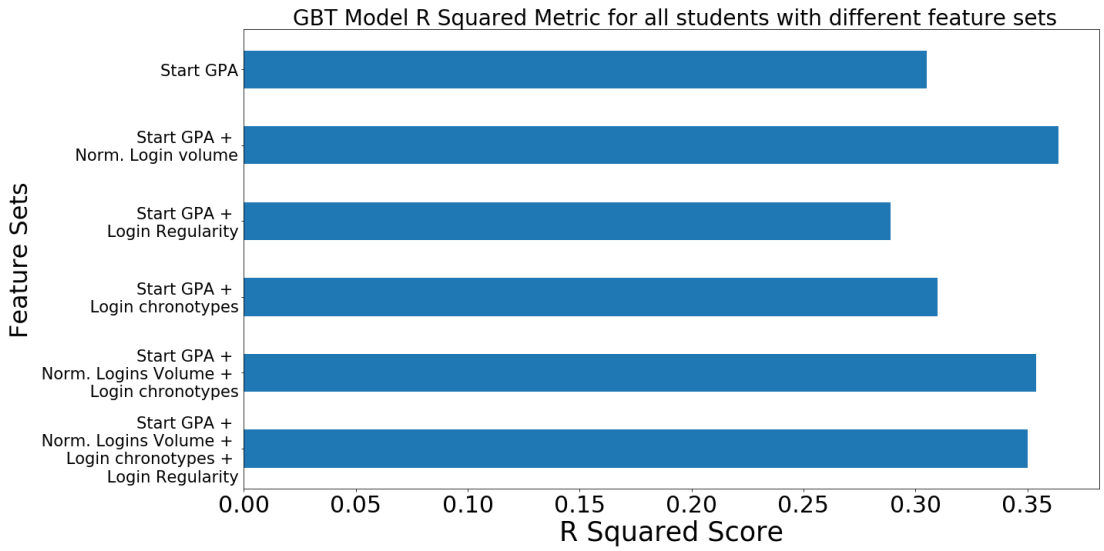

Figure 3. Compare performances of GBT model on different input feature sets.

size (7%) related to freshman cohort. From figure 2, it is also evident that there is a gradual increase in the performance of GBT model as we add data to predictive models as the semester progresses. Even though there is an increase in performance if we add all data captured during the semester, it doesn't help much for real-world interventions as activities that effects student performances will be completed by the end of the semester. Based on this understanding, we focus on data captured until the middle of the semester for feature importance study.

5.2 How do student login and time interval pattern across courses influence student learning outcomes?

To answer research question 2, we adopted a stepwise feature addition study that inputs features by adding one by one into the model and evaluates the performance based on R square and RMSE values. This study is performed on student data collected until the middle of the semester as models developed during this stage will help identify student level indicators and give enough time to deploy interventions that improve student performance. We first start with inputting student Start GPA (Cumulative GPA till the start of Fall 2019 semester) as start GPA showed a high correlation with end-of-term GPA based on our preliminary analysis. We then add normalized login volumes, login regularity, and login chronotypes in a step by step method. Figure 3 shows the R squared performance metric of student-centric models with different input variables.

From figure 3, we observe that students start GPA with normalized student login volumes across courses adds more predictive power to machine learning models. This observation is also supported by earlier studies [39, 40] that showed the importance of student login counts on student course grades and score predictions. Another observation is related to the importance of adding student self-regulation capability based on login regularity measured using entropy statistic. Based on figure 3, we observe that adding login regularity features with student login features and start GPA adds slightly more predictive power compared to model with only login regularity and start GPA features. In addition to these observations, we also observed that login counts based on login chronotypes with start GPA did not add much predictive power to machine learning models. From these results, we also imply that student aggregated login volumes might be adding the same information as login chronotypes.

5.3 Is there a significant variability in feature importance's for students coming from diverse demographics?

One limitation of using the earlier mentioned model-based feature importance study is its inability to explain each feature's importance on different student cohorts. To address this issue and understand the importance of login volumes and regularity features on different student groups, we adopt three approaches: one based on LIME, the second based on correlation analysis, and the third based on linear regression.

5.3.1 LIME based importance's

LIME based approach extract feature importance at the local level, also called local fidelity. By applying the LIME method explained in the methodology section, we extract feature importance's for different student groups categorized based on their demographics.

From figure 4, we can observe that cumulative student GPA at the start of the semester is an important feature to predict student end-of-term GPA. Student login volumes are the second important feature set for model predictions on different student demographics. This study's focus is also on student self-regulation capability measured by the regularity of logins (entropy). We observe that for students with GPA values less than 2, the regularity of logins feature played a key role compared to a student with a higher GPA. This observation also holds for students from minority ethnicity. One implication from these observations This observation suggests that introducing teaching practices that guide LMS use and time management will significantly impact students with low GPA and from a minority race. Start GPA played a slightly less significant role in transfer students than regular students as transfer students join in different years and their cumulative GPA might not be available at the start of the semester, similar to freshman.

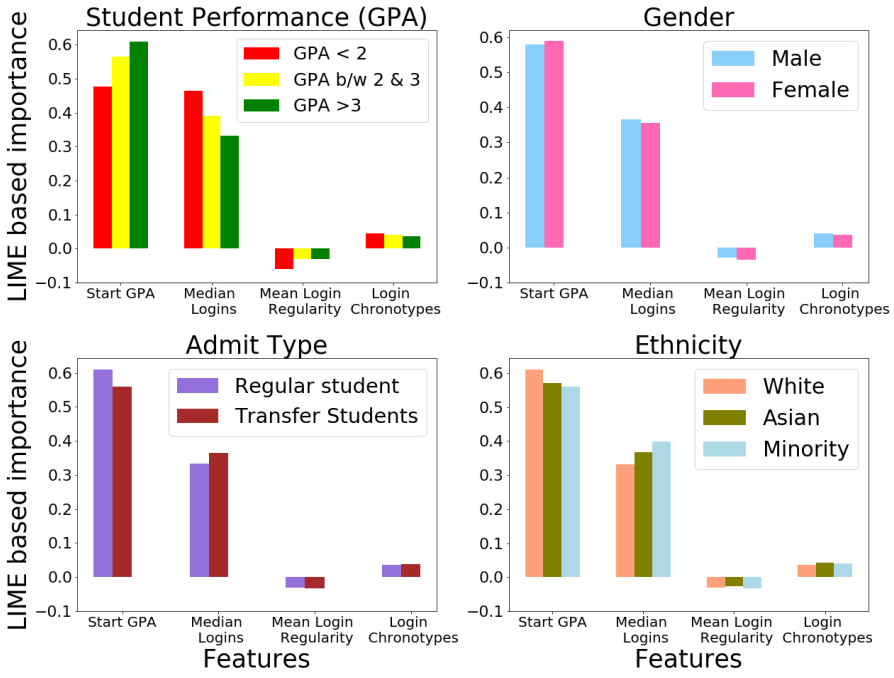

Figure 4. LIME importance's for different student groups divided based on GPA, ethnicity, admit type and gender.

Even though there is a huge imbalance in the number of male and female students present in the dataset, we do not observe any significant difference in feature importance's between these two genders. One limitation of the LIME method is related to global importance's. The importance's showed by LIME at the local level do not necessarily correspond to global importance's. Based on this limitation, we can infer which feature is essential for different students' groups but not quantify them as the importance's calculated in this study are the aggregate of importance's provided by LIME for each individual student.

5.3.2 Correlation based Feature Importance's

As earlier feature importance methods showed a significant impact of login volumes and login regularity measured by entropy statistic to predict student performance, we adopt Pearson correlation statistic to infer this relationship for different student groups. To do this, we create subsets of student data based on different groups: student GPA, gender, ethnicity, and admit type.

From figure 5, we observe that the student logins count and regularity in logins is highly significant for a student with a GPA lower than 2. We can also observe that as the entropy increases, the GPA reduces. This observation holds true as regularity in student logins represents their self-regulation capabilities. Earlier research showed that students with good self-regulation capabilities perform better in class [49, 50]. For other student groups divided based on gender and admit type, there is no significant variation in the importance of logins and entropy on student performances.

Even though the absolute values of correlation observed in figure 5 are not very strong, the comparison between different groups helps understand which features are significant for students from different demographics. In addition to this, we also observe a similar pattern in LIME based importance's discussed in earlier

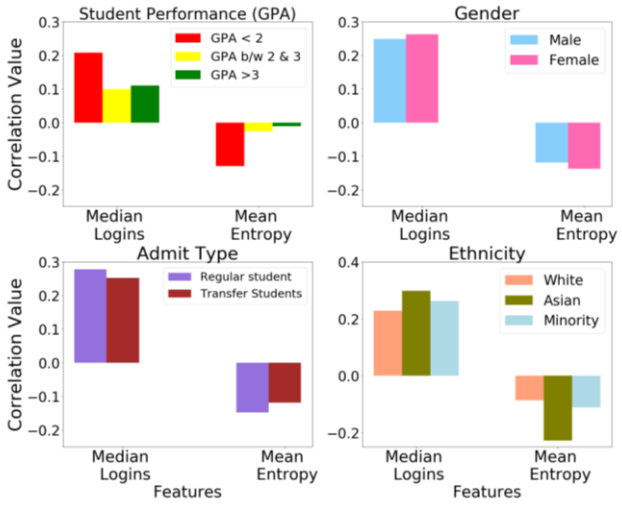

Figure 5. Correlation values for different student groups divided based on GPA, ethnicity, admit type and gender.

sections. We can infer that LIME based method also scales well for global feature importance in this study.

5.3.3 Regression Modeling for Feature Importance

One significant limitation of earlier methods is their inability to capture interaction effects as feature importance might change in the presence of other features. To study the interaction effects, we apply a linear regression model on different categories of student login data collected till the middle of semester. These student categories were divided based on GPA, gender, admit type and ethnicity of students. Even though linear regression models are applied on all features discussed in earlier sections, we only report the coefficients of median login volume and mean login regularity

in table 7, as these variables are the focus of this study. From table 7, we observe that login volumes, and login regularity features are following similar direction for students with lower GPA and students from minority ethnic backgrounds as observed in the LIME and correlation based analysis. There are some discrepancies in other observations as there is no statistical significance (high p values) for coefficients in these cases. Another reason for focusing on student from these two groups is their higher attrition rates found in earlier studies [43, 44]. Studying these groups closely will help develop targeted interventions in the future.

Table 7. Regression coefficients (Significance marked with *)

Student Demographic	Student Groups	Median Logins Coefficient	Mean Login Regularity Coefficient
GPA	**GPA <= 2**	**0.171***	**-0.398***
	GPA >2 & <= 3	-0.013	0.200
	GPA >3	0.065	-0.002
Gender	Male	0.135	0.130
	Female	-0.021	-0.157
Admit Type	Regular	0.399	-0.004
	Transfer	0.611	0.191
Ethnicity	White	0.204	-0.029
	Asian	-0.085	0.201
	Minority Race	**0.201***	**-0.153***

6. DISCUSSION & CONCLUSION

There is a growing interest in building models that capture student behavioral patterns while using LMS systems to predict their performance. Earlier research showed that building efficient models based on LMS data to predict student performances is not a simple task as multiple learning and demographic factors impact student learning processes. Although earlier research in EDM and LA tried to address different issues related to student performance tracking, there is still a gap in developing models that accurately predict overall student performance and explain underlying factors that improve their academic performance. As a step in this direction, this study presents a student-centric modeling approach based on aggregated LMS features to predict and explain the reasons behind varying student performances. This context is both relevant and timely given the increase of LMS adoption and a need for efficient and interpretable model development.

6.1 Key Contributions

One primary contribution in this study is the development of student-centric models on aggregated student LMS login data that are least biased towards the diverse course contents and instructor teaching styles. Using the feature extraction methods developed in this study, we were able to build efficient GBT model that is able to predict student end-of-term GPA with an average R squared of 0.37 across the semester. Furthermore, models built at different durations of a semester showed only slight improvement in predictive performance after crossing a specific duration (middle of the semester). This observation helps develop models in the middle of the semester to estimate student performance accurately.

In addition to developing student-centric models, this study also focused on understanding the impact of various LMS features on student performances. Earlier studies in this domain primarily focused on volume of logins. In this work, we also studied the impact of login regularity measured by entropy statistics on student performance by implementing LIME explanation, correlation, and linear regression methods. From our interpretation studies, we observed that students who login regularly into the LMS system have a positive relationship with performance improvement. This observation is highly significant for underperforming students (GPA < 2) and students from minority races.

We also found no significant difference in the impact of LMS features on Male and Female students. This observation is valid as LMS features used in this study are captured objectively rather than subjectively. This observation also holds for regular and transfer students.

Our study also extracted student interaction features based on concepts in chronobiology and chronopsychology to understand if there is a student performance variation based on different chronotypes. From the results, we observed no significant difference in performance. The impact of these features is negligible in the presence of aggregated student login volume.

6.2 Applications & Limitations

Student performance tracking is a complex process as it depends on multiple dimensions and facets. Developing student-centric models to predict student performance models helps student counselors and educational administrators design student level interventions that attract students' attention. Also, developing predictive models that estimate students' overall performance in the middle of the semester will make them aware of their predicted end-of-term performance. These predictions might act as an external intervention to improve their performance in the remaining part of the semester. By understanding the difference in the impact of LMS features on students from different demographics, researchers and administrators can build more personalized instructional methods that are suitable for diverse student cohorts.

There were also some limitations in this study. The predictive performance achieved by using aggregate features across different courses enrolled by students is moderate at best. It would be more helpful to explore ways to improve the performance of these models. One possibility is to add other features that target independent content access durations, mid-semester assessments, and other external factors. One major challenge that needs to be addressed in our future studies is to find an effective method to aggregate content level features across different courses enrolled by a student. The dataset used in this study is extracted in a single semester and students from two departments that are closely related to each other. To understand if the findings in this study are scalable to other undergraduate students, we will extend these models to students from various departments in the university.

To conclude, we built student-centric models to predict student performances that supports the development of student level interventions. We then use the LIME explanations to study LMS features' importance on student performance prediction. Finally, we study the univariate and multivariate feature importance's using correlation and regression methods and assess them with the feature importance's extracted in LIME method.

ABSTRACT

Access to high-quality education at scale is limited by the difficulty of providing student feedback on open-ended assignments in structured domains like programming, graphics, and short response questions. This problem has proven to be exceptionally difficult: for humans, it requires large amounts of manual work, and for computers, until recently, achieving anything near human-level accuracy has been unattainable. In this paper, we present generative grading: a novel computational approach for providing feedback at scale that is capable of accurately grading student work and providing nuanced, interpretable feedback. Our approach uses generative descriptions of student cognition, written as probabilistic programs, to synthesise millions of labelled example solutions to a problem; we then learn to infer feedback for real student solutions based on this cognitive model.

We apply our methods to three settings. In block-based coding, we achieve a 50% improvement upon the previous best results for feedback, exceeding human-level accuracy. In two other widely different domains—graphical tasks and short text answers—we achieve improvements over the previous state of the art by about 4x and 1.5x respectively, approaching human accuracy. In a real classroom, we ran an experiment with our system to augment human graders, yielding doubled grading accuracy while halving grading time.

Keywords

Generative models, automated feedback, Idea2Text, probabilistic programs, grammars, Zipf distribution, zero shot.

1. INTRODUCTION

Enabling global access to high-quality education is a long-standing challenge. The combined effect of increasing costs per student [3] and rising demand for higher education makes this issue particularly pressing. A major barrier to providing quality education has been the ability to automatically provide *meaningful and accurate* feedback on student work.

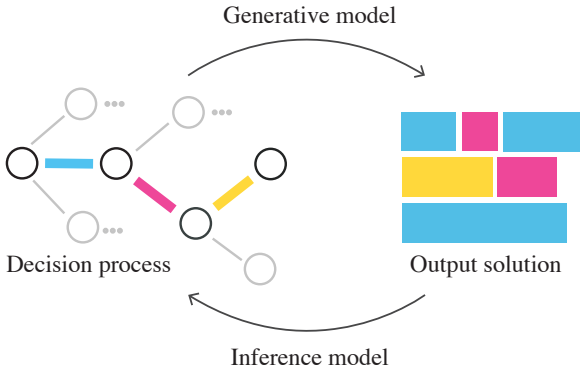

Figure 1: Students solve problems by making decisions that result in their final solution (generative model). Providing feedback requires the reverse task of seeing a solution and inferring the student decisions that lead to this solution (inference model).

Learning to provide feedback on richly structured problems beyond simple multiple-choice has proven to be a hard machine learning problem. Five issues have emerged, many of which are typical of human-centred AI problems: (1) student work is extremely diverse, exhibiting a heavy tailed distribution where most solutions are rare, (2) student work is difficult and expensive to label with fine-grained feedback, (3) we want to provide feedback (without historical data) for even the very first student, (4) grading is a precision-critical domain with a high cost to misgrading, and (5) predictions must be explainable and justifiable to instructors and students. Despite extensive research using massive education data [23, 1, 33, 28, 18, 14], these issues make traditional supervised learning inadequate for automatic feedback.

Human instructors are experts at providing feedback. When grading assignments, they have an understanding of the decisions and missteps students might make when solving a problem, and what corresponding solutions these choices would result in. For example, an instructor understands that a student wanting to repeat something in a programming assignment might use a `for` loop or manually write out repeated statements. And given that the student uses a loop, their loop could be correct or off-by-one.

Ali Malik, Mike Wu, Vrinda Vasavada, Jinpeng Song, Madison Coots, John Mitchell, Noah Goodman and Chris Piech "Generative Grading: Near Human-level Accuracy for Automated Feedback on Richly Structured Problems". 2021. In essence, instructors mentally possess *generative models* of student decision-making and how these decisions manifest in a final solution (Fig. 1, forwards). When providing feedback, the instructor does *inference*: given a student solution, they use their mental model to try and determine the underlying student decisions that could have resulted in this solution (Fig. 1, backwards).

In this paper, we propose an automated feedback system that mimics the instructor process as closely as possible. Firstly, the system elicits a literal generative model from an instructor in the form of a concrete student simulator. Secondly, it uses deep neural networks and a novel inference method with this simulator to learn how to do inference on student solutions, *without using any labelled data*. Finally, the inference model is used to provide automated feedback to real student solutions. We call this end-to-end approach **generative grading**.

When used across a spectrum of public education data sets, our automated feedback system is able to grade student work with close to *expert human-level* fidelity. In block-based coding, we exceed human-level accuracy, achieving a 50% improvement over the previous best results for feedback. In two other widely different domains—graphical tasks and short text answers—we achieve improvements over the previous state of the art by about 4x and 1.5x respectively, approaching human accuracy. We used our system in a real classroom to augment human graders in a CS1 class, yielding *doubled* grading accuracy while *halving* grading time.

1.1 Main contributions

In Sec. 4, we present an easy-to-use and highly expressive class of generative models called Idea2Text simulators that allow an instructor to encode their mental models of student decision-making. These simulators can succinctly express student decisions and how these decisions manifest in a final solution for a broad set of problem domains like graphics programming, short-answer questions, and introductory programming in Java. We provide a Python implementation that allows any instructor to easily write these simulators.[1]

In Sec. 5, we show how to use Idea2Text simulators with deep neural networks to infer students' decision processes from their solutions. This extracted decision process is a general representation of a student's solution and can be used for several downstream tasks such as providing automated feedback, assisting human grading, auditing and interpreting the model decisions, and improving the quality of the simulator itself.

In order to do inference successfully on our expressive class of simulators, we must overcome several interesting technical challenges (Sec. 5). Learning to map solutions to sequences of decisions specified by the simulator is a nonstandard machine learning task, with non-fixed labels, varied sequence lengths, and unexpected trajectories. Moreover, generating simulated training data from the simulators requires an intelligent sampling method to work effectively.

[1]All code publicly available at: `https://github.com/malik-ali/generative-grading`

In Sec. 6 we show the efficacy of our approach in practice on a diverse set of richly structured problems. We attain close to human-level accuracy on providing feedback and surpass many previous state of the art results. We also discuss several interesting extensions in Sec. 7 that use our system to go beyond just providing automated feedback.

The generative grading system is powerful because it addresses many of the issues of traditional supervised learning mentioned above. We find that the cost of writing simulators for a new assignment is orders of magnitude cheaper for instructors than manually annotating individual student work. The simulators allow us to sample infinite data, and our adaptive sampling strategy lets us explore diverse student solutions in our training data. It is "zero-shot", requiring no historical data nor annotation, and thus works for the very first student. Moreover, our novel inference system allows for interpretable and explainable decisions.

2. RELATED WORK

"Rubric sampling" [32] first introduced the concept of encoding expert priors in grammars of student decisions, and was the inspiration for our work. The authors design Probabilistic Context Free Grammars (PCFGs) to curate synthetically labelled datasets to train supervised classifiers for feedback. Our approach builds on this, but presents a more expressive family of generative models of student decision-making that are context sensitive and comes with new innovations that enable effective inference. From our results on Code.org, we see that this expressivity is responsible for significant improvements in our model's performance. Furthermore, this prior work only used to PCFGs to create simulated datasets of feedback labels for supervised learning. In contrast, we learn to infer the entire decision trajectory of a student solution, allowing us to do things like dense feedback and human-in-the-loop grading.

We draw theoretical inspiration for our generative grading system from Brown's "Repair Theory" which argues that the best way to help students is to understand the generative origins of their mistakes [4]. Building systems of student cognition has been used in K-12 arithmetic problems [16] and subtraction mistakes [8].

Automated feedback for open-ended richly structured problems has been studied through a few lenses. In many approaches, traditional supervised learning is employed to map solutions to feedback [21, 30, 1, 33]. These methods require large hand-labelled datasets of diverse student solutions, which is difficult due to heavy-tailed distributions. Feedback specific to computer programming problems has been explored based on executing student solutions and comparing to a reference solution [13, 19]. An interesting parallel to our work is found in [13], where the instructor is asked to specify the kinds of mistakes students can make. These approaches are limited to code and don't provide feedback on the problem-solving process of a student.

Extracting expert-written generative models for inference has seen enormous use in fields where domain expertise is critical. Some key example include medical diagnosis, engineering, ecology, and finance, where a generative model like a Bayesian network is elicited from experts. [20, 22]. In ed-

ucation, instructors have domain expertise about students, and Idea2Text serves as an easy-to-use generative model for instructors to encode this expertise.

Inference over decision trajectories of Idea2Text simulators is similar to "compiled inference" for execution traces in probabilistic programs. As such, our inference engine shares similarities to this literature [25, 17]. With Idea2Text simulators, we get a nice interpretation of compiled inference as a parsing algorithm.

3. BACKGROUND

In this section, we introduce the feedback challenge and what makes it a difficult machine learning problem.

3.1 Feedback as a Prediction Problem

The *feedback prediction* task is to automatically provide feedback to a given student solution. While this is easy to do for simple multiple-choice problems, we focus on the challenging task of providing feedback on richly-structured problems like computer programming or short-answer responses.

Both the type of student solutions and the type of feedback required for the task can take many forms. A student solution can be a piece of text, which could represent problems like an essay, a maths proof, or a code snippet. It could also be graphical output in the form of an image. Similarly, feedback can take the form of something simple like classifying solutions to a fixed set of misconceptions, or something complex such as highlighting and annotating specific parts of a student solution

3.2 Difficulty of Automated Feedback

Feedback prediction on richly structured problems has been an extremely difficult challenge in education research. Even limited to simple problems in computer science like beginner block-based programming, automated solutions to providing feedback have been restricted by scarce data and lack of robustness. We discuss a few of the properties of student work that make predicting feedback such a difficult challenge.

(1) Heavy-tailed Distributions: Student work in the form of natural language, mathematical symbols, or code follow heavy-tailed Zipf distributions. This means that a few solutions are extremely common whereas almost all other examples are unique and show up rarely. Fig. 2 plots the log-frequency of unique examples against the log of the rank across four datasets of student work in block-based programming code, Java code, and free response. For all datasets, we observe a linear relationship in log-log space, which is a characteristic property of Zipf distributions.

These heavy-tailed Zipf distributions pose a hard generalisation problem for traditional supervised machine learning: a handful of similar examples appear very frequently in the training data whereas almost all other examples are unique. This means at test time, examples are likely to introduce unseen tokens, new misconceptions, and novel student strategies. In a Zipf distribution, even if we observe a million student solutions, there is roughly a 15% chance that the next student generates a unique solution.

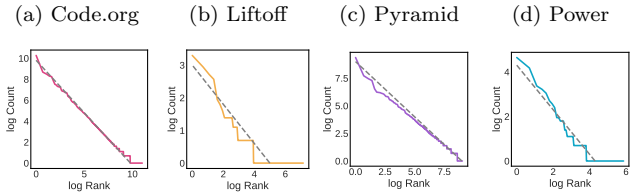

Figure 2: Student solutions (across many domains) exhibit heavy-tailed Zipf distributions, meaning a few solutions are extremely common but all other solutions are highly varied and show up rarely. This suggests that the probability of a student submission not being present in a dataset is high, making supervised learning on a small data set difficult.

(2) Difficulty of Annotation: Annotating student work with feedback requires an instructor-level expertise of the domain. Providing fine-grained feedback also takes effort to read and understand student solutions before inferring possible misconceptions. In [32], the authors found that it took 26 hours to label 800 student solutions to block-based programming.

This difficulty, combined with Zipf properties, makes supervised learning challenging. As an example, in 2014, Code.org, a widely used resource for beginners in computer science, ran an initiative to crowdsource thousands of instructors to label 55,000 student solutions in a block-based programming language. Yet, despite having access to an unprecedented amount of labelled data, traditional supervised methods failed to perform well on even these "simple" questions.

(3) Limitations on Data Size: Even if the Code.org approach succeeded, most classrooms do not share the same scale as Code.org. A method that relies heavily on historical data is not widely applicable in the average classroom setting. In our experiments, our data sets contain less than a few hundred examples, again disqualifying the application of supervised algorithms. The ideal feedback model will be zero-shot so that it works even for the very first student.

4. MODELLING STUDENT COGNITION

Having presented the feedback challenge and motivated why supervised learning cannot solve this problem alone, we discuss the idea of modelling the cognitive process of student decision-making when producing a solution.

When an instructor provides feedback on student work, they often have a latent mental model of student decision making; this captures the kinds of steps and mistakes they think students will make and what solutions are indicative of those steps. The instructor (or TAs) then grade solutions, one at a time, by essentially inferring the steps in the decision-making model that lead to the produced solution.

As a concrete example from introductory programming, suppose a student is trying to print a countdown of numbers from 10 to 1. An instructor understands that as a first step, a student might use a `for` loop or manually write ten `print` statements. Given that the student uses a loop, they could increment up or down. And given that they increment down, their loop comparison could be correct or off-by-one. At each of these decision points, the instructor can conceive how a specific choice would manifest in the solution.

We want to allow instructors to capture their mental model of student decision-making for a given problem and distil it into a concrete executable simulator that generates solutions. Such a generative model could be used to simulate unlimited student data, including their decision process and resulting solutions. This simulated dataset can then be used for learning how to provide feedback.

In this section, we formalise the idea of a student's decision process for generating the solution to a problem and discuss how we can represent the instructor's latent model of this generative process as a concrete simulator.

4.1 Student Decision Process (SDP)

A student's decision process (SDP) can be seen as the sequence of choices the student makes while solving a problem, and how those choices correspond to different outputs. The sequence is intended to reflect all of the critical decisions made by the student, and in particular those a teacher would like to recover from the solution. Importantly, not all students will encounter the same sequence of decisions since an early decision choice may determine which decisions are faced later in problem solving.

We can formally think of a decision point as a categorical random variable, X, and the specific choices that can be made as the different values, $x \in Val(X)$, that the random variable can take. The decision process of a student can be seen as a sequence trajectory $(X_t, x_t)_{t=1}^{T}$, of decisions encountered and made by the student in solving the problem.

Under this interpretation, specifying a model for an SDP amounts to defining the space of possible decision trajectories and a probability distribution over this space. By the chain rule for probabilities, we can decompose this overall distribution as a sequence of conditional probabilities $\mathbb{P}(X_t = x_t \mid \mathbf{X}_{<t} = \mathbf{x}_{<t})$. Here x_t is the choice made at step t from domain X_t and $\mathbf{X}_{<t}$ is shorthand for the sequence of decisions before time t.

We want to make this general formulation more tractable to allow us to specify useful SDPs as generative models we can sample from. Prior work [32] has attempted to express SDPs by restricting the class of generative models to probabilistic context free grammars (PCFGs). They found that instructor-written PCFGs could often be used to emulate student problem-solving and generate student solutions for small problems. In this setting, the non-terminal nodes of the PCFG represent decisions to be made (e.g. syntax confusion) and the production rules represent how decisions are made and manifested into output (e.g. the code is missing a semicolon). Instructors create student simulators by specifying decision points, rules, and probabilities for each rule (e.g. missing a semicolon is much more likely than missing a `function` statement).

A PCFG is compact and useful, but makes the independence assumption that that the choice made at time t is independent of past choices made while solving the problem i.e. $\mathbb{P}(X_t = x_t \mid \mathbf{X}_{<t} = \mathbf{x}_{<t}) = \mathbb{P}(X_t = x_t)$. This context-independence is a strong restriction that severely limits what instructors can express about the student decision-making process and fails to faithfully model student reasoning. As can be seen in even the simple countdown example above, the off-by-one error would manifest differently in student output depending on whether the student chose to increment up or down. Thus, context dependence of decision making is an important property to model.

Algorithm 1 Idea2Text Simulation

Input: Idea2Text simulator (D, Σ, S)
Output: Tuple (τ, y) of decision trajectory and output solution.

procedure SIMULATE(D, Σ, S)
  $\tau \leftarrow [\,]$
  $y \leftarrow$ GENERATE(S, τ) ▷ Begin from start node
  return (τ, y)
procedure GENERATE(N, τ)
  $a, X_a, \Pi_a \leftarrow N$ ▷ Unpack current decision node
  $x_a, y \leftarrow \Pi_a(X_a, \tau)$ ▷ Get decision choice and output
  $\tau.append((a, x_a))$
  for decision node N' in y **do** ▷ In order left to right
    $y' \leftarrow$ GENERATE(N', τ)
    $y \leftarrow$ REPLACE(y, N', y') ▷ Replace N' with y'
  return y

4.2 Idea2Text

In this section, we define a broader class of generative models that is powerful enough to capture more complexities of expert models of student cognition. Similar to PCFGs we structure our models around a set of non-terminal symbols that correspond to student decisions and contribute to the final output. However, drawing from work on probabilistic programs [10, 11], we allow these choices to be made depending on previous choices. While dependence on context leads to extremely expressive models, we will show that requiring some text to be generated at each step is enough for inference to remain tractable. We call this class of generative models Idea2Text.[2]

Concretely, an Idea2Text simulator consists of a tuple of (D, Σ, S) denoting a set of nonterminal decision nodes, a set of terminal nodes, and a starting root node, respectively. Intuitively, decision nodes correspond to decisions a student might make and the terminal nodes correspond to literal text tokens in the final output. Each run of the simulator also keeps a global state τ which stores the history of all decisions made during the execution (often called an *execution trace* for probabilistic programs [2, 29]).

Each decision node in D is a tuple (a, X_a, Π_a) consisting of a unique name, a random variable representing the decision choices, and a production program, which (1) specifies how this decision should be made based on the decisions made so far, and (2) produces an output solution for a given decision choice.

More concretely, the production program is a probabilistic function that takes the current decision history τ and does the following:

(1) Samples the random variable $x_a \sim X_a$, from a distribution, $\mathbb{P}(X_a|\tau)$, that can depend on the decision history.

[2] A very similar class of models, used in the very different domain of customer service, was independently named Idea2Text by scientists at Gamalon, Inc.

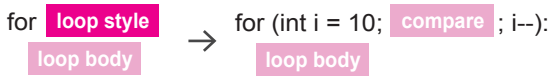

Figure 3: An example decision expansion step in an Idea2Text simulation. The "loop style" decision node chooses a type of for loop (e.g. increment vs decrement) and outputs a string containing the header of the for loop (terminals) plus another decision node.

(2) Based on the sampled choice, x_a, produces an output string, y, consisting of literal text (terminal nodes) and incomplete segments (decision nodes). These incomplete segments correspond to future decisions that will be expanded later (see Fig. 3).

(3) Returns the sampled choice and output string: (x_a, y).

An output from Idea2Text is a generation from the root node to a sequence of literal text by recursively expanding the decision nodes, as shown in Algorithm 1. Each output is associated with the final decision trajectory, $\tau = [(a_t, x_{a_t})]_{t=1}^{T}$, of random variables encountered during generation. Here, a_t denotes the unique name for the random variable encountered at timestep t, and x_{a_t} is the sampled value for that variable.

We point out some important properties of Idea2Text simulators. First, each decision node's choice can depend on the decision history τ, allowing past decisions to influence current behaviour. This is strictly more expressive than PCFGs [32] and allows instructors to write highly contextual models of student problem-solving. Second, production programs have the full power of programming languages at their disposal and can use arbitrarily complicated transformations to produce their output sequence. As an example, a production program can transform terminal nodes into images or use a machine-learning conjugator to conjugate it's produced text into a proper sentence.

5. INFERENCE

In this section we describe how we can use an instructor-written Idea2Text simulator to learn how to infer the decisions underlying a student solution.

At a high-level, the Idea2Text simulator contains the instructor's mental model for the sequence of decisions students make that result in different solutions. For inference we want to do the reverse: given a student solution, we want to find a trajectory of decisions in the simulator that would produce that solution.

A model that could successfully do this inference could be used to map real student solutions to decision steps in the simulator. These extracted decisions are a rich and general representation of a student's solution and can be used for downstream tasks such as automated feedback, assisting human grading, auditing and interpreting the model decisions, and improving the quality of the simulator.

More formally, let $\mathcal{G}$ be a given Idea2Text simulator. Each execution of $\mathcal{G}$ produces a decision trajectory τ and corresponding production y. Since the execution is probabilistic, the simulator induces a probability distribution $p_{\mathcal{G}}(\tau, y)$ over trajectories and productions.

Given a student solution, y, we are interested in the task of *parsing*: this is the task of mapping y to the most likely trajectory in the Idea2Text simulator, $\arg\max_\tau p_{\mathcal{G}}(\tau|y)$, that could have produced y. This is a difficult search problem: the number of trajectories grows exponentially even for simple grammars, and common methods for parsing by dynamic programming (Viterbi, CYK) are not applicable in the presence of context-sensitivity and functional transformations. What's more, in order to transfer robustly to real student solutions, we would like to be able to approximately parse solutions that are not possible to generate from the simulator, but are sufficiently "nearby".

At a high level, our approach is to construct a large data set from the simulator and then learn an inverse "inference" neural net that can reconstruct the decision trajectory from the solution.

5.1 Adaptive Grammar Sampling

To train our models, we generate a large dataset of N trajectories and their associated productions, $\mathcal{D} = \{(\tau^{(m)}, y^{(m)})\}_{m=1}^{N}$, by repeatedly executing $\mathcal{G}$.

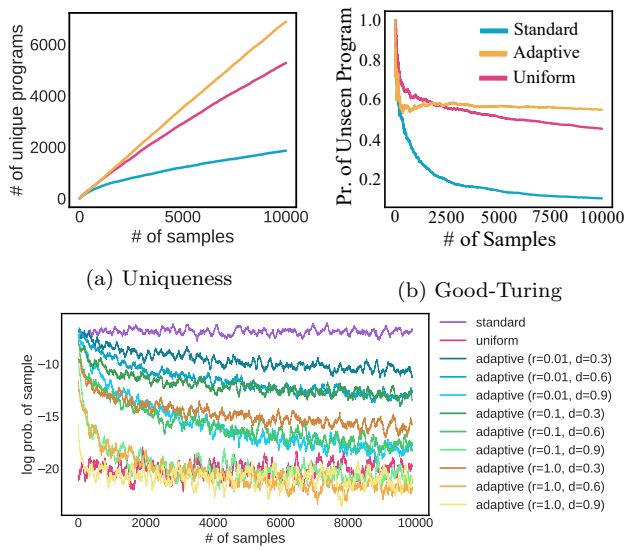
However, due to the Zipf-like nature of student work (see Sec. 3.2), standard i.i.d. sampling from the simulator will tend to over-represent the most probable productions. For our models, the more diverse student cognition we can simulate in the training data, the more we expect to generalise to the long tail of real students. Thus, we need sampling strategies that prioritise diversity.

A simple but flawed idea for generating diverse solutions would be to make choices at decision nodes uniformly randomly instead of using the expert-written distributions. This approach will generate more unique productions, but disregarding the expert-written distributions will result in unlikely and less realistic productions.

Ideally, we want to sample in a manner that covers all the most likely productions first, and then smoothly transition into sampling increasingly unlikely productions. This would generate unique productions efficiently while also retaining the expert-written distributions specified in the production programs. With these desiderata in mind, we propose a method called *Adaptive Grammar Sampling*. For each decision node in the simulator, we down-weight the probability of sampling each choice proportional to how many times it has been sampled in the past. To avoid overly punishing decision nodes early in the execution trace, we discount this down-weighting by a decay factor d that depends on the depth of the decision in the trajectory.[3] This method is inspired by Monte-Carlo Tree Search [5] and shares similarities with Wang-Landau sampling from statistical physics [27].

Fig. 4 shows a comparison of the effectiveness of adaptive sampling to uniform and i.i.d. sampling. Adaptive sampling interpolates nicely between sampling likely examples early on, as i.i.d. sampling does, to sampling unlikely examples

[3]The details can be found in the code.



(a) Uniqueness

(b) Good-Turing

(c) Likelihood of samples over time

Figure 4: Efficiency of sampling strategies for the Liftoff simulator. (a) Number of unique samples vs total samples so far. (b) Probability of sampling a unique next program given samples so far. (c) Likelihood of generated samples over time for different sampling strategies.

later, as uniform-choice sampling does. Note that adaptive sampling is customisable: as shown in 4c, the algorithm has parameters (r and d) that can be adjusted to control how fast we explore increasingly unlikely productions.

5.2 Neural Approximate Parsing

With good diverse samples available, we now aim to learn an approximation to the posterior $p_{\mathcal{G}}(\tau|y)$. We will do so by training a deep neural network to reconstruct the trajectory step-by-step. We call this approach *neural approximate parsing* with generative grading, or GG-NAP.

The challenge of inference over trajectories is a difficult one. Trajectories can vary in length and contain decision nodes with different support. To approach this, we decompose the inference task into a set of easier sub-tasks, similar to [25, 17]. The posterior distribution over a trajectory $\tau = (a_t, x_{a_t})_{t=1}^{T}$ given a production y can be written as the product of individual posteriors over each decision node x_{a_t} using the chain rule:

$$p_{\mathcal{G}}(x_{a_1}, \dots x_{a_T}|y) = \prod_{t=1}^{T} p_{\mathcal{G}}(x_{a_t}|y, \mathbf{x}_{<a_t}) \quad (1)$$

where $\mathbf{x}_{<a_t}$ denotes previous (possibly non-contiguous) nonterminals $(x_{a_1}, \dots, x_{a_{t-1}})$. Eqn. 1 shows that we can learn each posterior $p(x_{a_t}|\mathbf{x}_{<a_t}, y)$ separately. With an autoregressive model $\mathcal{M}$, we can efficiently represent the influence of previous nonterminals $\mathbf{x}_{<a_t}$ using a shared hidden representation over T timesteps. Since most standard choices for $\mathcal{M}$ (e.g. an RNN) require fixed-dimension inputs, we need to encode the solution and the history of choices into consistent vectors.

Firstly, to encode the solution y, we use standard machinery (e.g. CNNs for images, RNNs for text) with a fixed output dimension. To represent the nonterminal choices with different support, we define three layers for each random variable x_{a_t}: (1) a one-hot embedding layer that uses the unique name a_t to lexically identify the random variable, (2) a value embedding layer that maps the value of x_{a_t} to a fixed dimension vector and (3) a value decoding layer that transforms the hidden output state of $\mathcal{M}$ into parameters of the posterior for the next nonterminal x_{a_t+1}. Thus, the input to the $\mathcal{M}$ is a fixed size, being the concatenation of the value embedding, name embedding, and production encoding.[4]

To train the GG-NAP, we optimise the objective,

$$\mathcal{L}(\theta) = \mathbb{E}_{p_{\mathcal{G}}(\tau,y)}[\log p_\theta(\tau|y)] \approx \frac{1}{M}\sum_{m=1}^{N} \log p_\theta(\tau^{(m)}|y^{(m)}) \quad (2)$$

where θ are all trainable parameters and $p_\theta(\tau|y)$ represents the posterior distribution defined by the inference engine. At test time, given only a production y, GG-NAP recursively samples $x_{a_t} \sim p_\theta(x_{a_t}|y, \mathbf{x}_{<a_t})$ for $t = 1, \dots, T$ and uses each sample as the input to the next step in $\mathcal{M}$, as is standard for sequence generation models [12].

5.3 kNN Baseline

As a strong baseline for the parsing task, we consider a nearest neighbour classifier. We store our large dataset of samples $\mathcal{D} = \{(\tau^{(m)}, y^{(m)})\}_{m=1}^{N}$. At test time, given an input solution to parse, we can find its nearest neighbour in the samples with a linear search of $\mathcal{D}$, and return its associated trajectory. Depending on the problem, the solutions y will be in a different output space (image, text) and thus the distance metric used for the nearest-neighbour search will be domain dependent. We refer to this baseline as GG-kNN. Note that GG-kNN is quite costly in memory and runtime as it needs to store and iterate through all samples in the dataset.

6. EXPERIMENTS

We test generative grading on a suite of education data sets focusing on introductory courses from online platforms and large universities. For each dataset, we compare our approach to supervised learning, PCFGs, k-nearest neighbours, and human performance. In Sec. 6.1, we introduce the data sets, then present results in Sec. 6.3.

6.1 Datasets

We consider four educational contexts. Fig. 5 shows example student solutions for each problem.

Block-based Programming Code.org released a data set of student responses to eight Blocky exercises from one of their curriculums online, which focuses on drawing shapes with nested loops. We take the last problem in the curriculum (the most difficult one): drawing polygons with an increasing number of sides—which has 302 human graded responses with 26 misconceptions regarding looping and geometry (e.g. "missing for loop" or "incorrect angle") from [32].

Free Response Language Powergrading [1] contains 700 responses to a United States citizenship exam, each graded for

[4]Specific details can be found in the code.

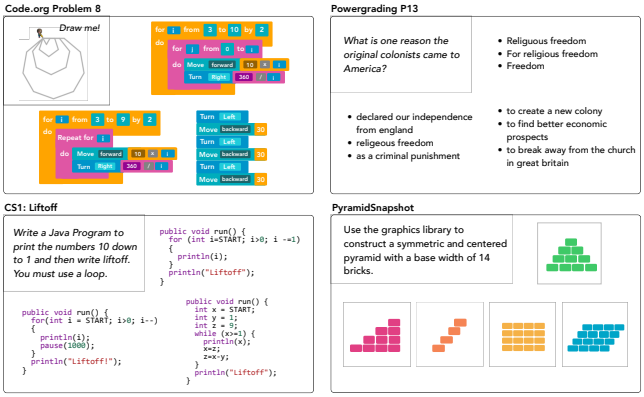


Figure 5: We show the prompt and example solutions for our four datasets.

correctness by 3 humans. Responses are in natural language, but are typically short (average of 4.2 words). We focus on the most difficult question, as measured by [24]: "name one reason the original colonists came to America". Correct responses span economic, political, and religious reasons.

Graphics Programming PyramidSnapshot is a university CS1 course assignment intended to be a student's first exposure to variables, objects, and loops. The task is to build a pyramid using Java's ACM graphics library by placing individual blocks. The dataset is composed of *images* of rendered pyramids from intermediary "snapshots" of student work. [33] annotated 12k unique snapshots with 5 categories representing "knowledge stages" of understanding.

University Programming Assignment Liftoff is a second assignment from a university CS1 course that tests looping. Students are tasked to write a program that prints a countdown from 10 to 1 followed by the phrase "Liftoff". In Sec. 7, we will use Liftoff for a human-in-the-loop study where experts generatively grade 176 solutions from a semester of students and measure accuracy and grading time.

6.2 Simulator Descriptions

We provide a brief overview of the Idea2Text simulators constructed for each domain.

Block-based Programming The primary innovation is to use the first decision node random variable to represents student ability. This ability variable will affect the distributions for random variables later in the trajectory such as deciding the loop structure and body. The intuition this captures is that high ability students make very few to no mistakes whereas low ability students tend to make many correlated misunderstandings. This simulator contains 52 decision nodes.

Free Response Language Idea2Text simulators over natural language need to explain variance in both semantic meaning and prose. We inspected the first 100 responses to gauge student thinking. Procedurally, the first random variable is choosing whether the production will be correct or incorrect. It then chooses a subject, verb, and noun dependent on the correctness. Correct answers lead to topics like religion, politics, and economics while incorrect answers are about taxation, exploration, or physical goods. Finally, we add a random variable to decide a writing style to craft a sentence. To capture variations in tense, we use a conjugator [7] for the final production. This simulator contains 53 decision nodes.

Graphics Programming The primary decision in this simulator decides between 13 "strategies" (e.g. making a parallelogram, right triangle, a brick wall, etc.) that the instructor believed students would use. Each of the 13 options leads to its own set of nodes that are responsible for deciding shape, location, and colour. The production uses Java to render an image output. This simulator contains 121 decision nodes, and required looking at 200 unlabelled student solutions in its design.

University Programming Assignment To model student thinking on Liftoff, this simulator first determines whether to use a loop, and, if so, chooses between "for" and "while" loop structures. It then formulates the loop syntax, choosing a condition statement and whether to count up or count down. Finally, it chooses the syntax of the print statements. Notably, each choice is dependent on previous ones. For example, choosing an end value in a for loop is sensibly conditioned on a chosen start value. This simulator contains 26 decision nodes.

6.3 Results for Feedback Prediction

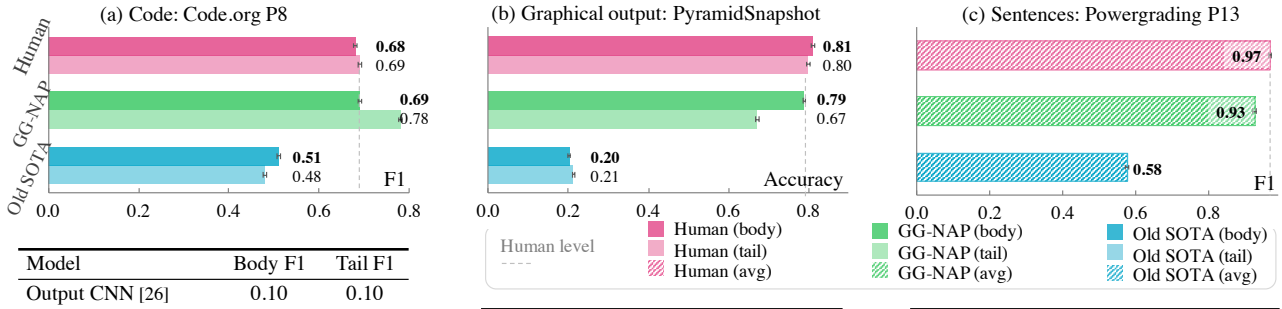
We show the results of generative grading for each of the datasets above.

For each dataset, we have access to a set of real student solutions and corresponding human-provided feedback labels, which we use for evaluation. We measure human accuracy relative to the majority label.

We ask instructors to create an Idea2Text simulator for each dataset, and train the deep inference network GG-NAP using simulated student solutions. At test time, we pass a real student solution into the inference model, and get back a trajectory of the simulator. This trajectory contains decision node choices that correspond to the human-provided feedback labels, and we use these as the predicted feedback.

Our performance metric for evaluating the model's predicted feedback labels is accuracy or F1 score, depending on the convention of prior work. Computing an average of the metric across the evaluation dataset would over-prioritise examples that appear frequently; this is particularly important to avoid for the Zipf distributed solutions. Since we care about providing feedback to struggling students in the tail of the distribution, we separately calculate performance for different "regions" of the Zipf. Specifically, we define the *head* as the k most popular solutions, the *tail* as solutions that appear only once or twice, and the *body* as the rest. As solutions in the head can be trivially memorised, we focus on performance on the body and tail.

Training Details We report averages over three runs; error bars are shown in Fig. 6. We use a batch size of 64, train for 20 epochs on 100k unique samples adaptively sampled from the simulator. We optimise using Adam [15] with a learning rate of 5e-4 and weight decay of 1e-7. For PyramidSnap-



Model	Body F1	Tail F1
Output CNN [26]	0.10	0.10

Figure 6: Summary of results for providing feedback to student work in three educational contexts: block-based programming, graphics programming, and free response language. Generative grading shows strong performance in all three settings, closely approximating human-level performance in two data sets, and surpassing human-level performance in the other.

shot, we use VGG-11 [26] with Xavier initialisation [9] as the encoder network. For other data sets, we use a Recurrent Neural Network (RNN) with 4 layers, a hidden size of 256. The deep inference network itself is an unrolled RNN: we use a gated recurrent unit with a hidden dimension of 256 and no dropout. The value and index embedding layers output a vector of dimension 32. These hyperparameters were chosen using grid search.

Code.org As feedback for Code.org exercises has been studied in prior work [32], we compare generative grading to a suite of baselines including supervised models trained to classify misconceptions from the hand-labelled dataset (Output CNN [28] + Program RNN [32]), unsupervised models that learn a latent vector representation of student work (MVAE), to the k-nearest neighbours baseline GG-kNN from Sec. 5. Most relevant to our approach is the "rubric sampling" [32] comparison, which uses a PCFG to simulate students and generate a supervised data set to train a RNN classifier. Human accuracy is measured by comparing the feedback of multiple annotators to the majority label.

As shown in Fig. 6, generative grading is able to provide accurate feedback (historically measured as F1) beyond the level of individual human annotators, setting the new state-of-the-art. We observe a large improvement over prior work, which perform significantly worse than human graders. Compared to rubric sampling, we find a 18% (absolute) improvement in the body and a 30% (absolute) improvement in the tail. This clearly demonstrates the practical importance of being context-sensitive. The global state of Idea2Text simulators allow us to easily write richer generative models that are capable of better simulating real students. The potential impact of a human-level autonomous grader is large: Code.org is used by 610 million students, and our approach could save thousands of human hours for teachers by providing the same quality of feedback at scale.

Powergrading We find similarly strong performance on the Powergrading corpus of short answer responses to a citizenship question. Fig. 6 shows that generative grading reaches a F1 score of 0.93, an increase of 0.35 points above prior work that used hand-crafted features to predict correctness [6], and 0.38 points above supervised neural networks [24]. We were unable to compare to rubric sampling [31] as it was too difficult to write a faithful PCFG to describe free response language. Generative grading takes a large step towards closing the gap to human performance (F1 = 0.97). We are especially optimistic about these results as Powergrading responses contain natural language, this is promising signal that ideas from generative grading could generalise beyond computer science education.

PyramidSnapshot Investigating a third modality of image output from a graphics assignment, we find similar results comparing generative grading to the k-nearest neighbour baseline and a VGG image classifier presented in [33], outperforming the latter by nearly 50% absolute.

Unlike other datasets, the PyramidSnapshot dataset includes student's intermediary work, showing stages of progression through multiple attempts at solving the problem. With our near-human level performance, instructors could use GG-NAP to measure student cognitive understanding over time *as* students work. This builds in a real-time feedback loop between the student and teacher that enables a quick and accurate way of assessing teaching quality and characterising both individual and classroom learning progress. From a technical perspective, since PyramidSnapshot only includes rendered images (and not student code), generative grading was responsible for parsing student solutions from just images alone, a feat not possible without the flexibility of probabilistic programs used in Idea2Text. For this reason, we could not apply rubric sampling in this context either.

7. EXTENSIONS

Our results show that generative grading is a powerful tool for the feedback prediction task. However, our system is much more general than this and has many interesting extensions that we discuss in this section.

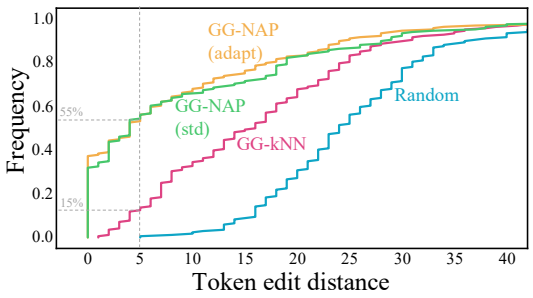

Figure 7: CDF of Levenshtein edit distance between student programs and nearest-neighbours using various algorithms.

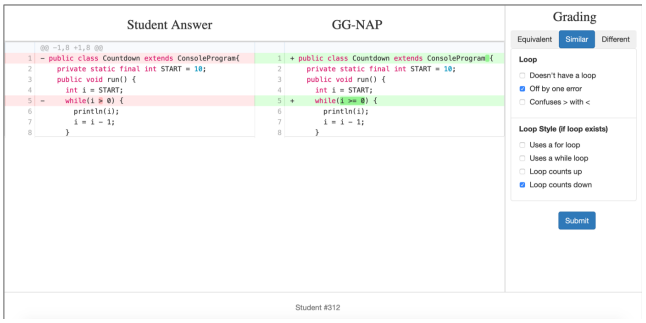

Figure 8: Human-in-the-loop Generative Grading UI

7.1 Nearest In-Simulator Neighbour

As described in Section 5, our inference model learns to map a given solution, y, to a decision trajectory in the simulator. So far, we have used this only to provide feedback with a fixed set of labels. However, the decision trajectory has a much more powerful interpretation; it represents the sequence of decisions in the simulator that the inference model thinks will produce y. Since we have the simulator in hand, we can actually execute it with these predicted sequence of decisions and inspect the simulated output, $\widehat{y}$.

If the simulated output is exactly equal to the original input solution, i.e. if $y = \widehat{y}$, then we can make a strong claim: the predicted trajectory from the inference model was provably correct and the corresponding labels can be assigned with 100% confidence. This is a claim that is seldom possible with traditional supervised learning methods and advances efforts towards creating explainable AI.

What about when $y \neq \widehat{y}$? In this case, the simulated output is not an exact match to the student solution, but we can still treat it as a "*nearest in-simulator neighbour*" to y. Fig. 7 shows the quality of these nearest neighbours to the student solutions using a distance metric like edit distance.

As we show below, these nearest neighbours can be used for powerful forms of feedback mechanisms.

7.2 Human-in-the-loop Grading

In a real-world setting, predicting feedback labels could be unreliable due to the high risk of giving students incorrect feedback. Beyond automated feedback, we explore how generative grading can be used to make human graders more effective using a human-in-the-loop approach.

To do this, we created a human-in-the-loop grading system using GG-NAP. For each student solution, we use the inference model to find the nearest in-simulator neighbour (Sec. 7.1); this nearest neighbour already has associated labels that are correct *for the nearest neighbour*. A human grader is presented with the original student solution, as well as a diff to the nearest neighbour; the grader then adjusts the labels of the nearest neighbour based on the diff to determine grades for the real solution. We show an image of the user-interface of this system in Fig. 8.

We investigated the impact of this human-in-the-loop system on grading accuracy and speed in a real classroom setting. We hired a cohort of expert graders (teaching assistants for a large private university) who graded 30 real student solutions to Liftoff. For control, half the graders proceeded traditionally, assigning a set of feedback labels by just inspecting the student solutions. The other half of graders additionally had access to (1) the feedback assigned to the nearest neighbour by GG-NAP and (2) a code differential between the student program and the nearest neighbour. Some example feedback labels included "off by one increment", "uses while loop", or "confused > with <". All grading was done on a web application that kept track of the time taken to grade a problem.

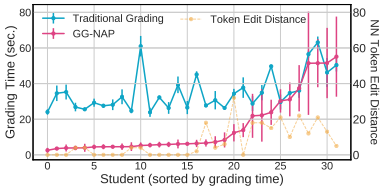
We found that the average time for graders using our system was *507 seconds* while the average time using traditional grading was *1130 seconds*, a more than double increase. Moreover, with our system, only *3 grading errors* (out of 30) were made with respect to gold-standard feedback given by the course professor, compared to the *8 errors* made with traditional grading. Fig. 9a shows these results for each of the 30 solutions.

The improved performance stems from the semantically meaningful nearest neighbours provided by GG-NAP. Having access to graded nearest neighbours helps increase grader efficiency and reliability by allowing them to focus on only "grading the diff" between the real solution and the nearest neighbour. By halving both the number of errors and the amount of time, GG-NAP can have a large impact in classrooms today, saving instructors and teaching assistants unnecessary hours and worry over grading assignments.

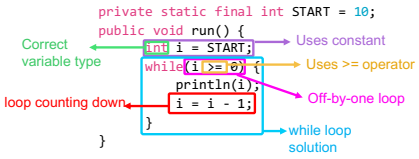
7.3 Highlighting feedback in student solutions.

The inferred decision trajectory for a student solution can also be used to provide "dense" feedback that highlights the section of the code or text responsible for each misunderstanding. This would be much more effective for student learning than vague error messages currently found on most online education platforms.

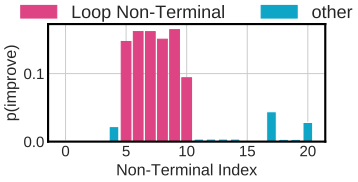
To achieve this, we leverage the fact that each decision node in the simulator gets recursively expanded to produce the final solution. This means it is easy to track the portions of the output that each decision node is responsible for. For decision nodes related to student confusions, we can highlight the portion of the output in the student solution which corresponds to this confusion. Fig. 9b shows a random pro-



(a) Classroom Experiment Results



(b) Automated Dense Feedback



(c) Auto-improving Simulators

Figure 9: (a) Plot of average time taken to grade 30 student solutions to Liftoff. Generative grading reduces grading time for 26 out of 30 solutions. The amount of time saved correlates with the token edit distance (yellow) to the nearest neighbour in the simulator. (b) Our approach allows for automatically highlighting which part of the student solution is responsible for a predicted misconception. (c) Given a Liftoff simulator that is missing a key "decrement loop" decision, we can automatically find decision nodes where inference often fails on real student solutions. The highest scoring decision nodes are all correctly related looping.

gram with automated, segment-specific feedback given by GG-NAP. This level of explainability is sorely needed in both education and AI.

7.4 Automatically Improving Simulators

Building Idea2Text simulators is an iterative process; a user wishing to improve their simulator would want a sense of where it is lacking. Fortunately, given a set of difficult examples where GG-NAP does poorly, we can deduce the decision nodes in the simulator that consistently lead to mistakes and use these to suggest components to improve.

To do this, for each nearest neighbour to a student solution we can find decision nodes that cause substring mismatches in the student solution, using regular expressions. This is possible because each decision node is responsible for a scoped substring in the nearest neighbour output solution (Sec. 7.3). By finding the decision nodes where the substring often differs between the neighbour and the solution, we can identify decisions that often causes mismatches.

To illustrate this, we took the Liftoff simulator, which contains a crucial decision node that decides between incrementing up or down in a "for" loop, and removed the option of incrementing down. We trained GG-NAP on this smaller simulator, and used a scoring mechanism to identify relevant decision nodes responsible for failing to parse student solutions that "increment down". Fig. 9c shows the distribution over which nodes GG-NAP believes to be responsible for the failed parses. The top 6 decisions that GG-NAP picked out all rightfully relate to looping and increments.

8. LIMITATIONS AND FUTURE WORK

Cost of writing good simulators. One of the most critical steps in our approach is the ability to write good Idea2Text simulators. Writing a good simulator does not require special expertise and can be undertaken by a novice in a short time. For instance, the PyramidSnapshot simulator that sets the new state of the art was written by a first-year undergraduate within a day. Furthermore, many aspects of simulators are re-usable: similar problems will share nonterminals and some invariances (e.g. the nonterminals that capture different ways of writing `for` loops are the same everywhere). This means every additional grammar is easier to write since it likely shares a lot in structure with existing grammars. Moreover, compared to weeks spent hand-labelling data, the cost of writing a grammar is orders of magnitude cheaper and leads to much better performance.

That being said, we believe there is room for interesting future work that explores how to make grammars easy to write and improve, with the extension in Sec. 7.4 already making some headway in this direction. There is also room for better formalising which types of problem domains can be faithfully modelled with Idea2Text simulators, and which domains are infeasible, like general essay writing. Lastly, more sophisticated inference approaches could be explored for handling semantic invariances in student output such as code reordering or variable renaming.

Connections to IRT. We find an interesting parallel of our work to Item Response Theory (IRT). IRT is essentially an extremely simple generative model that relates a student parameter θ to the probability of getting a question correct or incorrect. Some of our Idea2Text simulators also incorporate a student ability parameter θ to dictate likelihoods of making mistakes at different decisions, and can thus be seen as a more expressive and nuanced extension of the IRT generative model. Exploring this further is an interesting direction of research.

Generating questions with Idea2Text. We use Idea2Text simulators to model student decision-making and corresponding example solutions. This could be used to automatically generate example solutions with known issues to show students for pedagogical purposes. The Idea2Text library can also been used to generating questions corresponding to confusions instead of solutions corresponding to confusions.

9. CONCLUSION

We proposed a method for providing automated student feedback that showed promising results across multiple modalities and domains. Our proposed feedback system is capable of predicting student decisions corresponding to a given solution, allowing us to do nuanced forms of automated feedback. With it, "generative grading" can be used to automate feedback, visualise student approaches for instructors, and make grading easier, faster, and more consistent. Although more work needs to be done on making powerful grammars easier to write, we believe this is an exciting direction for the future of education and a step towards combining machine learning and human-centred artificial intelligence.

ABSTRACT

The needs for precisely estimating a student's academic performance have been emphasized with an increasing amount of attention paid to Intelligent Tutoring System (ITS). However, since labels for academic performance, such as test scores, are collected from outside of ITS, obtaining the labels is costly, leading to label-scarcity problem which brings challenge in taking machine learning approaches for academic performance prediction. To this end, inspired by the recent advancement of pre-training method in natural language processing community, we propose DPA, a transfer learning framework with **D**iscriminative **P**re-training tasks for **A**cademic performance prediction. DPA pre-trains two models, a generator and a discriminator, and fine-tunes the discriminator on academic performance prediction. In DPA's pre-training phase, a sequence of interactions where some tokens are masked is provided to the generator which is trained to reconstruct the original sequence. Then, the discriminator takes an interaction sequence where the masked tokens are replaced by the generator's outputs, and is trained to predict the originalities of all tokens in the sequence. We conduct extensive experimental studies on a real-world dataset obtained from a multi-platform ITS application and show that DPA outperforms the previous state-of-the-art generative pre-training method with a reduction of 4.05% in mean absolute error and more robust to increased label-scarcity.[1]

Academic Performance Prediction, Deep Learning, Transfer Learning, Discriminative Pre-training

1. INTRODUCTION

Predicting a student's future academic performance is a fundamental task for developing modern Intelligent Tutoring System (ITS) which aims to provide personalized learning experience by supporting educational needs of each individual. However, labels for academic performance, such as test scores, are often scarce since they are external to ITS. For example, as shown in Figure 1, test scores are not automatically collected inside of ITS. Obtaining a test score requires a student to take the test in the designated test center, receive the score, and report the score to ITS. Transfer learning is a commonly taken approach to address such label-scarcity problems across different domains of machine learning. In this framework, a model is first pre-trained to optimize auxiliary objectives with abundant data, and then fine-tuned on the task of interest. In Artificial Intelligence in Education (AIEd) community, [3] introduced Assessment Modeling (AM), a set of pre-training tasks for label-scarce educational problems including academic performance prediction. AM proposed a pre-training method where first, a masked interaction sequence is generated by replacing a set of interactive features which can serve as criteria for pedagogical evaluation with artificial mask tokens. Then, given the

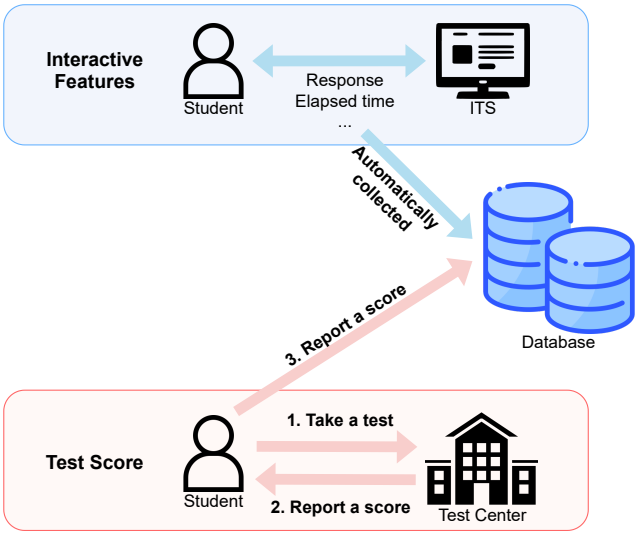

Figure 1: Interactive features, such as student response and elapsed time for the response, are automatically recorded to the database whenever a student interacts with ITS. On the other hand, more complicated steps are necessary to obtain a test score: a student should take the test in the designated test center, receive the test score, and report the score to ITS.

EDM '21 June 29 - July 02 2021, Paris, France

masked interaction sequence, a model is pre-trained to predict the masked interactive features. The idea was borrowed from the Masked Language Modeling (MLM) pre-training method proposed in [7]. In the MLM pre-training method, given a masked word sequence where some words in the sequence are replaced with an artificial mask token, a model is pre-trained to predict the masked words. However, recently, [6] pointed out that the MLM pre-training method has poor sample efficiency and suffers from pre-train/fine-tune discrepancy due to the artificial mask token, and proposed a new discriminative pre-training method. Considering the problems are also inherent in AM, potential gains are expected to be obtainable when the discriminative pre-training method is applied to academic performance prediction.

To this end, we propose DPA, a transfer learning framework with **D**iscriminative **P**re-training tasks for **A**cademic performance prediction. There are two models in DPA: a generator and a discriminator. In DPA's pre-training phase, the generator is trained to predict the masked interactive features in the same way as AM. Then, given a replaced interaction sequence which is generated by replacing the masked features with the generator's outputs, the discriminator is trained to predict whether each token in the sequence is the same as the one in the original interaction sequence. After the pre-training, the generator is thrown away and only the discriminator is fine-tuned on academic performance prediction. Also, we investigate diverse pre-training tasks for the generator and show that pre-training the generator to predict a student's response is more effective than to predict the correctness and timeliness of their response which were considered as the most pedagogical interactive features in AM. Extensive experimental studies conducted on a real-world dataset collected from a multi-platform ITS application show that DPA outperforms AM with a reduction of 4.05% in Mean Absolute Error (MAE) and more robust when the degree of label-scarcity increases.

2. SANTA: A SELF-STUDY SOLUTION EQUIPPED WITH AN AI TUTOR FOR ENGLISH EDUCATION

In this paper, we conduct experiments on a real-world dataset obtained from *Santa*[2], a multi-platform ITS with more than a million users in South Korea available through Android, iOS, and Web that exclusively focuses on the Test of English for International Communication (TOEIC) standardized examination. The publicly accessible version of the dataset was released under the name *EdNet* [4]. The TOEIC consists of two timed sections, Listening Comprehension (LC) and Reading Comprehension (RC). There are a total of 100 multiple choice exercises in each section, and the total score for each section is 495 in steps of 5 points. *Santa* provides learning experiences of solving exercises, studying explanations, and watching lectures. When a student consumes a specific learning content, *Santa* diagnoses their current academic status based on their learning activities records and recommends another learning content appropriate for their current position. *Santa* records diverse types of interactive features, such as student response, the duration of time the student took to respond, and the time interval between the current and previous learning activities. However, unlike the interactive features automatically collected from *Santa*, obtaining the official TOEIC score requires more steps: a student should register and pay for the test, take the test in the designated test center, receive the test score from the Educational Testing Service, and report the score to *Santa* (Figure 1). *Santa* collected students' TOEIC score data by offering small gifts to students when they report their scores.

3. TRANSFER LEARNING FOR ACADEMIC TEST PERFORMANCE PREDICTION

To overcome the label-scarcity problem in academic test performance prediction, we consider burgeoning machine learning discipline of transfer learning. There is an open issue of what information to transfer or which pre-training task is the most effective for academic test performance prediction. Previous studies proposed two types of pre-training methods for AIEd Tasks: interaction-based method which models students' dynamic learning behaviors [13, 15, 8, 3], and content-based method which learns representations of learning contents [14, 23, 19, 24, 29]. [3] showed that interaction-based pre-training method outperforms content-based pre-training methods when the pre-trained model is fine-tuned on several label-scarce educational tasks including academic test performance prediction. Following this line of research, we propose a transfer learning framework where a model is pre-trained using only student interaction data, and fine-tune the pre-trained model on academic test performance prediction. In this paper, we consider the following interactive features:

- *eid*: A unique ID assigned to an exercise solved by a student. There are a total of 14419 exercises in the dataset.
- *part*: Each exercise belongs to a specific part that represents the type of the exercise. There are a total of 7 parts in the TOEIC.
- *response*: Since the TOEIC consists of multiple choice exercises and there are four options for each exercise, a student response for a given exercise is one of the options, 'a', 'b', 'c', or 'd'.
- *correctness*: Whether a student responded correctly to a given exercise. Note that *correctness* is a coarse version of *response* since *correctness* is processed by comparing *response* with a correct answer for a given exercise.
- *elapsed_time*: The amount of time a student spent on solving a given exercise.
- *timeliness*: Whether a student responded to a given exercise under the time limit. Note that *timeliness* is a coarse version of *elapsed_time* since *timeliness* is processed by comparing *elapsed_time* with the time limit recommended by domain experts for a given exercise.
- *exp_time*: The amount of time a student spent on studying an explanation for an exercise they had solved.
- *inactive_time*: The time interval between the current and previous interactions.

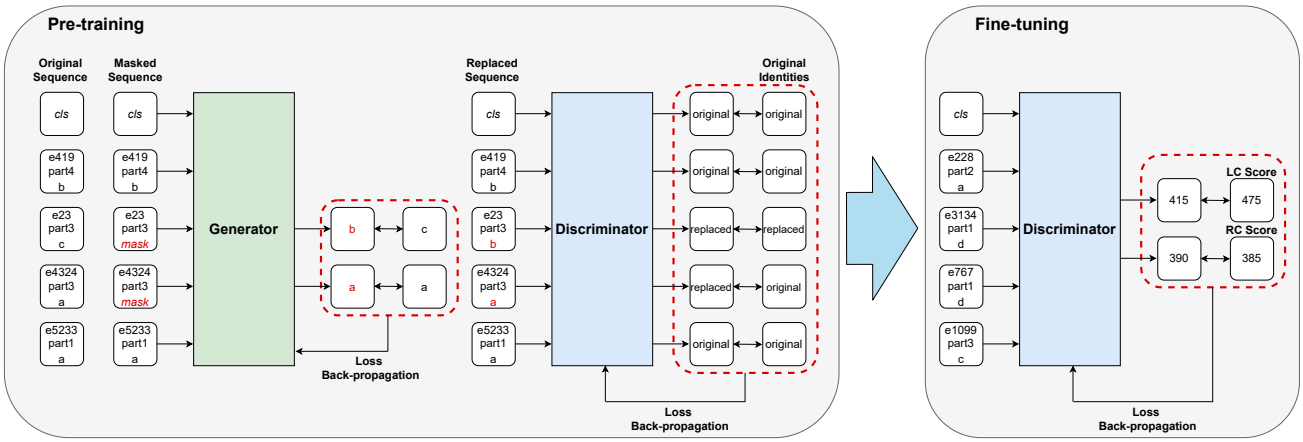

Figure 2: The overall pre-training/fine-tuning process of DPA when each token in an interaction sequence is a set of *eid*, *part*, and *response*, and *response* is a feature being masked. *mask* and *cls* are special tokens for mask and classification, respectively, which are the same as the ones used in [7].

In our experiments, we normalize the values of *elapsed_time*, *exp_time*, and *inactive_time* so they are between 0 and 1 to stabilize the training process.

4. PROPOSED METHOD

Figure 2 depicts our proposed method. There are two models in DPA: a generator and a discriminator. In pre-training phase, given a sequence of interactions $I = [I_1, \ldots, I_T]$, where each interaction $I_t = \{f_t^1, \ldots, f_t^k\}$ is a set of interactive features f_t^i, such as *eid*, *part*, and *response*, a masked interaction sequence $I^M = [I_1^M, \ldots, I_T^M]$ is generated by first randomly selecting a set of positions to mask $M = \{M_1, \ldots, M_m\}$ $(m < T)$, and for the masked position M_i, masking out a fixed set of features $\{f_{M_i}^1, \ldots, f_{M_i}^n\}$ $(n < k)$. For instance, in Figure 2, if the original interaction sequence is [(e419, part4, b), (e23, part3, c), (e4324, part3, a), (e5233, part1, a)] where each token in the sequence is a set of *eid*, *part*, and *response*, a masked interaction sequence where $M = \{2, 3\}$ and *response* as a masked feature is [(e419, part4, b), (e23, part3, *mask*), (e4324, part3, *mask*), (e5233, part1, a)]. Then, the generator takes the masked interaction sequence I^M as an input, and outputs predicted values O_{ij}^G for the masked features $f_{M_i}^j$. After that, a replaced interaction sequence $I^R = [I_1^R, \ldots, I_T^R]$ is generated by replacing the masked features $f_{M_i}^j$ with the generator's predictions O_{ij}^G. In Figure 2, since the generator's outputs for the masked features are 'b' and 'a', a replaced interaction sequence is [(e419, part4, b), (e23, part3, b), (e4324, part3, a), (e5233, part1, a)]. Then, the discriminator takes the replaced interaction sequence I^R as an input, and predicts whether each token in the sequence is the same as the one in the original interaction sequence (original) or not (replaced). After the pre-training, we throw away the generator and fine-tune the pre-trained discriminator on academic test performance prediction. We provide detailed explanations of each component in the generator and the discriminator, and training objective functions in the following subsections.

4.1 Interaction Embeddings

The embedding layer produces a sequence of interaction embedding vectors by mapping each interactive feature to an appropriate embedding vector. We take two different approaches to embed the interactive features depending on whether they are categorical (*eid*, *part*, *response*, *correctness*, and *timeliness*) or continuous (*elapsed_time*, *exp_time*, and *inactive_time*) variables. If an interactive feature is a categorical variable, we assign unique latent vectors to possible values of the feature including special values for mask (*mask*) and classification (*cls*). Take *response* as an example, there is an embedding matrix $E_{response} \in \mathbb{R}^{6 \times d_{emb}}$ where each row vector is assigned to one of 'a', 'b', 'c', 'd', *mask*, and *cls*. If an interactive feature is a continuous variable, we assign a single latent vector to the feature. Then, an embedding vector for the feature is computed by multiplying the latent vector and a value of the feature. For instance, we compute an embedding vector for *elapsed_time* as $et * E_{elapsed\_time}$, where et is a specific value and $E_{elapsed\_time} \in \mathbb{R}^{d_{emb}}$ is a latent vector assigned to *elapsed_time*. Also, mask and classification for the continuous interactive features are indicated by setting their values to -1 and 0, respectively. Not only embeddings for interactive features, positional embeddings are also incorporated into Transformer-based models [27] to consider chronological order of each token. Rather than using conventional positional embeddings which stores an embedding vector for every possible position, we adopt axial positional embeddings [17] to further reduce memory usage. The final interaction embedding vector of dimension d_{emb} for each time-step is the sum of all embedding vectors in the time-step. The interaction embedding layer is shared by both the generator and the discriminator.

4.2 Performer Encoder

Since its successful debut in Natural Language Processing (NLP) community, Transformer's attention mechanism has become a common recipe adopted across different domains of machine learning including speech processing [18], computer vision [1, 9], and AIEd [21, 2, 11, 22]. Compared to Recurrent Neural Network (RNN) family models, Transformer's attention mechanism has benefits of capturing longer-range

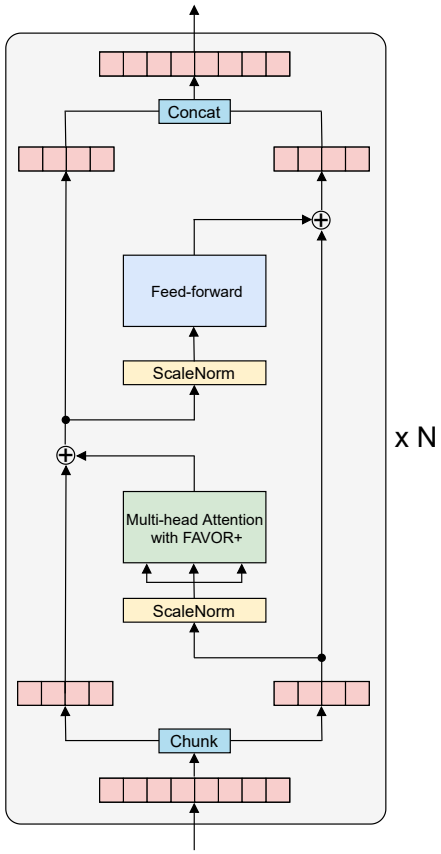

Figure 3: The reversible layer in the Performer encoder is composed of the FAVOR+-based multi-head attention layer and the point-wise feed-forward layer.

dependencies and allowing parallel training, which enables the model to achieve better performance with less training time. However, despite these advantages, the time and memory complexities of computing the attention grow quadratically with respect to input sequence length, requiring demanding computing resources for training the model on long sequences. For instance, if L is input sequence length and d is dimension of query, key, and value vectors, Transformer's attention is computed as follows:

$$\text{Attention}(Q, K, V) = \text{softmax}\Big(\frac{QK^\top}{\sqrt{d}}\Big)V,$$

where $Q, K, V \in \mathbb{R}^{L\times d}$. The time and memory complexities for computing $QK^\top$ in the above equation are $O(L^2 d)$ and $O(L^2)$, respectively. Therefore, the cost for training Transformer becomes prohibitive with large L, preventing training the model even on a single GPU.

The problem of improving the efficiency of Transformer's attention mechanism is a common concern of machine learning community. Recent studies have proposed several methods to reduce the computing complexities lower than the quadratic degree with respect to input sequence length [17, 28, 16, 25, 5]. In this paper, we adopt Performer [5] since it uses reasonable memory and makes a better trade-off between speed and performance [26]. Performer approximates attention kernels through Fast Attention Via positive Orthogonal Random features (FAVOR+) approach. For those who want to know more about FAVOR+, please refer [5].

With the efficient attention mechanism by FAVOR+, we propose the Performer encoder which is stacks of several identical reversible layers described in Figure 3. The reversible layer is based on Reversible Transformer [12, 17] architecture to further improve memory efficiency in backpropagation. An input of the reversible layer $x \in \mathbb{R}^{L\times d_{hidden}}$ is first chunked to $x_1, x_2 \in \mathbb{R}^{L\times d_{hidden}/2}$. Then, scaled l_2 normalization (ScaleNorm) [20] and FAVOR+-based multi-head attention layer (MultiHeadAttn) are applied to x_2, and the result is added to x_1 to compute $y_1 \in \mathbb{R}^{L\times d_{hidden}/2}$.

$$y_1 = x_1 + \text{MultiHeadAttn}(\text{ScaleNorm}(x_2)).$$

After that, the scaled l_2 normalization and point-wise feed-forward layer (FeedForward) are applied to y_1, and the result is added to x_2, computing $y_2 \in \mathbb{R}^{L\times d_{hidden}/2}$.

$$y_2 = x_2 + \text{FeedForward}(\text{ScaleNorm}(y_1)).$$

An output of the reversible layer $y \in \mathbb{R}^{L\times d_{hidden}}$ is a concatenation of y_1 and y_2. We stack the reversible layer multiple times to allow the final model to sufficiently represent underlying data distribution.

4.3 Generator

The generator computes hidden representations $[h_1^G, \ldots, h_T^G]$ by feeding the masked interaction sequence I^M to a series of the interaction embedding layer (InterEmbedding), a point-wise feed-forward layer (GenFeedForward1), the Performer encoder (GenPerformerEncoder), and another point-wise feed-forward layer (GenFeedForward2):

$$[I_1^{ME}, \ldots, I_T^{ME}] = \text{InterEmbedding}([I_1^M, \ldots, I_T^M])$$
$$[h_1^{GF}, \ldots, h_T^{GF}] = \text{GenFeedForward1}([I_1^{ME}, \ldots, I_T^{ME}])$$
$$[h_1^{GP}, \ldots, h_T^{GP}] = \text{GenPerformerEncoder}([h_1^{GF}, \ldots, h_T^{GF}])$$
$$[h_1^G, \ldots, h_T^G] = \text{GenFeedForward2}([h_1^{GP}, \ldots, h_T^{GP}]),$$

where $I_t^{ME}, h_t^G \in \mathbb{R}^{d_{emb}}$ and $h_t^{GF}, h_t^{GP} \in \mathbb{R}^{d_{gen\_hidden}}$. Then, depending on whether the masked features are categorical or continuous variables, generator outputs are computed differently. If the masked features are categorical variables, the outputs are sampled from a probability distribution defined by the following softmax layer:

$$O_{ij}^G \sim P_G(f_{M_i}^j | I^M) = \text{softmax}(E_j h_{M_i}^G).$$

If the masked features are continuous variables, the outputs are computed by the following sigmoid layer:

$$O_{ij}^G = \text{sigmoid}(E_j^\top h_{M_i}^G).$$

Similar to the case of categorical masked features, one can sample the outputs from a probability distribution defined by I^M and parameters of the generator when the masked features are continuous variables. For instance, the outputs can be sampled from the Gaussian distribution where the mean and the variance are determined by I^M and the generator's parameters. However, we make the outputs deterministic because sampling the outputs underperforms in our preliminary experiments when the masked features are continuous variables.

4.4 Discriminator

In pre-training, outputs of the discriminator $O^D = [O_1^D, \ldots, O_T^D]$ is computed by applying a series of the interaction embedding layer (InterEmbedding), a point-wise feed-forward layer (DisFeedForward1), the Performer encoder (DisPerformerEncoder), and another point-wise feed-forward layer (DisFeedForward2) to the replaced interaction sequence I^R:

$$[I_1^{RE}, \ldots, I_T^{RE}] = \text{InterEmbedding}([I_1^R, \ldots, I_T^R])$$
$$[h_1^{DF}, \ldots, h_T^{DF}] = \text{DisFeedForward1}([I_1^{RE}, \ldots, I_T^{RE}])$$
$$[h_1^{DP}, \ldots, h_T^{DP}] = \text{DisPerformerEncoder}([h_1^{DF}, \ldots, h_T^{DF}])$$
$$[O_1^D, \ldots, O_T^D] = \text{DisFeedForward2}([h_1^{DP}, \ldots, h_T^{DP}]),$$

where $I_t^{RE} \in \mathbb{R}^{d_{emb}}$, $h_t^{DF}, h_t^{DP} \in \mathbb{R}^{d_{dis\_hidden}}$, $O_t^D \in \mathbb{R}$, and the sigmoid is applied to the last layer of the discriminator. After the pre-training, we slightly modify the discriminator by replacing the last layer with a layer having appropriate dimension for academic test performance prediction.

4.5 Training Objectives

The objective for pre-training is to minimize the following loss function:

$$\sum_{i=1}^{m}\sum_{j=1}^{n} \text{GenLoss}(O_{ij}^G, f_{M_i}^j) + \lambda \sum_{t=1}^{T} \text{DisLoss}(O_t^D, \mathbb{1}(I_t^R = I_t)),$$

where GenLoss is the cross entropy (or mean squared error) loss function if the masked features are categorical (or continuous) variables, DisLoss is the binary cross entropy loss function, and $\mathbb{1}$ is the identity function. For ease of notation, we omit an index for each input sample in the above equation. If there are more than one masked features in each time-step ($n > 1$), the generator is trained under the multi-task leaning scheme. The objective for fine-tuning is to minimize the mean squared error loss between the model's predictions and score labels.

5. EXPERIMENTS

5.1 Effects of Generator's Pre-training Tasks

There are multiple interactive features to be masked in each token of the interaction sequence, which raises a question of how to construct a set of masked interactive features, and accordingly, which pre-training task for the generator is the most effective for academic test performance prediction. By default, all interactive features listed in Section 3 are taken as inputs for both the generator and discriminator. However, if *response* (or *elapsed_time*) is masked, *correctness* (or *timeliness*) is excluded from the inputs and vice versa since there is an overlap of information that the features represent. For example, when both *response* and *correctness* are taken as inputs, and *correctness* is masked, the generator can predict the masked *correctness* by only looking at *eid* and *response* without considering other interactions, which leads to poor pre-training. The results are described in Table 1.

The best result was obtained under the pre-training task of predicting *response* alone, which is slightly better than that of predicting *correctness*, and both *response* and *correctness*. Predicting correctness of student response is an important task in AIEd as can be seen from the large volume of studies about Knowledge Tracing. Also, [3] empirically showed that student response correctness is the most pedagogical interactive feature for academic test performance prediction. However, rather than pre-training a model to predict whether a student correctly responded to a given exercise, the pre-training task of predicting student response itself injects more fine-grained information into the model, which leads to the more effective pre-training for academic test performance prediction. Interestingly, the underperformed results were obtained when predicting *elapsed_time* or *timeliness* in pre-training despite the benefits their information bring to several AIEd tasks [10, 30, 22]. We hypothesize that *elapsed_time* and *timeliness* may introduce irrelevant noises and thus guide the model towards a direction inappropriate for academic test performance prediction. In the case of *exp_time* and *inactive_time*, we observed that the generator failed to learn to predict their values when only given the interactive features listed in Section 3, which leads to unstable pre-training. From these observations, in the following subsections, we conduct experimental studies based on the pre-training task of predicting *response* alone.

Table 1: Comparison between different pre-training tasks.

Pre-training task	MAE
response	**50.65** $\pm$ 1.26
response + *elapsed_time*	54.86 $\pm$ 1.64
response + *timeliness*	52.91 $\pm$ 1.38
response + *exp_time*	57.54 $\pm$ 1.47
response + *inactive_time*	60.69 $\pm$ 1.74
correctness	51.36 $\pm$ 0.97
correctness + *elapsed_time*	53.36 $\pm$ 1.43
correctness + *timeliness*	52.60 $\pm$ 1.20
correctness + *exp_time*	54.36 $\pm$ 1.62
correctness + *inactive_time*	55.04 $\pm$ 1.58
response + *correctness*	51.13 $\pm$ 1.60
response + *correctness* + *elapsed_time*	52.15 $\pm$ 1.43
response + *correctness* + *timeliness*	53.05 $\pm$ 1.81
response + *correctness*+ *exp_time*	53.09 $\pm$ 1.25
response + *correctness* + *inactive_time*	56.41 $\pm$ 1.72

5.2 DPA vs. Baseline Methods

We compare DPA with the following pre-training methods:

- No pre-training: We train the fine-tuning models only on the fine-tuning dataset.
- Autoencoding: Autoencoding (AE) is a generative pre-training method widely used across different domains of machine learning including AIEd [13, 8]. Given an unmasked interaction sequence, AE pre-trains a model to reconstruct the input interaction sequence.
- Assessment Modeling: Assessment Modeling (AM) [3] is the previous state-of-the-art generative pre-training method for academic test performance prediction. In AM, a model takes a masked interaction sequence as an input and is pre-trained to predict masked features. AM is exactly the same as fine-tuning the pre-trained generator in DPA.

Also, we investigate whether DPA is effective with the following different fine-tuning models:

Table 2: Comparison of DPA with baseline methods.

Pre-training method	Fine-tuning model	MAE
No pre-training	MLP	82.89 ± 3.23
	BiLSTM	84.05 ± 2.06
	Transformer encoder	107.06 ± 2.52
	Performer encoder	81.76 ± 1.24
AE	MLP	79.46 ± 1.15
	BiLSTM	85.64 ± 1.89
	Transformer encoder	75.13 ± 3.10
	Performer encoder	64.80 ± 1.43
AM	MLP	77.17 ± 2.14
	BiLSTM	58.16 ± 1.28
	Transformer encoder	57.16 ± 2.08
	Performer encoder	52.79 ± 1.39
DPA	MLP	77.24 ± 1.59
	BiLSTM	57.59 ± 1.76
	Transformer encoder	55.99 ± 1.62
	Performer encoder	$\mathbf{50.65} \pm 1.26$

- MLP: Multi-Layer Perceptron (MLP) is stacks of simple fully-connected layers. Given an interaction sequence, interaction embedding vectors of all time-steps are summed together to compute a fixed-dimensional vector which is fed to a series of the fully-connected layers.
- BiLSTM: Bi-directional Long Short-Term Memory (BiLSTM) is a model widely used for time series data prediction tasks. The global max pooling layer is applied on top of the BiLSTM layer to obtain a fixed-dimensional intermediate representation from an input sequence of varying length.
- Transformer Encoder: Transformer Encoder is a series of several identical layers composed of a multi-head self-attention layer with the softmax attention kernel and a point-wise feed-forward layer. We set the Transformer encoder's attention window size to 512 due to the out of GPU memory occuring when training the Transformer encoder of 1024 attention window size on our single GPU machine.

As described in Table 2, transferring the pre-trained knowledge brings better results in most cases, and the best result is obtained from DPA. Especially, when the Performer encoder, the best performing fine-tuning model, is used as the fine-tuning model, DPA reduces MAE by 4.05%, 21.84%, and 38.05% compared to AM, AE, and No pre-training, respectively. Among the baseline pre-training methods excluding No pre-training, the worst result is obtained from AE beacuse the pre-training task of AE is much easier than that of AM and DPA. We observed that the loss curve of AE converged to near zero within the first pre-training evaluation.

5.3 Robustness to Increased Label-scarcity

Since the motivation behind our proposal of DPA is the label-scarcity problem, we investigate how MAE changes at varying degrees of label-scarcity. Figure 4 and Table 3

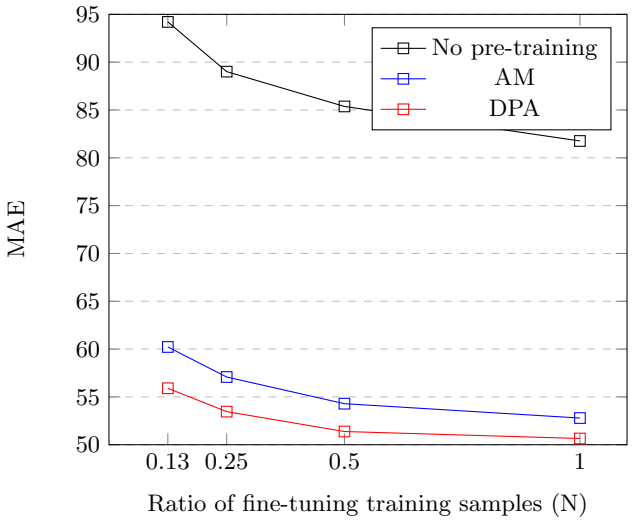

Figure 4: The black, blue, and red lines represent MAEs for No pre-training, AM, and DPA, respectively, when the number of fine-tuning training samples becomes 1/2, 1/4, and 1/8 of the entire dataset.

Table 3: Comparison of DPA with AM and No pre-training at varying degrees of label-scarcity.

N	No pre-training	AM	DPA
1/8	94.21 ± 8.40	60.22 ± 1.86	55.90 ± 1.97
1/4	89.01 ± 2.14	57.08 ± 1.75	53.46 ± 1.45
1/2	85.37 ± 1.15	54.29 ± 1.50	51.38 ± 1.16
Full	81.76 ± 1.24	52.79 ± 1.39	50.65 ± 1.26

describe the results when using 1/2, 1/4, and 1/8 of the total number of fine-tuning training samples. In all degrees of label-scarcity, DPA consistently outperforms AM. Also, DPA fine-tuned on 1/2, 1/4, and 1/8 of the dataset outperforms AM fine-tuned on the entire dataset, 1/2, and 1/4 of the dataset, respectively, which shows that DPA is more robust to label-scarcity than AM. Compared with No pre-training, the gap between No pre-training and the other two pre-training methods increases as the number of labels becomes scarce. Furthermore, the other two pre-training methods fine-tuned on 1/8 of the dataset outperform No pre-training fine-tuned on the entire dataset.

6. CONCLUSION

In this paper, we proposed DPA, a transfer learning framework with discriminative pre-training tasks for academic performance prediction. Our experimental results showed the effectiveness of DPA for the label-scarce academic performance prediction task over the previous state-of-the-art generative pre-training method. Avenues of future research include investigating more effective pre-training tasks for academic performance prediction and pre-train/fine-tune relations in AIEd.

ABSTRACT

Student modeling is useful in educational research and technology development due to a capability to estimate latent student attributes. Widely used approaches, such as the Additive Factors Model (AFM), have shown satisfactory results, but they can only handle binary outcomes, which may yield potential information loss. In this work, we propose a new partial credit modeling approach, PC-AFM, to support multi-valued outcomes. We focus particularly on the amount of assistance, that is, the number of error feedback and hint messages, a student needs to get a problem step correct. Because errors and hint requests may not only derive from student ability, but also from non-cognitive factors (e.g., students may game the system), we first test PC-AFM on synthetic data where this source of variation is not present. We confirm that PC-AFM is indeed better than AFM in recovering the true student and knowledge component (KC) parameters and even predicts student error rates better than a model fit to error rates. We then apply the approach to six real-world datasets and find that PC-AFM outperforms AFM in reliable estimation of KC parameters and produces better generalization to new students, which requires better KC estimates. However, consistent with the hypothesis that student assistance behavior is driven by motivational or meta-cognitive factors beyond their ability, we found that PC-AFM was not better in reliable estimation of student parameters nor in generalization across items, which requires accurate student estimates. We propose *cross-measure cross-validation* as a general method for comparing alternative measurement models for the same desired latent outcome.

1. INTRODUCTION

Student modeling has been an important tool that researchers can use to estimate latent student abilities. Similarly, intelligent tutoring systems also depend on how accurately we can predict student mastery to deliver efficient adaptive learning. Current popular approaches, such as Additive Factors Model (AFM) [4, 18, 13] and Bayesian Knowledge Tracing (BKT) [5, 13], perform reasonably well by including the growth factors in their models. However, they are restricted by using only binary student performance (e.g. correct/incorrect response), which could suffer from an information loss due to its dichotomized nature.

For example, many existing intelligent tutoring systems (ITS) support step-by-step interactions [22], which usually allow students to try multiple attempts or request for hints until they are able to complete the step correctly. These interactions are important for an ITS because it allows the system to provide immediate feedback or support an adaptive experience, while collecting a rich interaction dataset on student actions. However, since AFM and BKT can only handle binary outcomes, the student data is needed to be aggregated through a rollup procedure before we can use it in student modeling. This means only success on students' first attempt on each step will be included in the data, and the rest of the actions (e.g. other attempt or hint requests) will be ignored. To illustrate how this could be problematic, let's imagine student A who had one incorrect attempt on a step before correctly completing it and student B who had multiple incorrect attempts and asked for multiple hints on the same step before getting it right. The dichotomous model like AFM and BKT would treat both students as the same on this particular step, but we can see that it is more likely that student A has demonstrated better knowledge than student B.

In our case, we are concerned with having a raw measure of student success at each assessment opportunity. There are different functions for producing or deriving an outcome measure for the data available in a tutoring system. Perhaps the most typical function is: first transaction correct = 1; otherwise = 0 where both hints and incorrect responses are both counted as a failure. While there are multiple ways to elicit polytomous outcomes from ITS student data, in this work we focus on an assistant score, which is a total number of incorrect attempts and hint requests combined for each step. From our preliminary analysis, we found that

there are correlations between assistance scores and AFM's predicted error rate, which suggests that there could be an extra information in assistance scores compared to a binary correctness outcome.

In this work, we are interested in whether or not an assistance score model could be a better predictor of student's change in performance than a dichotomous model like AFM. Particularly, our research questions are: (1) How can we develop an effective statistical measurement model that uses assistance scores? and (2) How do we compare two different response models?

A popular approach to compare different cognitive models in Educational Data Mining is to use goodness-of-fit (e.g. Bayesian Information Criterion), but it is not applicable in our scenario because our model is based on different outcomes (correctness vs assistance score). Alternative versions of measures of predictor variables can be contrasted through cross validations, but it becomes inadequate when the outcome variables are different. We also discuss a set of strategies for addressing the general problem of how to compare alternative measurement models for the same desired latent outcome. Particularly, how do we compare a binary correctness model with a polytomous Assistance Score model?

We propose a new cognitive modeling approach to support polytomous outcomes and demonstrated its ability to recover parameters and predict student error rates better than AFM in synthetic data. We then evaluated our model to six real-world datasets spanning five different domains from the DataShop repository [10]. We found that our model outperforms AFM in most Student-blocked CVs and estimating KC parameters, but it falls short at estimating student intercepts. We hypothesize that our model is struggling to estimate student parameters in the real-world datasets due to variance in students' help-seeking behavior, such as gaming-the-system, that leads to the extra variance in Assistance Scores above and beyond the variance associated with student ability.

2. RELATED WORK

2.1 Item Response Theory with Partial Credit

Item Response Theory (IRT) models [6] is the preferred method used in several state assessments in the United States and international assessments [8]. The goal of the IRT model is to estimate the latent construct (e.g. student ability) and item characteristics (item difficulty) based on only a collection of responses.

The simplest variation of IRT is the Rasch model (1PL model) [19], which is characterized by a single parameter representing item difficulty (d_j), and a single parameter representing student ability (a_i). As Eq.1 is equivalent to a logistic function, the Rasch model is essentially a logistic regression model.

$$p(r_{ij} = 1) = \frac{1}{1+^{-(a_i - d_j)}} \quad (1)$$

Other variations increase the complexity by introducing extra parameters. For example, the 2PL model adds a discrimination parameter for each item that controls the slope of the logistic function, and the 3PL model that also includes a pseudo-guessing parameter for each item. Even though, these models are characterized by a different number of parameters, they are all based on dichotomous response data (e.g. correctness). There is another class of IRT models that can be applied to polytomous outcomes, where each response can be a different value [17, 21]. An example of responses that is applicable to this class of models are Likert scale. There are different variations of polytomous IRT models, such as Partial Credit Model (PCM) [14], Generalized Partial Credit Model (GPCM) [15], and Graded Response Model (GRM) [20].These polytomous models are generalized from the dichotomous IRT models and can be reduced to the dichotomous IRT models when there are only two response categories. Our model extends the polytomous model to include growth factor by applying a similar approach to PCM to AFM.

2.2 Knowledge Tracing Approaches

Intelligent tutoring systems (ITS) have been shown to be effective in improving student learning outcomes across different domains [2, 9], and mastery learning strategies have been an important component in these systems. To implement mastery learning, knowledge tracing techniques are regularly utilized by ITSs [7] to adaptively assess students' knowledge states, which is used to decide when students have mastered skills and are ready to move on to other skills.

In many existing ITSs, such as Cognitive Tutor Authoring Tools (CTAT) [1], students are given a number of practice opportunities for each skill , and students are usually allowed to try multiple attempts or request for hints until they are able to successfully complete the step on each practice opportunity. The goal of a knowledge tracing algorithm when used for mastery learning is to determine when to stop giving students practice opportunities for the given skill.

Knowledge tracing is often performed by a statistical model of student learning that could be fit to data. There are two popular families of methods [12]: Bayesian Knowledge Tracing (BKT) [5, 13] and Additive Factors Model (AFM) [4, 18, 13]. Both methods include growth factors in order to estimate students' performance as it is changing with learning. BKT models student knowledge as a latent variable in a Hidden Markov Model. AFM is an extension of the IRT model that includes learning opportunity counts in the model. Even though these methods have been proven to work well in many scenarios, they are based on the binary error measurement model (correct or incorrect) and thus do not make use of potential added information from the number of error and hint messages a student may receive. Our approach explores this opportunity by extending AFM to use such multi-valued or polytomous outcomes in hopes of better estimating student knowledge. While other variations on AFM, such as Performance Factor Analysis (PFA) [18] and individualized AFM (iAFM) [13], have been shown in some cases to produce better prediction fit than AFM, we chose to use AFM to simplify the contrast between binary and polytomous measurement models and with the goal of producing more parsimonious and interpretable parameter estimates. Future work can explore alternatives.

2.3 DataShop Data Features

In this work, we use a variety of real world datasets across different domains from the DataShop repository [10]. LearnLab's DataShop (http://learnlab.org/datashop) is an open data repository of educational data with associated visualization and analysis tools, which has data from thousands of students derived from interactions with on-line course materials and intelligent tutoring systems.

In DataShop terminology, Knowledge Components (KCs) are used to represent pieces of knowledge, concepts or skills that students need to solve problems [11]. When a specific set of KCs are mapped to a set of instructional tasks (usually steps in problems) they form a KC Model, which is a specific kind of student model.

Each dataset in DataShop consists of a set of student transactions, which is a collection of students' interactions with ITSs. The collected students' actions include (but not limited to) correct attempts, incorrect attempts, and hint requests. The transactions that belong to the same practice opportunity get aggregated into a single students' step through the rollup procedure. The correctness of the step depends on the result of the student's first response for the practice opportunity, and the total number of incorrect attempts and hint requests is reported as an Assistance Score of the step. Most existing knowledge tracing algorithms use students' steps, rather than transactions, in their models.

3. METHOD

The Additive Factors Model (AFM) [4] is a logistic regression that extends Item Response Theory by incorporating a growth or learning term. The model gives the probability p_{ij} that a student i will get a problem step j correct based on the student's baseline ability (θ_i), the baseline difficulty of the related KCs on the problem step (β_k), and the learning rate of the KCs (γ_k). The learning rate represents the improvement on a KC with each additional practice opportunity, so it is multiplied by the number of practice opportunities (T_{ik}) that the student already had on the KC.

$$log(\frac{p_{ij}}{1-p_{ij}}) = \theta_i + \Sigma_k(q_{jk}\beta_k + q_{jk}\gamma_k T_{ik}) \tag{2}$$

Our extension of AFM to support a polytomous outcome measure, like Assistance Score, is inspired by the Partial Credit Model (PCM) [14], which is an adjacent-categories logit model [21]. The model was designed to work with ordered polytomous response categories with a specific order or ranking of responses, which is the case for Assistance Score. It is widely applied in aptitude testing to allow for partial credit for near correctness of a response. In adjacent-categories logit models, we model the odds of a higher category relative to the adjacent lower one, and this paired comparison creates the ordering of the categories.

Assistance Score can be interpreted in the partial credit framework as follows. A student who gets a problem step correct on their first try or after fewer errors or hint requests is more likely to have the associated competence than a student who makes many errors or requests multiple hints before getting the step correct. Thus, students making no errors and needing no hints get full credit (Assistance Score = 0) and students with errors and/or hint requests get partial credit in rough proportion to the number hint and errors.

The Partial Credit Additive Factors Model (PC-AFM) builds upon these two different statistical models, AFM and PCM. For a student i and a step j, there is a set of probabilities $P_{ij} = \{p_{ija}; a = 0, 1, ..., A\}$ describing the chance for student i to get Assistance Score a on the step j, where A is the maximum Assistance Score. In this work, we decided to limit an Assistance Score at 5 because values above this tend not to be meaningful and rare, but extreme outliers (e.g., where assistance score is over 20 or even 140!) would significantly bias the model. 98% of our data have an Assistance Score of 5 or less. We extend AFM to use multivariate generalized linear mixed model, and the link function in logistic regression takes the vector-valued form.

$$f_{link}(P_{ij}) = \begin{pmatrix} f_{link,1}(P_{ij}) \\ ... \\ f_{link,A}(P_{ij}) \end{pmatrix} = \begin{pmatrix} log(\frac{p_{ij1}}{p_{ij0}}) \\ ... \\ log(\frac{p_{ijA}}{p_{ijA-1}}) \end{pmatrix} \tag{3}$$

Note that $f_{link,0}$ is not included due to the number of non-redundant probabilities. PC-AFM use adjacent-categories logits as a link function based on PCM. The ath adjacent-categories logit is the logit of getting an Assistance Score a versus $a-1$. Each link function is an extended version of AFM's linear model (Eq. 2) with a level parameter (α_a), which represents the difficulty to improve from an Assistance Score a to $a-1$.

$$f_{link,a}(P_{ij}) = \theta_i + \alpha_a + \Sigma_k(q_{jk}\beta_k + q_{jk}\gamma_k T_{ik}) \tag{4}$$

Inverting this function gives an expression for the probabilities of student i to complete a problem step j with each of the possible Assistance Scores a.

$$\begin{aligned} p_{ija} &= \frac{e^{\lambda_a}}{\Sigma_{i=0}^{A} e^{\lambda_i}} \\ \lambda_a &= \begin{cases} 0 & \text{if } a = 0 \\ \Sigma_{l=1}^{a} f_{link,l}(P_{ij}) & \text{otherwise} \end{cases} \end{aligned} \tag{5}$$

4. EXPERIMENT

We conduct experiments on both synthetic data and real student data to evaluate the performance of PC-AFM. We used the synthetic data to validate PC-AFM's parameter recovery capability and examine our evaluation strategy in a synthetic environment in which Assistance Score is stochastically derived from student ability alone. In particular, Assistance Scores in the synthetic data are not confounded by other student variations, such as their motivational state. We hypothesized that PC-AFM would work less effectively with the real student data because of non-ability effects on Assistance Score, such as students' help seeking strategies or propensity to game the system.

While goodness-of-fits metrics, such as BIC, are widely used

to compare different cognitive models [16], such as knowledge tracing algorithms, it is not applicable in our case due to the difference of outcome measures between AFM and PC-AFM. The challenge is how we can compare models that are based on different outcomes (error rate vs Assistance Score), while targeting the same desired latent measure (e.g. student's ability).

We explore two strategies to tackle this comparison problem. The first approach is to use parameter estimate reliability in split-half comparisons. Since both AFM and PC-AFM share the majority of their parameters (student intercepts, KC intercepts, and KC slopes), we can compare their parameter recovery capability. However, unlike synthetic data, the true parameters are not known in real data, so we need to use the reliability of parameter estimates in split-half comparisons instead. Another strategy is to compare cross-measure predictions. The assumption is that if a model based on polytomous outcomes (Assistance Score) yields better accuracy than a model based on binary outcomes (error rate) in predicting both polytomous and binary outcomes, the polytomous model will be demonstrated to be a better measurement model. This strategy is applicable in our scenario because there are connections between both outcomes. Since a student step is considered correct only when there is no assistance, the error rate can be derived by calculating the probability of Assistance Score = 0. On the other hand, we can convert the error rate to a probability of an Assistance Score by calculating the likelihood, where given an error rate p, the probability of having an Assistance Score a is $(1-p)p^a$. Then we can use CVs on both measures to compare the models.

4.1 Experiment 1: Synthetic Data

In order to validate PC-AFM capability to recover student and KC parameters, we synthetically generate datasets of student steps based on a logistic regression model. Given a set of student and KC parameters together with an opportunity count, a distribution over Assistance Scores is determined. We then sample once from the distribution to generate an Assistance Score of that student step. We generated 6 datasets of varying numbers of students and KCs, of which the true student and KC parameters are known, to examine parameter recovery capacity of PC-AFM in comparison to AFM. In each generated dataset, student intercepts range from -2 to 2, KC intercepts range from -1 to 1, and KC slopes range from 0 to 0.5. The number of KCs ranges from 8 to 32, and the number of students range from 25 to 200.

We also evaluate both models with three types of cross-validation (CV), Random (data points are split randomly), Student-blocked (data points are split by student), and Item-blocked (data points are split by item), to demonstrate if our model training on Assistance Score, can outperform a dichotomous model training on error rate in predicting dichotomous outcomes.

We report on results for each of six different synthetic datasets by comparing PC-AFM and AFM. We found that PC-AFM better recovers the true student and KC parameters than AFM in almost all comparisons using correlation (Table 1). All contrasts are the same using mean absolute error. As the number of students goes up, both models tend to better recover the true parameters. The correlations of parameters in split-half comparison are reported in Table 2, which show a similar pattern to the correlation between estimated and true parameters. This demonstrates that the parameter correlation in split-half comparisons, which can be computed in real data, is a reasonable proxy for true parameter recovery, which cannot be computed in real data.

Figure 1 illustrates better true parameter recovery using Assistance Score and PC-AFM than using error rate and AFM. PC-AFM parameter estimates (red x's) are generally accurate across the spectrum of known parameter values (x-axis), as can be seen by their closeness to the line, which is identity function (intercept of 0, slope of 1). AFM estimates (blue dots) are generally biased toward the extremes. For student intercepts (Figure 1a), low prior knowledge students are estimated by error rate/AFM to be worse than they are and high prior knowledge students are estimated to be better than they are. For KC intercepts (Figure 1b), hard KCs (on the left) are estimated by error rate/AFM to be even harder than are. For hard KCs, most responses are errors, yielding quite low estimates by error rate/AFM. But, these same steps show more variance in Assistance Score/PC-AFM as somewhat better students and higher opportunities will produce lower, but non-zero Assistance Scores (i.e., not changing in error rate).

In error rate CV results, except Item-blocked CV where both models perform similarly, PC-AFM outperforms AFM in all other CVs (Table 4). Recall that these CV evaluations require PC-AFM, while fit to Assistance Score (polytomous outcome), to predict error rate (dichotomous outcome). When we turn the tables and compare methods on predicting Assistance Score, we find a similar pattern where PC-AFM yields better accuracy in most CVs (Table 3).

4.2 Experiment 2: Real student data

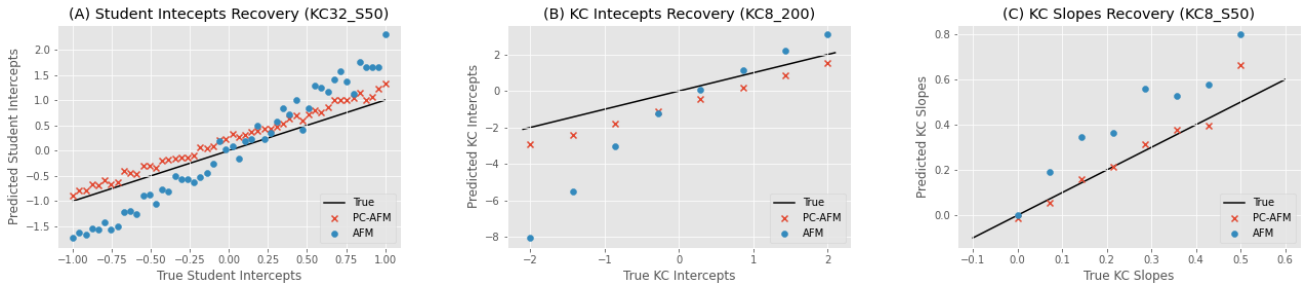

Figure 1: Using Assistance Score and PC-AFM on synthetic data produces better estimates of the true parameters, for all three of student intercepts, KC intercepts, and KC slopes than does using error rate and AFM.

In the second experiment, we examine PC-AFM across a variety of real world datasets. We used 6 datasets across different domains (statistics, English articles, algebra, and geometry) from the DataShop repository. Table 5 shows the number of students, items, KCs, total transactions for each dataset. For each dataset, we use the KC model that achieves the best BIC reported on the DataShop repository. All KC models coded a single KC per step. The number of KCs ranges from 9 to 64, and the number of students ranges from 52 to 318.

For each dataset, we evaluated both PC-AFM and AFM on 5 independent runs of 3-fold CVs of each type predicting both Assistance Score and error rate. We report the result of Assistance Score CVs in Table 6 and the results of error rate CVs in Table 7. We found that PC-AFM outperforms AFM in Student-blocked in both Assistance Score and error

rate CVs in most datasets, which suggests that PC-AFM can achieve better estimates of KC parameters. To validate the hypothesis, we investigated split-halves parameters correlation of both models. We splitted the datasets on students to evaluate KC slopes and intercepts correlation, and we splitted the datasets on KCs to evaluate students' intercepts (Table 8). On average, PC-AFM yields better correlations of both KC intercepts (0.954 vs 0.946) and KC slopes (0.600 vs 0.563), but correlations of student intercepts is significantly higher for AFM (0.784 vs 0.495).

5. DISCUSSION

Assistance score should, in principle, improve model parameter estimates and predictions based on them. A student who gets a step correct after just one error or one hint (Assistance Score = 1) is likely to be closer to full acquisition of a KC than a student who makes an error and requests 3 hints (Assistance Score = 4). However, the error rate metric commonly used with BKT and AFM treats these the same, since the student was not correct on their first attempt at the step without a hint. Thus, there is potentially extra in-

formation about students' level of knowledge acquisition in the Assistance Score not present in error rate. On the other hand, prior research, for example on gaming the system [3], suggests there are other reasons students may produce repeated incorrect entries or hint requests. These may produce enough confounding variance to make using Assistance Score worse at accurate latent parameter estimation than using error rate.

In developing a statistical model, PC-AFM, to convert Assistance Scores to knowledge acquisition estimates, we first wanted to confirm that PC-AFM works as intended and is able to benefit from extra information in Assistance Score when no confounding sources for Assistance Score variation are present. Indeed, when we generate synthetic data where Assistance Scores are stochastically produced from known latent parameters, we demonstrate better parameter recovery using Assistance Score and PC-AFM than using error rate and AFM. As shown in Figure 1, PC-AFM estimates of student parameters are better correlated with true parameters and the AFM estimates are baised at the extremes.

This parameter recovery method for comparing these two different measurement models cannot be applied to real datasets because the true parameters are unknown. Thus, we employed we explored two other approaches: parameter estimate reliability and our novel cross-measure cross-validation approach. We demonstrated better parameter estimate reliability (in split-halves comparisons) using PC-AFM than AFM. We also show how it is possible to use cross-measure predictions to evaluate which of two different measurement models works better, call them M1 and M2. We show that estimating based on M1 (e.g., assistant score) can predict M2 (e.g., error rate) on held-out data better than estimating based on M2 itself (e.g., error rate). We believe this cross-measure cross-validation is a novel approach for comparing measurement models.

Assessing whether Assistance Score is a better measure than Error Rate in real student data is complicated in two ways. First, we do not have access to the true parameters in real datasets, so we turn to measures of reliability and predictive validity. Second, we know from models of gaming the system and help seeking that students may produce Assistance Scores for motivational and metacognitive reasons that are potentially independent of a mastery source. In other words, Assistance Scores have a student-driven source of variation that may reduce their effectiveness in estimating student mastery. We hypothesize that our model is struggling to estimate student parameters in the real-world datasets due to variance in students' help seeking behavior.

We found that in real world datasets PC-AFM can better estimate KC parameters than AFM, which results in PC-AFM outperforming AFM in Student-blocked CVs. KC parameters estimates significantly impact Student-blocked CVs because they are the sole driver of these predictions. Poor student estimates do not impact Student-blocked CVs because they are not carried from the training to test as blocking means there are different students in the test than training. It does impact Random CVs and Item-blocked CVs because they are likely to have some students showing up in both test and training.

6. CONCLUSION AND FUTURE WORK

We investigated whether or not Assistance Score provides a better measurement model than error rate for estimating student's ability. To pursue this question, we developed a statistical model, PC-AFM, that utilizes Assistance Score. We also faced the more general problem of how to compare alternative measurement models for the same desired latent outcome. In typical model comparison the predicted outcome measure stays the same, but such comparison does not work when the outcome measures are different. We proposed two strategies to tackle this problem: parameter estimate reliability in split-halves comparisons and a new approach we call, cross-measure cross-validation. We demonstrated that these strategies work well by using synthetic data to show that a model that better recovers parameters will also yield better results with these strategies.

We demonstrated that PC-AFM outperforms AFM when Assistance Scores are synthesized to be meaningful, but its performance is hindered by non-ability variance in students' behavior in the real-world datasets. Future work can explore this finding by synthesizing Assistance Scores that derive from both ability and motivational factors.

Future work can also test our measurement model comparison strategies. For example, while it has been standard practice in many tutoring systems to count hints as errors (M1), some have wondered whether it would be better to not count hints as errors (M2). Our measurement model comparison techniques, split-half reliability and cross-measure cross-validation, can be used to compare M1 and M2 to infer which provides better estimates of student ability.

ABSTRACT

There has been great progress towards Reinforcement Learning (RL) approaches that can achieve expert performance across a wide range of domains. However, researchers have not yet applied these models to learn expert models for educationally relevant tasks, such as those taught within tutoring systems and educational games. In this paper we explore the use of Proximal Policy Optimization (PPO) [25] for learning expert models for tutoring system tasks. We explore two alternative state and action space representations for this RL approach in the context of two intelligent tutors (a fraction arithmetic tutor and a multicolumn addition tutor). We compare the performance of these models to a computational model of learning built using the Apprentice Learner architecture. To evaluate these models, we look at whether they achieve mastery and how many training opportunities they take to do so. Our analysis shows that at least one PPO model is able to successfully achieve mastery within both tutors, suggesting that RL models might be successfully applied to learn expert models for educationally relevant tasks. We find that the Apprentice model also achieves mastery, but requires substantially less training (thousands of times less examples) than PPO. Finally, we find that there is an interaction between the PPO representation and task (one representation is better for one tutor and the other representation is better for the other tutor), suggesting that the design of the state and action representations for RL is important for success. Our work showcases the promise of RL for expert model discovery in educationally relevant tasks and highlights limitations and challenges that need further research to overcome.

1. INTRODUCTION

Researchers have made great progress towards developing Reinforcement Learning (RL) models that can meet or exceed human skill at complex tasks across a broad range of domains. For example, the recently developed Proximal Policy Optimization (PPO) algorithm [25] can learn to play a broad range of Atari games at an expert level through trial and error. A team of five PPO-trained models can beat a team of five human professional champions at DOTA2, a collaborative online multiplayer battle arena game [4]. Researchers have applied a related RL approach called A3C [19] to develop agents that can beat top human experts at Starcraft2, a multiplayer real-time strategy game [28]. Finally, RL has been applied widely to the area of robotics and autonomous systems; e.g., RL models can fly an F16 to beat a expert human pilots in simulated 1v1 dogfights [7].

Despite these successes, there has been surprisingly little work exploring the applicability of RL to educationally relevant tasks, such as those found in K12 or higher education. We do not mean that RL has not been applied to support learning and education; in fact, there is a large amount of work exploring how RL can be applied to optimize students instructional sequences [9]. However, we assert that there has been very little exploration of how emerging RL approaches perform on the kinds of educationally relevant tasks that humans often engage in; e.g., learning math.

Given this gap we might ask, what are the benefits of applying RL to educationally relevant tasks? The recent work on computational models of learning highlights many possible benefits. First, machine learning agents can support researchers and instructional designers in authoring cognitive models [17, 30] and discovering knowledge component models [14] that can drive personalized learning technologies. Although RL models utilize different representations than more traditional expert-system models (e.g., statistical representations), learned models do still represent an expert model.[1] Thus, tutors might apply these models to provide feedback on student behaviors. Researchers and designers might also use machine learning agents to cognitively crash test instruction before more costly human trials [16, 15, 31].

Given these benefits, why has more work not explored the use of recent RL methods for these tasks? One possibility is that applying RL to educational tasks is not straightforward. There exist toolkits, like GymAI [5], MuJoCoEnv [23], and PyBullets [6], for interfacing RL algorithms with simulation

environments and games platforms like Atari, StarCraft2, and DOTA2. These toolkits have powered the explosion of RL research. Unfortunately, no such interfaces exist for educational tasks, such as those found in intelligent tutoring systems or educational games. Also, many educational tasks do not fit cleanly into the standard RL paradigm of observing the state, choosing an action, receiving a reward, and repeating; e.g., many tutors let learners request hints and worked examples, which RL systems cannot leverage.[2]

Beyond these challenges, it is possible that the tasks themselves are less attractive for RL research. For example, educationally relevant tasks, such as fraction arithmetic, seem simple when compared to tasks such as flying an F16 or playing DOTA2. It is possible that these tasks do not challenge current RL systems. However, it is also possible that these tasks present challenges that have prevented researchers from successfully applying RL to them. For example, tutor tasks often have much larger action spaces than game-based tasks where RL has been successfully applied (e.g., actions for inputting the numbers 1-50 in any interface field vs. six buttons on an Atari controller).

In this paper, we set out to investigate these ideas and to lay a foundation for future research programs to apply RL to the kinds of educationally relevant tasks that humans regularly engage with. Our goal is not to show that RL provides a good model of human learning and behavior (we do not think that it does). Instead, we simply aim to show how RL methods might be applied to tasks relevant to human learning. Our hope is that RL approaches might offer new means for authoring and evaluating educational technologies.

To support these investigations we present TutorGym, an open-source toolkit for interfacing RL agents (as well as other kinds of machine learning agents) with intelligent tutoring system tasks. This toolkit lets us apply RL models to two educational environments: a fraction arithmetic tutor and a multicolumn addition tutor. We developed two PPO models that vary in their features and action representations. We also compared these models to a previously developed Apprentice Learner model [16], which is a more cognitively inspired model of how people learn from examples and feedback within intelligent tutors. We conducted a factorial study design where we applied these three models to our two educational tasks. Our key findings are:

1. The PPO models are able to achieve mastery at these tasks, suggesting that they do generalize from games and robotics tasks to educationally relevant tasks;
2. The PPO models require much more training than our Apprentice Learner model to achieve mastery (thousands of times more training), even when we provide PPO with the same background knowledge as Apprentice (the PPO-Operator variant). This suggests that human-like models, such as Apprentice, are more efficient than PPO.
3. We find that there is an interaction between PPO's representation and the task, suggesting that representation is central to RL performance and that it needs to be tailored for each task.

[2]Inverse RL [1] can learn from expert examples, but typically this is done offline in batch rather than interactively interleaved with RL.

We claim that there is an synergistic opportunity to do research at the intersection of RL and education that has not yet been fully explored and this paper aims to lay the foundation for these future explorations. There are many potential ways that educational data mining and learning analytic communities might benefit from the development and use of RL models, such as PPO. Similarly, there is an opportunity to improve RL by exploring its application to the kinds of educationally relevant learning tasks that humans engage in during K12 and higher education.

2. BACKGROUND

2.1 OpenAI Gym

OpenAI Gym is an open-source toolkit for RL development [5]. Gym provides an standardized interface for applying RL to tasks. An environment created with Gym has standardized state and action descriptions and supports methods, for querying the state, taking an action, and collecting rewards. Gym currently supports multiple environments such as robot simulations or Atari games. Our research builds on Gym, so that we can directly interface existing RL implementations with educationally relevant tasks without having to create custom implementations.

2.2 Proximal Policy Optimization (PPO)

PPO is a deep RL algorithm that was recently developed by OpenAI [25]. It is a policy gradient method that achieves state-of-the-art performance across many tasks. We chose PPO over alternatives, such as TRPO [24] and ACER [29], because it supports a broad range of state and action representations and is much easier to tune than alternatives. For this work, we use the stable-baselines3 implementation of the PPO algorithm, which has verified performance on multiple RL benchmarks [22].

2.3 Apprentice Learner Architecture

The open-source Apprentice Learner Architecture [16] generalizes prior simulated student models [13, 18] and provides a platform for investigating and comparing alternative simulated student models. Apprentice models have been successfully applied to learn expert models for 8 different tutor tasks spanning multiple domains (math, language, chemistry, and engineering) [17]. Emerging work explores the use of Apprentice models for supporting domain experts, such as teachers, in authoring tutors through teaching rather than programming [30]. In this work, we use one of the standard Apprentice models as a baseline for evaluating the PPO models because it have been successfully applied in previous work to learn expert models for educationally relevant tasks. For a complete description of this model see [17].

3. TUTORGYM

To support the development of machine learning agents we created TutorGym, a toolkit that provides a machine interfaces for multiple tutor environments.[3] TutorGym leverages the Gym [5] to enable existing RL implementations (that support Gym) to interface with these environments.

Our toolkit extends Gym to enable agents to request worked examples. Tutors generate both next-step hints and feedback, so the examples are automatically generated by the

[3]We have open-sourced TutorGym under an MIT license and made it publicly available here: https://tutorgym.ai

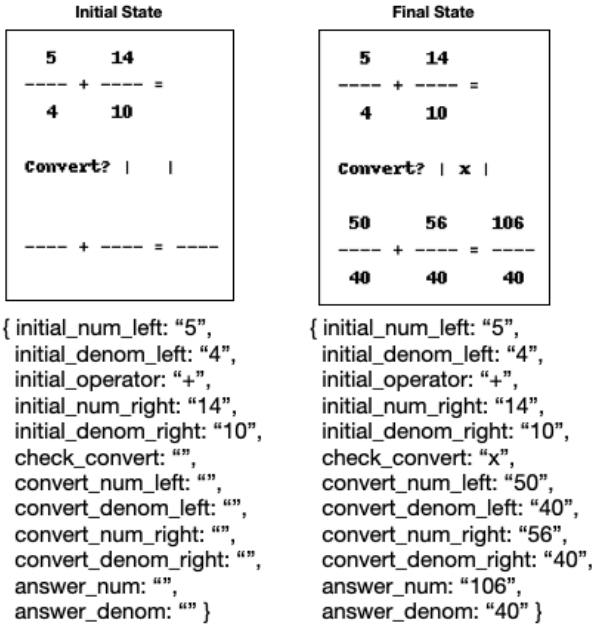

Figure 1: Fractions tutor, as rendered within TutorGym with its underlying base feature representation.

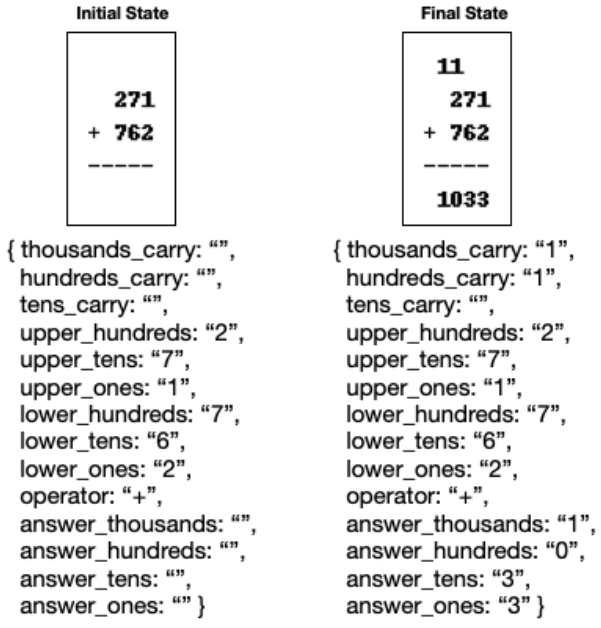

Figure 2: Multicolumn tutor, as rendered within TutorGym with its underlying base feature representation.

underlying tutor. As RL models only learn from feedback on actions, these interactions are mainly used by the Apprentice models, which learn from both examples and feedback.

TutorGym logs agent interactions in DataShop format [12], which is a common educational data format. Outputting data in this format lets us analyze it using the same techniques used to analyze human tutor data. In particular, it lets us conduct learning curve analysis to investigate agents' first attempt correctness as they receive more practice.

We implemented two tutors within TutorGym: a fraction arithmetic tutor [21] and a multicolumn addition tutor [30]. We chose these tutors because they exhibit interesting state and action spaces characteristics that are relevant to our analysis of emerging RL approaches.

3.1 Fraction Arithmetic Tutor

This tutor was used to study both human [21] and agent [16] learning. It presents students with three kinds of fractions problems: addition with the same denominator, addition with different denominators, and multiplication. The students check a box indicating whether they need to convert to common denominators before solving. If the fractions need to be converted, then they input values into the conversion fields. The tutor requires students to convert fractions to common denominators using cross multiplication. If students do not need to convert, then they directly enter values into the final fraction fields. Figure 1 shows the visual representation of the tutor state generated by TutorGym along with the underlying attribute-value representation that it maintains internally. The tutor gives students randomly generated problems where the initial numerators range from 1-15, the initial denominators range from 2-15, and the type of problem can be either addition or multiplication. There is also an "easy" version of the tutor that generates a much smaller range of numbers (numerators range from 1-5 and denominators range from 2-5). The tutoring system also has a done button (not shown) that the agent can select and it can provide worked examples on request.

3.2 Multicolumn Addition Tutor

The second tutor was used in previous research on simulated students [30]. It presents students with two numbers to add, with each digit presented in its own field. To compute the solution, the students needs to add and carry values where necessary. The tutor requires students to enter the answer values right to left, carrying where necessary. The tutor will mark an answer incorrect if they have not yet filled in the answer field to the right or they have not yet carried over a value from the previous column (if required). Figure 2 shows a simple visual output created by TutorGym along with the underlying attribute-value representation. The tutor also has a done button (not shown) and can provide worked example on demand.

4. LEARNING MODELS

4.1 Apprentice Learner

We created three alternative learning models to train within the TutorGym tutors. We built our first model using the Apprentice Learner architecture [16, 30]. From this architecture, we used the an Apprentice model developed in prior work [17]. For each tutor, we provided the apprentice model with background relational knowledge (for augmenting the state description) and primitive operators (for explaining demonstrations). For the fractions tutor, we provided equality knowledge, which adds features to the state description for each pair of fields denoting whether they have equal values. We also provided three primitive operators: copy, add, and multiply, which give the agent the ability to copy, add, and multiply values from the interface.

For the multicolumn tutor, the knowledge was slightly more complicated. We added four relational knowledge operators: add2-ones, add2-tens, add3-ones, and add3-tens. The first two add the values from every pair of fields in the interface and add features to the state denoting the ones component and tens component of each sum. Add3-ones and add3-tens do the same, but for every triplet of fields. This provides the agent with the ability to determine if a column of numbers (either of length two or three) will generate a value that needs to be carried or not. We also added these exact same operators as primitive operators, so the agent can use them to explain and perform the actual steps of computing each column sums and generating the appropriate carry values.

4.2 PPO-Number

A PPO model is defined in terms of its state (input) and action (output) representations. For the fractions and multicolumn tutors, the PPO-Number model makes use of the base state-representations shown in Figures 1 and 2. To convert these representations into a format that is acceptable to PPO (a fixed-length feature vector), we used an approach called one-hot encoding. Under this scheme, every unique attribute-value pair from the state is mapped to a particular feature in a feature vector. If the attribute-value is present in the state, then the feature is a 1, otherwise it is a 0.

Unfortunately, precomputing all possible attribute-values is non-trivial. To address this issue, we created an *online* one-hot encoder that always outputs a vector with a fixed length preselected by the user. Whenever the encoder encounters a new attribute-value, it maps it to a previously unused feature within the vector. After a mapping between an attribute-value and a feature has been made, that feature is only ever used to represent that particular attribute-value. This scheme enables the use of RL approaches that expect fixed-length vectors (PPO) even though the system might encounter a large number of sparse features that are not known in advance. The end result is that states from the fraction and multicolumn tutors are mapped to fixed length feature vectors, where every feature is either a 0 or a 1 (e.g., the initial state from Figure 2 would have a feature for $upper\_tens = 7$ with a value of 1). For the fractions tutor, 2000 features was sufficient to describe states in the standard tutor and 900 features was sufficient to describe the states in the easy tutor (with a smaller set of problems). For the multicolumn tutor, 110 features were sufficient.

Given this state representation, PPO-Number utilizes a multidiscrete output. This type of output has multiple independent discrete action outputs; e.g., in Atari it might have an output for the arrow pad (left, right, up, down) and another output for the action action buttons (A, B, or None). PPO-Number also has two outputs: one that outputs a field to enter a value into (e.g., answer_num) and a second that outputs a number to enter into that field (e.g., 1).

For the fractions tutor, there are eight fields that can be selected for input and there are 450 possible numbers that can be entered into one of these fields (1-450). For the easy version of the tutor, there are only 50 possible numbers (1-50). Taken together, this means that the standard tutor has 3,600 unique actions ($8 \times 450 = 3600$) and the easy tutor has 400 unique actions ($8 \times 50 = 400$). There are slightly less actions in practice because outputs are ignored in certain cases; if the system selects the done or the check_convert fields, than the number component is ignored.

For the multicolumn tutor, there are also eight possible fields that can be selected. Each field represents a single digit, so there are only 10 numbers that can be input into each field (0-9). This yields a total action space of 80 actions ($8 \times 10 = 80$). Similar to fractions, the total is slightly less in practice because the number component of the output is ignored when the done button is selected.

4.3 PPO-Operator

This model uses a different state and action representation from PPO-Number. The representation aims to mirror the representation used by the Apprentice model. We apply the relational knowledge used by Apprentice to augment the base state representation from each tutor. In the fractions tutor, we apply the equality relation to add an additional feature describing which pairs of fields are equal. For the multicolumn tutor, we apply the add2-one, add2-tens, add3-ones, and add3-tens relations to compute the ones and tens values for the sums of every unique pair and triple of values from the tutor fields. We applied the same one-hot encoding approach used for PPO-Number to convert attribute-values into fixed-length feature vectors. We increased the size of the feature vectors to support the combinatorial number of additional relational features (2000 for fractions and 5000 for multicolumn).

The action space is multidiscrete, but the number and type of outputs are slightly different from PPO-Number. For the fractions tutor, the model has four outputs. The first is similar to PPO-Number's selection output, it identifies the field to update with a result. There are eight possible fields that might be updated by an action. The second output corresponds to an operator to apply. The operators are the same as those available to Apprentice: copy, add, or multiply. The remaining two outputs correspond to fields in the interface that provide the two argument for each operator and there are ten possible fields that can be used for either of these arguments. Using this scheme, an agent might choose to update the answer_num field using the add operator, and it might provide the initial_num_left and initial_num_right as arguments. There are 2400 possible unique actions under this representation ($8 \times 3 \times 10 \times 10 = 2400$). However, this number is smaller in practice. If the model chooses to update the done or check_convert fields than the reset of the action outputs are ignored. Additionally, if the model chooses to use the copy operator, than only the first argument is used (the second is ignored).

For the multicolumn tutor there are five outputs instead of four. The first corresponds to a field to update (there are eight possible fields). The second corresponds to the operator to apply. There are five operators corresponding to those used by Apprentice: copy, add2-tens, add2-ones, add3-tens, add3-ones. Finally, there are three argument fields because some of the operators (add3-tens and add3-ones) take three arguments. There are 13 possible options for each argument. With these outputs, there are 87,880 unique actions ($8 \times 5 \times 13 \times 13 \times 13 = 87880$). In practice this number is much smaller because if the done field is updated, then all the other outputs are ignored. Similarly if the copy operator is selected, than only the first argument is used (second and

Model	Domain	# Inputs	# Discrete Outputs
Number	Fractions	2000	8, 450
Number	Fractions-Easy	900	8, 50
Number	Multicolumn	110	8, 10
Operator	Fractions	2000	8, 3, 10, 10
Operator	Multicolumn	5000	8, 5, 13, 13, 13

Table 1: Size of PPO model input/output for each task.

third arguments are ignored). Finally, if the add2-tens or add2-ones operator are selected, than the third argument is ignored. Table 1 shows a summary of the number of inputs and outputs for each model and tutor.

5. SIMULATION STUDY

5.1 Tuning and Training Models

We conducted a simulation study with a factorial design, where every agent (Apprentice, PPO-Number, and PPO-Operator) was trained in each environments (fractions and multicolumn). The hyperparameters used by PPO greatly affect its performance [10] and they must be tuned independently for each model and task. We used Optuna, an open-source hyperparameter optimization framework to automate hyperparameter search [2]. Using Optuna, we ran approximately 100 iterations of hyperparameter tuning for each PPO model and task pair. Tuning one model for one task took approximately 38 hours. The Apprentice model does not have any hyperparameters that need to be tuned.

We trained each model in each environment using the best hyperparameters. We trained Apprentice on 500 fractions problems and 5000 multicolumn problems. These amounts provided enough practice to reach mastery while minimizing unnecessary computation. We trained each PPO model for 1 million steps, which translates into a varying number of problems depending on the amount of incorrect steps. To analyze the simulation logs, we assigned knowledge component labels to each field for each problem type (e.g., answer one's place for multicolumn), computed the first-attempt correctness on each knowledge components for each problem, and plotted this correctness on a log scale with values smoothed using binomial Gaussian additive smoothing (to account for the 0/1 nature of the correctness values).

5.2 Results

See Appendix A for the results of hyperparameter tuning. During tuning, we were unable to get PPO-Number to converge to a correct model in the fractions tutor. We hypothesized this was due to the large number of actions for this model/task. To test this hypothesis, we trained PPO-Number on the easy fractions tutor, which has substantially less actions. PPO-Number converged to correct behavior on this tutor, supporting our hypothesis.

Figures 3 and 4 shows the learning curves for the different models in the two tutor environments. We find that Apprentice converges to mastery after 10 opportunities for each knowledge component in the fractions tutor and 125 in the multicolumn tutor. In contrast, PPO-Number requires over 10,000 opportunities to reach mastery on the *easy* fractions tutor and over 10,000 practice opportunities to reach mastery in the multicolumn tutor. PPO-Operator requires less opportunities (3,000) within the fractions tutor , but never quite reaches mastery within the multicolumn tutor, even after 10,000 opportunities. Even though both PPO-Number and PPO-Operator receive the amount of training steps (1 million), PPO-Operator makes more mistakes per problem and receives less problems as a result.

5.3 Discussion

At least one PPO model was able to achieve mastery in each tutor. PPO-Operator achieved mastery in the fractions tutor and PPO-Number achieved mastery in the multicolumn tutor. This suggests that PPO can generalize from game and robotics tasks to tutor tasks. However, the finding that no single representation is best suggests that the representations must be customized for each task.

PPO-Number was unable to master the standard fractions tutor. We suspect this is due to the single output channel

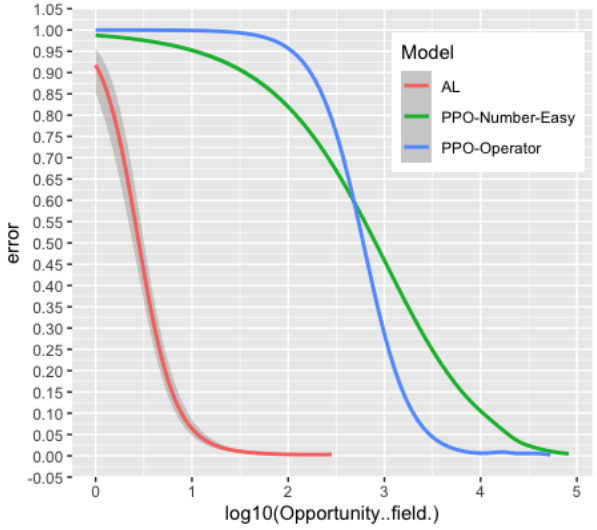

Figure 3: Fraction arithmetic learning curves.

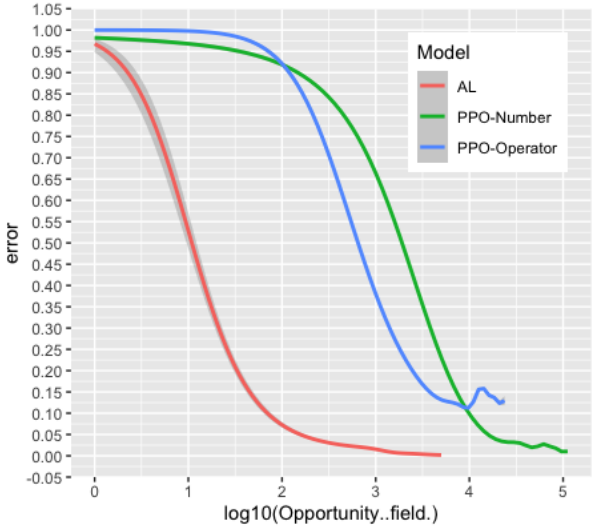

Figure 4: Multicolumn addition learning curves.

with 450 actions. Based on our experience, model performance degrades when the number of actions on one of the multidiscrete outputs gets large. Future work should explore replacing the 450 action output with three outputs: a hundreds digit output (0-4) a tens digit output (0-9) and a ones digit output (0-9). We also found that PPO-Operator was unable to achieve mastery in the multicolumn tutor. It may achieve mastery with more training (e.g., 1.5 million training steps rather 1 million). Assuming this is true, then PPO-Operator, which uses the same relational and operator knowledge as Apprentice seems to be more generally applicable than PPO-Number. Apprentice achieves mastery in both tasks with substantially less practice (thousands of times less), suggesting Apprentice has more efficient learning. Apprentice models have been shown to have similar learning curves to human students [16] for the fractions tutor. This implies that PPO models require substantially more training than human learners.

One limitation of the current study is that PPO may be more efficient when trained with multiple simultaneous environments (e.g., 8 tutors in parallel). Parallel training provides more diversity and improves learning. We tested this idea by training PPO models on 8 parallel environments for both the fractions and multicolumn tutors. We found that parallel PPO required an equivalent amount of practice to achieve mastery as non-parallel PPO; however, parallel PPO took less total wall time to train (e.g., 12 instead of 48 hours). Future work should explore the benefits and trade-offs of parallel training. Also, PPO is an on-policy RL approach, as opposed to an off-policy approach like Deep Q-Networks (DQN) [20]. As such, PPO only trains on the data that is immediately sampled from the environment; it discards old training data because it will cause the model to diverge. In contrast, DQN saves all experiences and continues to train on them over the course of learning. We would have liked to compare PPO to DQN, but DQN does not support multidiscrete action outputs, so could not be evaluated using the current Number and Operator representations. Future work should explore modifications of DQN (or other off-policy models) to see how they perform on these tasks.

6. RELATED WORK

There has been substantial work exploring the use of RL to optimally sequencing students' practice [9]. Unfortunately, this approach requires a large amount of data. One solution is to train models using simulated student data. However, simulated student models are often simplistic and not representative of real student behavior [8]. As a result, sequencing models built from synthetic data typically perform poorly with human students. The RL models we propose might serve as better simulated student models. Adopting a rational analysis perspective [3, 11], we hypothesize that agents that face the same task and processing constraints as humans will have similar behavior; i.e., sequencing models that are best for agents should be best for humans. However, future work is needed to investigate this hypothesis.

A similar parallel hypothesis is that when the task and processing constraints between RL and humans differ, the their behavior is likely to differ. To investigate this idea, Stamper et al. [26] explore differences in human vs. RL expertise for two games: Connect Four and Space Invaders. We view our work as complementary to this research, and future work should compare the behavior of expert models learned in this work to the behavior of human experts.

Simulated students have been used for a wide range of applications including theory testing [16], expert model authoring [17, 30], and teachable agents [18]. However, we are unaware of previously developed simulated students that make use of RL. Some of this prior work aims to model human learning and behavior. In contrast, this work makes little effort to model humans. We view this as a shortcoming of our current study, due to its preliminary nature. Future work should explore how RL approaches, such as those explored here, might be integrated within human-like simulated student models, such as Apprentice.

7. FUTURE WORK

TutorGym and our initial PPO models lay the foundation for a number of novel research directions. One promising directions we hope to explore concerns the use of RL to discover buggy student knowledge. During learning, RL agents make many mistakes. We should explore how these mistakes relate to the kinds of mistakes that humans make. VanLehn [27] investigated the "mind bugs" that human students exhibit in multicolumn arithmetic. Future work should explore how RL bugs compare to human bugs and if RL can support the discovery of bug knowledge for tutor tasks.

8. CONCLUSIONS

We explore the application of the PPO—an emerging RL approach—to educationally relevant tasks. While RL has been successfully applied to learn expert models across many tasks and domains, it has not yet been applied in the context of educationally relevant tasks. To support this exploration, we created TutorGym, a toolkit for interfacing RL models with educational training environments. We created two tutor-based environments within TutorGym: a fraction arithmetic tutor and a multicolumn addition tutor.

We created two PPO models that differ in their state and action representations (PPO-Number and PPO-Operator). For comparison purposes, we created a simulated student model using the Apprentice Architecture that has a similar state and action representation to the PPO-Operator model, but uses different (non-RL) learning mechanisms that are specifically designed to model human learning. We conducted a factorial study that varied the model and task. We found that at least one PPO model is able to achieve mastery within each tutor, suggesting that PPO is applicable to educationally relevant tasks. Despite this success, we found that both PPO models require substantially more training to reach mastery than Apprentice. This suggests that educationally relevant tasks present an interesting use case for the study and advancement of RL research. We also found an interaction between the type of PPO model and the task (PPO-Operator is best for fractions, but PPO-Number is best for multicolumn). This suggests that PPO's representation affects its performance and must be customized specifically for each task.

This work lays the foundation for future research to study and develop RL approaches for educationally relevant tasks. Our hope is that TutorGym and our initial models enable new research into how RL can support human education.

APPENDIX

A. HYPERPARAMETER TUNING

For each tuning trial, Optuna selects hyperparameter from a prior sampling distribution, trains the model using these values, and measures the resulting performance. Within a trial, the PPO model is trained for 350,000 steps. The final model performance is used to update the hyperparameter sampling distribution, so subsequent iterations sample more promising hyperparameters. Optuna also implements a sample pruner, which detects PPO trials that are under performing (e.g., if PPO performance gets worse with training rather than better) and prunes these samples early.

Table 2 shows the hyperparameters that were identified by Optuna for each PPO model and domain. The hyperparameter values are not particularly interpretable, but we report them here so other researchers can replicate our results. It is worth noting that we manually fixed the gamma value at 0.0, since tutoring systems provide immediate reward and future rewards do not need to be factored into decision making. Additionally, the tiny net architecture used a neural network with two layers and 32 nodes per layer, the small network used 64 nodes per layer and the medium network used 128 nodes. If the architecture was shared, then the second layer of the network was shared by both the value and the policy head of the network. However, if they were not shared then there were separate second layers for the value and policy heads. Finally, a constant lr_schedule means that the learning rate is held constant over the course of training, whereas a linear schedule means that learning rate is decreased linearly towards 0 over the course of training.

Do Common Educational Datasets Contain Static Information? A Statistical Study

ABSTRACT

In Intelligent Tutoring Systems (ITS), methods to choose the next exercise for a student are inspired from generic recommender systems, used, for instance, in online shopping or multimedia recommendation. As such, collaborative filtering, especially matrix factorization, is often included as a part of recommendation algorithms in ITS.

One notable difference in ITS is the rapid evolution of users, who improve their performance, as opposed to multimedia recommendation where preferences are more static. This raises the following question: how reliably can we use matrix factorization, a tool tried and tested in a static environment, in a context where timelines seem to be of importance.

In this article we tried to quantify empirically how much information can be extracted statically from datasets in education versus datasets in multimedia, as the quality of such information is critical to be able to accurately make predictions and recommendations. We found that educational datasets contain less static information compared to multimedia datasets, to the extent that vectors of higher dimensions only marginally increase the precision of the matrix factorization compared to a 1-dimensional characterization. These results show that educational datasets must be used with time information, and warn against the dangers of directly trying to use existing algorithms developed for static datasets.

Keywords

Knowledge tracing, Recommender systems, collaborative filtering, static models, matrix factorization

1. INTRODUCTION

Knowledge tracing tries to model the knowledge of students as they learn, and is a key component of Intelligent Tutoring Systems (ITS). In such systems, the aim is to recommend resources, such as exercises (or "problems"), to students in the most effective way, that is, to recommend resources which correspond to their learning needs. These resources can be of various forms, but in this article we focus solely on recommending new problems for the student to solve. In order to perform any recommendation, we believe that we should be able to predict the outcome of one particular student trying to solve one particular problem; we call this a *(student, problem)* pair. Ideally, we have perfect information for all such *(student, problem)* pairs, whether that information is actual (extracted from observation) or deduced (based on previous observation). This would allow us, for instance, to skip problems that are predicted as being too easy or too hard for a student.

Each *(student, problem)* pair could reflect a level of "difficulty" indicating the student's proficiency. In such a system, one would derive existing difficulty levels from known interactions, for instance through how much time was required for a student to solve a problem, or how many attempts it took to successfully solve it. A "good" system would then predict difficulty levels for interactions that did not happen, possibly with a confidence measure of the outcome prediction. It would also provide an understanding of the structure of the problem set. For example, it would enable the recognition of problems that train similar skills or use similar knowledge, without relying on expert knowledge components that require human expertise.

Historically, the field of knowledge tracing has been independent of recommender systems. With expert knowledge components, one can explicitly measure student proficiency with simple models like Item Response Theory and Bayesian Knowledge Tracing [2]. Using data mining on large datasets, it is possible to relax the knowledge components to be latent features that do not require human experts to partition the domain into explicit student skills [11]. Techniques in educational data mining are inspired from techniques used in collaborative filtering [1], such as factorization methods [20, 18], but also from techniques used in deep learning such as deep knowledge tracing [11, 19, 20, 13].

In this article, we will focus on matrix factorization methods. These are traditionally used in contexts where the available data is not very sensitive to time, for instance movie tastes and shopping habits. In contrast, students learn each time

Théo Barollet, Florent Bouchez-Tichadou and Fabrice Rastello "Do Common Educational Datasets contain Static Information? A Statistical Study". 2021. they practice and should normally improve with time, so it would make sense to take history into account when analyzing datasets, making predictions and doing structural studies. However, we do not know how much impact this has on the results. The question that we would like to raise here is whether taking history into account is that important or if it is still possible to make good predictions when considering datasets as timeless. Recommending a good problem in terms of teaching is not an easy task, but it is even more difficult when we cannot reliably predict whether the student will succeed or fail, and how long it will take them to do so. In the rest of this article, we will study how the matrix factorization algorithm behaves in three datasets from the educational data mining community compared to one dataset from the traditional collaborative filtering community. We will often deliberately *leave out* chronological information in the educational datasets to see how much information can still be extracted, compared to a traditional dataset.

This article makes two main claims:

- Educational datasets contain much less static information than usual datasets found in multimedia recommendation. Hence, treating educational datasets without any dynamic method should be avoided;
- The little static information they contain amounts to a one-dimensional value per student or problem.

We also propose in Section 3 a pre-processing procedure for educational datasets meant to facilitate prediction, even though we could not find any variable that is accurately predicted among all tested datasets, as well as a filtering procedure to try to find clusters among students and problems that are particularly accurately predicted in Section 5.

2. RELATED WORK

2.1 Data Pre-processing

It is sometimes necessary or advantageous to perform preprocessing of the data before trying to extract information. For example, it was possible to improve the classification error in the MNIST database from 12% to 8%, keeping the same linear classifier, by using deskewing pre-processing [8]. Regarding our knowledge tracing problem, many corrections to the ASSISTment dataset [4] are proposed by Xiong et al. [19]. They are now included in the public dataset that we use later. We also propose some more pre-processing in Section 3.

2.2 Matrix Factorization

Matrix factorization (MF) is a widely used technique in recommender systems, as illustrated by its extgensive usage in the 2009 Netflix Prize Competition [7]. We consider a set U of N *users*, a set I of M *items*, and a set of *ratings* R. These sets are usually given as *records* $(u, i, r_{u,i})$, representing how much $(r_{u,i})$ a given user u likes item i. From these we can build a sparse rating matrix $X \in \mathbf{R}^{N \times M}$. The goal of matrix factorization is to find two matrices $W \in \mathbf{R}^{N \times k}$ and $H \in \mathbf{R}^{M \times k}$ (usually with low rank $k \ll N, M$) such that X is close to $WH^\intercal$. This is an optimization problem written as:

$$\underset{\substack{W \in \mathbf{R}^{N \times k} \\ H \in \mathbf{R}^{M \times k}}}{\operatorname{argmin}} \sum_{(i,j) \in \Omega} (X_{ij} - w_i h_j^\intercal)^2 + \lambda(\|W\|_F^2 + \|H\|_F^2) \quad (1)$$

Where λ is a regularization meta-parameter and $\|.\|_F^2$ is the Frobenius norm [21]. Equation 1 may vary in regularization terms (bias, sparsity penalty...) and can incorporate a loss function between X_{ij} and $w_i h_j^\intercal$. We can now estimate unknown ratings within the product $WH^\intercal$. In other words, we look for signatures for users and items in the same latent space of dimension k (i.e., vectors of rank k), such that the outcome of the user rating an item is close to the dot product of these signatures.

This optimization problem is non-convex in general, but different methods exist [7]. The Alternating Least Square (ALS) method is the most popular method as it converges better than the Stochastic Gradient Descent (SGD) method due to non-convexity. When large-scale data is needed, as ALS is not easy to parallelize, and Coordinate Descent is preferred [6, 21]. In a knowledge tracing setting, users are *students* and items are *problems* [20, 16, 18]. Problems are usually split into smaller components that are the *problem steps*. We will see in subsection 3.1 why we recommend a first regrouping pass in order to work with whole problems.

2.3 Cold Start Problem and Online Settings

The *cold start* problem is a typical problem in recommender systems that corresponds to the initial phase of a "nude" system (no data collected yet). The lack of data makes the prediction accuracy unreliable at that early stage. MF techniques are not designed to tackle the cold start problem but, some extensions seek to solve it partially [22, 10]. As we are not focused on prediction accuracy, we will not consider these extensions in this article but we will try to evaluate when the cold start problem ends in Section 4, that is, when there is enough data for MF to start giving results. Trivedi et al. [17] try to solve a cold start problem in an ITS environment with spectral clustering to help refine raw prediction, but they work on the raw features of datasets without student or item signatures.

Even after the cold start, the system usually benefits from new data in general. This is referred to as online recommendation, and MF is widely studied in such a context [5, 9, 12]. These works consider extremely large datasets, about the order of millions of users and items, but it is still feasible to redo a factorization after adding a few elements, as we will see for instance in Section 4 and 5.

3. FLAT PREDICTION AND AGGREGATION

In this section we studied matrix factorization (MF) on four different datasets, and found that not all datasets were directly usable without some pre-processing, compared to classical datasets. We use the basic version (L2 regularization) of Equation 1 with a fixed rank of 20 (apart from the last section where we measure the impact of rank variation). We use coordinate descent for the optimization [21] because some experiments in sections 4, 5, and 6 require numerous factorizations.

3.1 Educational Datasets and Pre-processing

We will use three common educational datasets for the rest of the article: Algebra I 2006–2007 [14], Bridge to Algebra I 2006–2007 [15] (both of these come from the Cognitive Tutor problem set) and ASSISTment09 (we use the corrected

Table 1: Raw data sets overview

Data set	Users	Problems	Steps	Steps occurring once	Mean samples per step	Samples
Algebra I 2006-2007	1338	5644	418 060	314 198	5.4	2 270 384
Bridge to Algebra I 2006-2007	1146	14 787	202 672	46 935	18.1	3 679 199
ASSISTment09	4217	17725	26 688	3123	13.0	346 660
ML-1M	6040	3706	N/A	N/A	269.9	1 000 209

Table 2: Preprocessed data sets overview

Data set	Users	Problems	Samples	Density	Mean samples per problem	Success percentage
Algebra I 2006-2007	1147	3111	152 709	0.043	49.1	0.79
Bridge to Algebra I 2006-2007	1068	8736	235 147	0.025	26.9	0.91
ASSISTment09	2025	12587	238 746	0.009	19.0	0.98
ML-1M	6040	3706	1 000 209	0.045	269.9	N/A

and collapsed version of the dataset) [4]. All three datasets record scaffolding problem statistics (also called *steps* in Cognitive Tutor datasets – we will use both terms here). For each record (also named *sample*), we extract:

1. A student and a *main problem* ID;
2. A *scaffolding problem* ID;
3. A *timestamp* when a student starts a step and the *duration* to complete the step;
4. If the student succeeded at his first attempt: *Correct-First-Attempt* (CFA);
5. The number of *hints* and *errors* of the student for this step.

To our surprise, these datasets are not very usable without pre-processing in comparison with well-established recommender system datasets like the MovieLens dataset. We will compare most experiments with the ML-1M version of this dataset, which will act as a "control" dataset: multimedia recommendation datasets being the canonical use of matrix factorization for recommender systems. The two main reasons for this poor usability that we try to mitigate with pre-processing are the following:

- The notion of scaffolding problem is not standardized between the datasets and is hard to use as is. Some of them are optional, which makes the number of steps for a main problem vary between students. The step order may also change between users, which makes matching between users more difficult at the problem level.
- There is no guarantee of the minimum number of occurrences for a student or a step. Moreover, many steps are done by a single student across the whole dataset, as seen in Table 1 (especially for the Algebra I dataset, where steps can be generated for a student from a template, and are thus unique. These constitute up to 3 quarters of the steps).

Our first pre-processing pass, which is motivated by the very low number of samples per step on average, corresponds to aggregating all the steps of a common main *(student/problem)* pair together. Aggregating timestamps and durations is straightforward (the beginning of a problem is the beginning of the first step and the total duration is the sum of the steps' durations). To aggregate "Correct-First-Attempt" we take the mean across a *(student/problem)* pair so we obtain a floating point value between 0 and 1 instead of a boolean value.

Simply aggregating hint and error counts by summing them is not satisfactory because ultimately we want to have an idea of how much a student struggled on a problem. Summing these quantities is not sufficient to access some basic information such as "*Has the given student reached the end of the problem or given up?*" This information is not provided in the datasets, so we had to build a proxy variable. To answer this question, we need to know, for a given problem, the number of basic steps it decomposes into. To find this quantity, which we call the *problem size*, we counted for each problem/student pair the number of samples. For a student who succeeded (possibly with hints and intermediate mistakes), the problem size and this number should match. We assumed that for a given problem, the most represented number (among all students) was the actual problem size. We believe that this high representativeness comes from the fact that the ITS providing the datasets give enough hints for most students to reach the end of the problem before giving up. This makes the number of hints and errors valuable information to measure the difficulty of a problem for a given student.

Once we have a boolean proxy indicating success by reaching the end of a problem, we can derive two variables: reaching the end without errors and reaching the end without hints. We can also build a difficulty variable to aggregate the hint and error counts: we sum the two counts with a 0.5 coefficient for hints. We represent failure by assigning a difficulty value of twice the maximum value.

After aggregation, we have six variables (called *target variables* or simply *targets* from now on) of interest for each student/problem interaction: *duration* (0-1 scale value), *difficulty* (0-1 scale value), *correct-first-attempt* (0-1 scale value) and *success-reached* (boolean value), *success-no-error* (boolean value), *success-no-hint* (boolean value). The first three are normalized per problem so that for each problem, the "worst" student gets a value of 0, and the best one a value of 1 (giving rise to what we called above a 0-1 scale value). ML-1M has a single target which is the movie rating (also normalized for comparison). After aggregation, we filter out users who have done fewer than 20 problems and problems that are done fewer than 5 times (same threshold than for ML-1M). Table 2 shows the size of the datasets after pre-processing.

3.2 Influence of Aggregation on Datasets

Figures 1, 2, and 3 report the ability of a factorization to accurately model the different target variables on the four

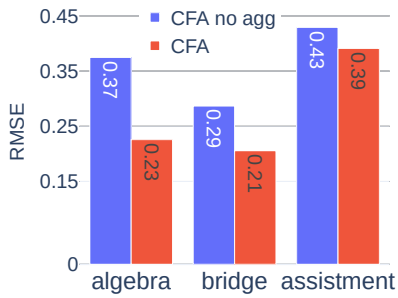

Figure 1: RMSE between no aggregation and aggregation for correct first attempt

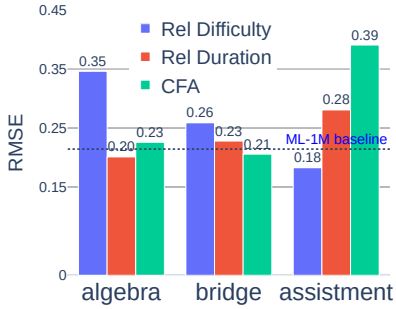

Figure 2: RMSE for duration, correct first attempt and difficulty

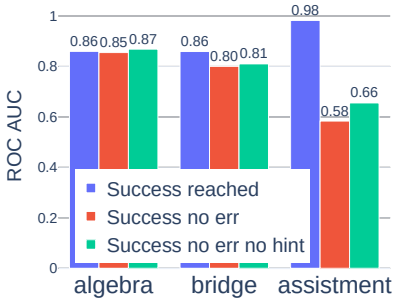

Figure 3: ROC AUC for success and derivatives (higher is better)

datasets and compare the effect of aggregation. For 0-1 scale variables we use the root mean square error (RMSE – the smaller the better) as the error metric, and for boolean variables we use Receiving Operating Curve Area Under Curve (ROC AUC – the closer to 1 the better). For ML-1M, the only possible target variable is the movie rating. We report it in Figure 2 as a horizontal line.

In Figure 1, we see that the aggregation and filter procedure improve the prediction quality of the Cognitive Tutor datasets in a notable way, but only by a small margin for the ASSISTment dataset. We believe that if the pre-processing removed about one third of the problems and half of the students, the density would still be very low compared to the others. In all the remaining experiments, we will use the aggregated versions of the datasets.

It is hard to find any trend regarding the RMSE differences in Figure 2. Variations seem to indicate that different datasets favor different target variables. MF can have about the same prediction capability for educational datasets and multimedia datasets if the target variables are chosen carefully, which suggests that situations call for pre-analyses in order to select the target variable which will be the most accurately predicted.

In Figure 3 we can see that accuracy on success classification is reasonably good. However, we cannot explain the difference in ASSISTment between success-reached and the two other success target variables. This might stem from the aggregation procedure that relies on approximated methods to obtain the number of steps in a problem. We will not do any further experiments on these target variables (which are boolean), as they are barely comparable with the 0-1 scale variable of the ML-1M dataset.

4. ONLINE PREDICTION

In this section, we will try to evaluate the point at which there is enough information to predict reasonably well with MF techniques. This allows the system to stop using whatever bootstrapping technique it was using to solve the cold start problem.

To evaluate this we start by getting either the full student set (and no problem) or the full problem set (and no student). We then progressively add new problems in the first case and new students in the second case, adding 20 new elements at each iteration. At each iteration we redo a full factorization and evaluation as if the system was complete.

We independently measure RMSE of correct-first-attempt and difficulty variables. To evaluate whether the order in which new elements are added makes a difference or not, we considered three orders: (i) elements sorted by their number of occurrences either in decreasing (*high* density first); (ii) or in increasing (*low* density first) order; (iii) and following the chronological order (*chrono*). Only the chronological order makes sense in an online context, but we still use the number of occurrence orders to evaluate whether or not we benefit from a higher density.

We report in Figure 4 the results of this experiment. We can see that for three out of four datasets (not ASSISTment), adding elements by highest density makes the system converge really fast (about 200 elements for Bridge), which was to be expected as those elements carry the most information. For all datasets, adding elements by lowest density, as we might expect, makes the system converge really slowly. We believe that the extremely accurate prediction on some of the curves for the first few iterations of the growing process is due to overfitting (recall that the factorization uses a rank of $k = 20$ in those experiments).

Still, there are some artifacts to these results. In Figure 4e, the previous claims are reversed for difficulty target. Maybe this is a hint that this aggregated variable may not be robust enough on all systems. Our advice is to systematically test target variables on a system to make sure that the ones we choose are consistent and can be trusted.

Finally, we do not observe any "dramatic" drop of the RMSE in curves representing the chronological order that we could clearly label as the "cold start" (although it sometimes takes a few "adds" to stabilize). Of course, the highest accuracy is obtained whenever all the data is used, but this suggests that MF accuracy starts to get close to the maximum early in the process. However, bear in mind that we only evaluated our ability to model existing data (we evaluate on the matrix we factorize), but did not evaluate our ability to predict (by evaluating on the remaining, not factorized, part of the matrix).

5. STUDENT OR PROBLEM PREDICTION KERNELS

In this section we search for a subset of students and problems where the prediction is more accurate than on the rest of the dataset. Having such a subset can be of interest in various ways: further analysis like signature clustering might work better on a subset with high accuracy prediction, or this can be a first step towards building a confidence measure for new predictions using a similarity measure with this accurate subset.

Note that we briefly tried some clustering algorithms on the student and problem signatures given by MF, but they were not promising. We will explain in Section 6 how the signatures we can obtain with MF may not be appropriate to such a study.

5.1 Iterative Filtering

We describe an iterative procedure to filter students and problems that have the least accurate predictions.

We alternately remove students and problems: at each iteration we remove the 8% of the considered set that are the least accurately predicted in terms of RMSE (or 15 elements if 8% is lower than 15). We report in Figure 5 and Figure 6 the evolution of the density of the rating matrix and RMSE for the difficulty target variable.

Figure 5 presents the variations in density as we progressively remove students and problems. Interestingly, removing items usually increases the density while removing students decreases it in the three educational datasets, meaning that the students that solved many problems are viewed as "problematic" by the system. This behavior is not observed in the reference ML-1M dataset. Figure 6 confirms the tendency that removing students in the beginning tends to improve prediction accuracy. This result is disturbing as it means that, for the educational datasets, MF prefers less dense matrices with regard to the users, i.e., less information for a given student. This suggests that MF performs best when a problem was done by many students, but when the students have done few problems. What is interesting here is that this scenario is the one that resembles most closely the ML-1M dataset: by having students that did fewer problems, we are indeed eliminating students that likely *progressed* during the experiment, hence whose behavior cannot be represented by a single vector across all their interactions. This is a first solid hint that MF alone does not seem suited to educational datasets, as it shuns chronological subtleties.

6. INFLUENCE OF RANK VARIATION

In this section we repeat the experiments from previous sections with different rank values. In addition to rank $k = 20$ that we already measured, we use rank 5 and a rank of 1. We deliberately choose a rank of 1 to mimic a Whole History Rating (WHR) [3]. Even though it is not an exact correspondence, we believe that the information extracted by a MF with rank 1 can also be extracted by a WHR.

We see in Figures 7, 8, 9 and 10 a clear difference between the educational datasets and ML-1M regarding the influence of ranks. This benefit from rank increase agrees with the intensive use of MF techniques in multimedia recommender systems. However, the benefit of such an increase for educational datasets is almost negligible. This is particularly apparent in Figure 10, where the ML-1M RMSE curves get lower with increasing rank while all other curves are nearly indistinguishable by rank. This shows that, when the chronological information is not used, vectors of size 5 or 20 do not improve accuracy compared to a simple vector of size 1, i.e., a single float. This suggests that we cannot do better than assign a single number to problems and students, which could be interpreted as having a "difficulty"

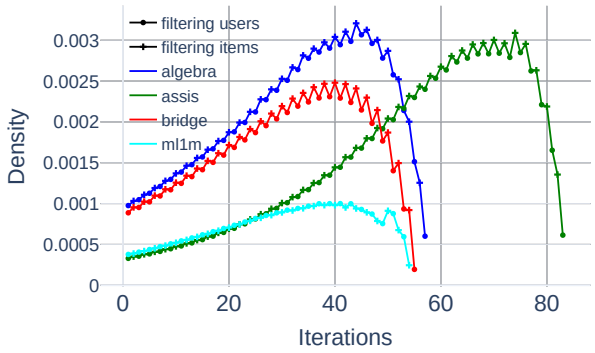

Figure 5: Evolution of density during filtering with target **Difficulty**

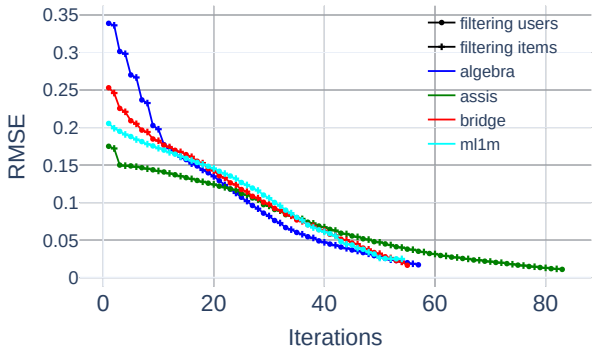

Figure 6: Evolution of RMSE during filtering with target **Difficulty**

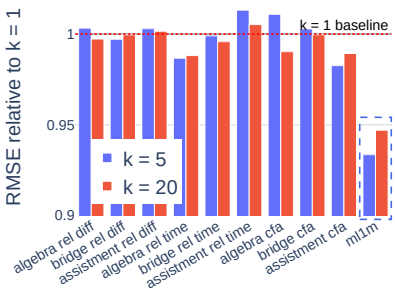

Figure 7: Evolution of flat factorization RMSE depending on rank relatively to k = 1

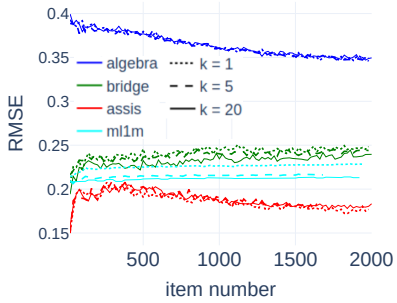

Figure 8: Evolution of RMSE while adding problems with target **Difficulty**

(a) Duration (b) Difficulty (c) Correct First Attempt

Figure 10: Evolution of RMSE during filtering with various target

rating for problems and a "skill" rating for students, mimicking a WHR rating system. This is a second strong hint that educational datasets do not have the same structural properties as datasets from multimedia recommenders, and that if we want to extract more information and discover a better characterization of students and problems, it is necessary to consider chronological information.

7. CONCLUSION

We applied preprocessing to common educational datasets to try to improve the accuracy of MF techniques. While these did improve the results, we also showed that when MF techniques from the collaborative filtering community are directly applied, they do not benefit from having ranks higher than 1, meaning that the attribution of a single value to students and problems is about as effective as we can get. This seems to indicate that MF techniques might not be the most efficient model to extract static information from these datasets, or, more probably, that static information is scarce. We believe that this stems from the fact that, unlike users in multimedia recommender systems, students change over time as they are faced with new problems but also from outside interactions not recorded in ITS, hence chronological information needs to be taken into account in order to improve accuracy and make predictions. Still, in the eventual absence of more sophisticated analyses in a recommender system, MF can be used to extract a crude measure of what could be labeled as a level of difficulty of a problem and a level of proficiency or skill of a student.

ABSTRACT

Finding the optimal topic sequence of online courses requires experts with lots of knowledge about taught topics. Having a good order is necessary for a good learning experience. By using educational recommender systems across different platforms we have the problem that the connection to an ontology sometimes does not exist. Thus, the state of the art recommenders can suggest courses with an optimal order within a platform. But on a more global view, a recommendation across different platforms with optimal order is not existing as long as no ontology was defined or courses are not connected to an existing ontology. Nowadays experimental approaches manipulate the learning paths to find the optimum. As this can impact the learning experience of participants, this approach is ethically unacceptable. To overcome this problem, we propose a data-driven approach using the search engine result pages (SERPs) of Google. In our experiment, we used pair-wise search queries to get access to web pages, those 38.000 texts were used to test some NLP metrics. 10 different metrics were examined to create an optimal order that was compared to the optimal sequence defined by experts. We observed that the Gunning Fog Index is a good estimator to determine the optimal order within a cluster of topics.

Keywords

Course Sequencing, educational recommender system, web search, adaptive courseware, personalization.

1. INTRODUCTION

Providing the optimal sequence of topics in online courses is of high interest because it influences the learning outcome as well as motivation. Lots of MOOCs are existing, but in which order they should be done is defined by experts and this is a time-consuming procedure. Large-scale educational recommender systems [1] suggest online courses across different platforms. Creating an optimal sequence based on an ontology is an easy solution as an ontology includes the optimal order, defined by human experts. This can be done within single platforms, but an ontology across different courses across several platforms is not existing. McCrae et al. [2] state that it "is difficult to link to ontologies". The willingness to create a connection of own online courses to an existing public ontology is low as this is expensive due to manual work on the one hand but can also result in course recommendations of other suppliers on the other hand, which does not meet the interests of the suppliers.

The optimal sequence is missing in recommender systems as long as no manually created large-scale ontology or optimal sequence exists. Recommender systems only provide a ranking based on how well the suggested courses fit into the user's learning situation. There are existing approaches, e.g. linked data to create a structured semantic web [3]. Their idea is to create a network that contains the meaning of the data. But there is the problem that the semantic web is limited to specific domains. If the networks have not been created for the topics that we need, we cannot use them. Besides, the structure in the semantic web is designed to understand relationships between objects, not whether there is a dependency from the educational perspective. Further on, there is the problem that topics for online courses often consist of multiple words to describe the topic or concept. Finding the correct corresponding concept within the semantic web can be challenging.

Having an optimal order of online courses is of high interest in online education as many topics require the knowledge of subtopics. Knowledge dependencies can be modeled by experts manually on the one hand, but this is a cost-intense procedure that requires lots of knowledge about the taught topics and provided courses as well. On the other hand, the world wide web is full of contents of different quality. Every topic that can be taught can be found there, but the contents of web pages are still not used for topic sequencing in education. Crawlers get access to all the texts and companies like Google define an order of pages related to a search query. Within a search engine, we get access to all pages that they define to satisfy the user intent [4]. Using this large number of pages for each topic could be beneficial in creating optimal topic sequences for online courses.

An optimal order is very important for a good learning experience in online courses. We define an optimal order as the sequence of course topics where each topic should be taught when all pre-requirements are fulfilled based on the previous courses. As long as topics are taught where the requirements are missing, the dropout rate will be high. Using courseware (single parts of a course) [5] to generate a new online course it is important to have an optimal order. Otherwise, the participant cannot understand the topic because of missing knowledge. The same problem exists in AI-generated learning paths of online courses, which must be consistent according to the fundamental didactical method of starting teaching basics, not with specialized knowledge.

Sylvio Rüdian and Niels Pinkwart "Finding the optimal topic sequence for online courses using SERPs as a Proxy". 2021. EDM '21 June 29 - July 02 2021, Paris, France

Observing the world wide web, we can get a variety of texts on any topic. We want to use this already existing large set of pages to find the optimal topic order of online courses with an experimental approach. To access all the pages with corresponding texts that we need, we use the search engine Google, especially the Search Engine Result Pages (SERPs) [6]. It is known that Google uses the semantic web in the background, depending on the search query, which helps to overcome the challenge to find the optimal corresponding concept of the semantic web using the search engine as a proxy [7]. This is beneficial for the case that for specific domains no linked data is existing – as the search engine tries to provide related resources, even if they are misspelled and the search engine can give results for queries that they have never seen before.

Using topics as keywords results in a list of pages that satisfy the user intent according to Google [4]. This can be used as a base for having access to different features for ordering course topics. SERPs help to understand the popularity of how many pages are indexed by the search engine, which could be an indicator for good sequencing as less specialized topics are existing compared to general basic topics. Besides, having a lookup for two topics in one search, we get pages that contain both keywords, those frequency or deviation could be an indicator for finding the optimal sequence. If we observe online courses, then we usually have an increasing difficulty level. Using the complexity of texts could help to estimate the optimal order based on the difficulty.

In this paper, we concentrate on the three research questions:

1) Is the SERP popularity of all topics a good indicator to find an optimal topic sequence for online courses?

2) Is the topic frequency of page texts that are listed within the SERPs an estimator to determine the optimal topic sequence in online courses?

3) Does ordering topics' texts by text difficulty metrics result in a sequence that is appropriate to be used as a sequence in online courses?

2. RELATED WORK

Brusilovsky et al. [5] define this problem as "sequencing of lessons" where each lesson is connected to a topic. This contains numerous chunks of educational material, ranging from videos and texts to different interactive tasks. The authors use a domain concept structure, that is stored independently from teaching materials. Each concept needs to be linked to the teaching material. It has the advantage of being able to use the courseware to generate a personalized online course according to the interests and knowledge gaps of a learner. This approach is comparable to using an ontology that needs to be defined by experts, based on rules and graph representation. It is the fundamental model to define an optimal sequence of online courses but requires the creation of the ontology by experts.

S. Fischer [8] uses an ontology knowledge base, namely a "knowledge library" to create an optimal course sequencing. Therefore, they use modularized media content as courseware together with metadata that describes the link to the ontology model. With that, they have access to a taxonomy that can be used to create a good ordering of topics as well as generating questions with right and wrong answers (depending on the granularity of the ontology). The modular resources can be used to generate courses, according to the knowledge gaps of learners.

Xu et al. [9] propose to learn from users providing specific course sequences for testing and use their performance to create an optimal sequence for new users. While this approach works it has the disadvantage that it requires real test users which may perform badly within the scenario. Doing this in a field study is acceptable but using real students is not sustainable from an ethical point of view. We want to emphasize that we do not want to use this experimental user behavior data as this is ethically not acceptable.

Cucuringu et al. [10] used already captured student participation in courses to create pair-wise comparisons using ranking aggregation to create a global ranking. This ranking proposes an order of how courses should be taken by students. One major problem is incomplete data as some pairings are not existing for a comparison.

S. Morsy [11] states that a global ranking of online courses cannot be used for personalized recommendations. But having a global ranking can be helpful to determine which courses should be done in which order. Combining this knowledge with personalized courses or topic recommendations is helpful as the course dependencies (e.g. what knowledge is necessary to understand a topic) are the same for personalized recommendations, which are filtered by topics/concepts that the learner is already aware of. Thus having a global ranking can be beneficial for personalization as well.

Using the information of chosen courses by students and their performance is a good way to determine an optimal course sequence. A major limitation with that approach is the limitation of data and to have access to chosen courses and the resulting performance. This approach does not comply with the GDPR as the information on whether students passed or failed an exam is classified to be sensitive personal data, that cannot be accessed for course sequencing in general [12]. Thus, their application does not work in a real-world scenario in the EU. Based on the limitations of being dependent on user performance or manually created ontologies, we propose a new methodology to create an optimal order of online courses, based on their topic.

3. METHODOLOGY

As we learned from Rüdian et al. [13]: Even if experts are scoring the same results of educational tasks, their scores vary among each other. If we observe the order of topics, then we know that there is not always a perfect solution regarding the whole sequence because of ambiguous expert opinions. In the pre-study, four experts (AI instructors) had the task to create the optimal order of 20 AI-related topics to be taught within online courses. We used the following topics: *neural networks, voice recognition, chatbots, Linux, data visualization, Python, statistic basics, part-of-speech tagging, LSTM, data preparation, deep learning, TensorFlow, object recognition, Naïve Bayes, natural language processing, ethical principles, clustering, reinforcement learning, cross-validation, and regression*. The resulting sequences are then used to make a pair-wise comparison to understand the overlap across instructors and to see where we have a high overlap. The pair-wise sequence score S is defined as followed: For every topic A and B of the expert sequence with $A \neq B$ and every topic C and D of the sequence derived by the algorithms or another expert with $C \neq D$ we count all hits where $(A < B \; and \; C < D)$ or $(A > B \; and \; C > D)$. Thus, the topics have the same order within both sequences. This number is divided by the number of possible combinations, defined as S.

Some topics have dependencies; e.g. neural networks should be introduced before teaching LSTM or natural language processing should be taught before starting with part-of-speech tagging; others do not have strong relations and can be taught somewhere, e.g. ethical principles or Linux.

The idea of the main study is to compare the sequences created by instructors with algorithmic ones. Therefore, it is a good fundament

to measure tutors' decisions among each other first to define accuracy as a gold standard that we want to achieve with our methodology. Thus, we need a realistic generalizable accuracy that we should achieve instead of over-optimizing our approach with high accuracy that is the optimum for a sequence of one expert only. Besides, the pre-study identifies the optimal order of the topic subsets that are the same for all experts. The order of these topic subsets will be compared to the order that we get from our algorithms to see how well the algorithms perform in a real-world scenario.

Our approach is to use the Search Engine Result Pages of Google (SERPs) and we derive different metrics based on the results. A search engine can be used to find web pages that are related to given keywords. One of the main purposes of the search engine Google is to satisfy the user intend by providing a list of web pages that are related to the search query [4]. Thus, using it allows us to get pages that have a high authority according to the Google ranking algorithm, which is, according to them, a metric of high quality. We use this list of pages with our topics as search queries to understand the popularity, the number of user searches, the complexity of topics, and which topics have a semantic connection. These metrics are then used to create a sequence, based on a linear order of the observed data. These sequences are compared to the experts' ones to understand whether there is a connection between our metrics and the optimal order, defined by experts.

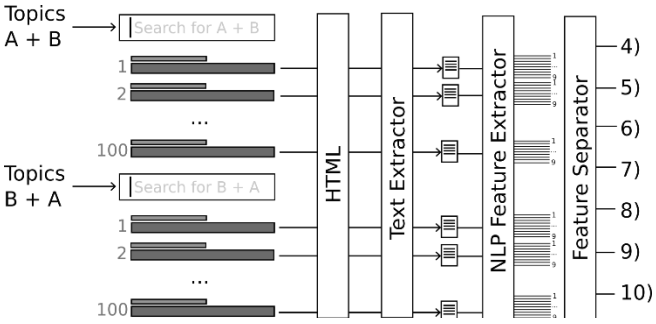

Figure 1. Pipeline for pair-wise search, extraction, and separation of features.

The approach of using a search engine as a basis has the advantage that we do not need to do experiments with students where they may be badly influenced due to bad testing sequences. Thus we are independent and can use our approach on a larger scale. That makes our approach more practically usable. We use different data as a basis, use them to rank our 20 topics, and compare the order with the instructors' ones. Our approaches are the following:

1) We use the number of topic results that are estimated by the search engine by searching for every keyword separately.

2) We use the number of topic results pair-wise keyword combinations and observe the number of estimated results.

3) We use the keyword search estimator and rank our topics according to the estimated search amount.

4) We use the first 100 results of all pair-wise keyword combinations and count how often both keywords within the 100 listed pages exist.

5) We use the first 100 result pages as in 4), search for both keywords on the pages, and summarize how often each keyword occurs at first in the text.

We use the 100 result page texts and apply three algorithms to estimate the text complexity, namely 6) Flesch-Reading-Ease (FRE) [14], 7) RIX [15], and 8) Gunning Fog Index (GFI) [16]. Then we use the 100 result page texts with basic NLP metrics: 9) The type-token ratio (TTR) and 10) the number of words per sentence (NoW). We assume that observing how many pages are existing in combination helps to identify topics that have a semantic connection. Using the information on how many pages are existing gives hints about the popularity (1,3), where for complex topics mostly less content exist than for basics. Observing the complexity of the contents (4-7) could help to identify the difficulty level of topics to find the optimal sequence. Figure 1 visualizes the method for 4)-10) to get features based on a pair-wise topic search.

The Flesch-Reading-Ease Index is based on the "Standard Text Lessons in Reading" [17] and is calculated from the average sentence and word length [14]. The main idea of the Gunning Fog Index is to reduce the complexity in newspapers as a kind of warning system for authors that texts are not "unnecessary complex". Therefore, the author uses the sentence lengths, the number of syllables, easy words, and hyphenated words to estimate the complexity of a text [18]. The "Regensburger Index" (RIX) uses difficulty parameters like passive, sentence complexity, and predications to derive the complexity [15]. All approaches differ in the selection of features that are used to create the indexes.

Finally, we use a random forest regressor [19] to predict the pair-wise sequence, using the data of 4)-10) to estimate the feature importance to support our findings. To get all the data, including the SERPs, all pages, and the estimated search amount, we use a commercial web crawler for SERPs[1]. This is necessary as the pair-wise lookup of 20 keywords results in $20 * 20 - 20 = 380$ searches, where we need to download 100 web pages each, resulting in 38.000 files. A simple crawler that we used in our lab before, was banned after 20 crawls, thus using a commercial one is the most efficient option.

Each data source 1) – 10) is then used to create a ranking of topics, based on their linear order. These sequences are compared with the expert ones to find the optimal feature that can be used in a real-world setting. To compare the sequences of the experts with the algorithmic ones, we use a pair-wise topic comparison to test whether the order is the same in both sequences and summarize the hits. Thus we can compute the overlap that represents the accuracy in our experiments.

4. RESULTS

The overlaps across the expert sequences range from 0.6 to 0.8 (Table 1). Thus we have an orientation of the resulting overlap that can be achieved with our approach at maximum. While the overall sequences defined by experts are partly different, we identified some partial sequences that are identical across all expert-based rankings and use them as ground truth. We detected some matching sequences of topics:

A = ["data preparation" → "data visualization" → "clustering"], B = ["neural networks" → "deep learning" → "LSTM"], and C = ["natural language processing" → "part-of-speech tagging" → "voice recognition" → "chatbots"],

[1] https://seorld.com/crawler

where [A → B] means that topic A needs to be explained before topic B. This makes sense as each topic mostly requires knowledge of the previous one(s), e.g. "neural networks" have to be introduced first and after that, "LSTM" can be explained. We use the three clusters (A, B, and C) to visualize whether our rankings make sense in a real-world scenario as the overlap of sequences defined by a number only is too abstract. All in all, in our pre-study we can conclude that we identified three clusters using sequences of four experts.

Table 1. Pair-wise sequence overlaps of 4 AI experts.

	Expert 1	Expert 2	Expert 3	Expert 4
Expert 1	-	.60	.65	.80
Expert 2	-	-	.65	.65
Expert 3	-	-	-	.75
Expert 4	-	-	-	-

Then we used all the different data points that we got from the crawler separately and created a sequence based on their linear order. Table 2 shows all the results of our experiments. We calculated the pair-wise overlap to compare estimated sequences with the expert ones. Also, we tested whether our partial sequences of the topic sets in A, B, and C have the same order as defined by our experts.

Observing 1) - 3) we can answer the first research question as these metrics represent the popularity of topics within the SERPs. The ordered list of topic pages is not a good indicator to find an optimal topic sequence for online courses. Thus, popularity is not a good indicator of course sequencing.

Table 2. Overlap of sequences with four experts (E1…E4) and the information on whether the orders of our clusters A, B, and C are the same as defined by experts.

Approach	E1	E2	E3	E4	A	B	C
1)	.55	.40	.45	.50	No	No	No
2)	.60	.50	.40	.50	Yes	No	No
3)	.45	.45	.40	.53	No	No	No
4)	.53	.63	.53	.53	No	No	No
5)	.58	.53	.53	.40	No	Yes	No
6) FRE	.35	.50	.55	.50	No	No	No
7) RIX	.50	.50	.50	.45	No	Yes	No
8) GFI	**.55**	**.65**	**.60**	**.60**	**Yes**	**Yes**	**Yes**
9) TTR	.45	.40	.40	.40	No	No	No
10) NoW	.50	.50	.50	.50	No	No	No

Observing the pair-wise searches in 4) and 5) we can conclude, that topic frequency within the related texts is also not a good indicator to get an optimal sequence of topics, which answers the second research question. We limited the search to exact matches. Further, using n-grams or other methods to detect variants could be beneficial.

We identified the Gunning Fog Index as an estimator to create an optimal order. This answers our third research question. Using this metric for text complexity is the most robust feature to create a good sequence of topics in our experiment. Also, the order we got from our clusters is the same as in the sequence that we got by using the GFI. This is very important for a practical educational environment as the orders of topics that have a taxonomy with knowledge dependencies need to be done correctly. The overlap with the expert sequences ranges from 0.55 to 0.65, which is acceptable as the overlap of sequences across experts was in the range of 0.6 and 0.8. The remaining text complexity metrics (6, 7, 9, 10) are not as robust as the GFI.

To get more insights into the importance of the identified predictor, we use the random forest regressor [19] as we investigate linear

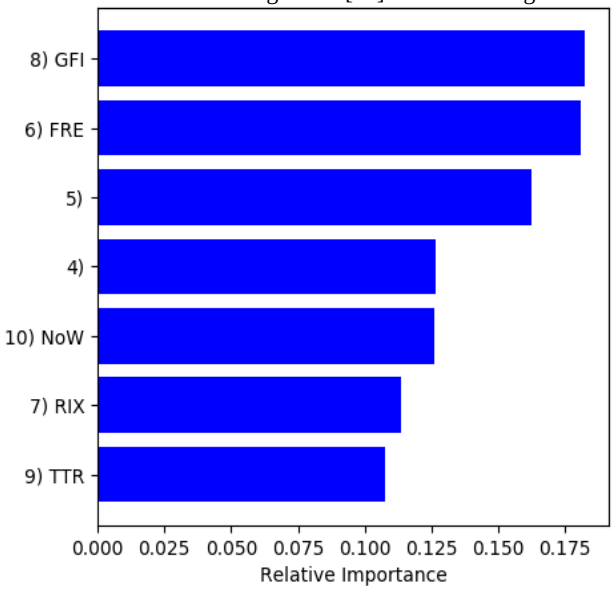

Figure 2. Relative importance of features according to the random forest regressor.

features only and – for future work – we want to identify features of high importance that also work for non-linear dependencies to predict the optimal sequence. Therefore, we use all pair-wise approaches (4-10) to train a decision tree using the random forest regressor. As prediction target, we used all pairings orderings (e.g. topic "neural networks" needs to be taught before topic "LSTM"). This is a classical approach to predict the ordering of items, based on different features. Figure 2 displays the relative importance of features that we got. The most relevant feature is the Gunning Fog Index (GFI), which performs best in our experiments as well.

5. DISCUSSION

Automated analysis of the pair-wise SERPs and the text complexity using the GFI can help to assist instructors during planning course sequences. From an ethical point, doing experiments with students is not justifiable as it could corrupt the learning outcome as a bad implication. As our approach is independent of experimenting with users, this method can be applied on a large scale. Combining this approach with educational recommender systems, we can provide a sequence of topics, based on the topic set that we get from the recommender system, even if no ontology is defined in the background. Using the text complexity helps to start with topics that can be explained more easily than the following ones. Having automatic composed online courses based on courseware, it can be beneficial to use the third party data of SERPs to find an optimal order. This is an important step to create personalized online

courses that are adaptive to the knowledge level, where no pre-defined ontology exists.

There are various fields of application where we can use our approach. This method can be used for planning lecture sequences at school or university, based on the complexity of taught topics. It is the same in preparing new lectures, based on existing learning material, that can be composed in an optimal order. Besides, the curricula at universities could be optimized, where students participate in courses of different universities. Having a recommendation for a good order on which courses should be visited at which point of time is beneficial.

From a practical point of view, it is important to note that the number of searches, while using a commercial crawler, is a cost factor. If $n = "number\ of\ topics"$, then the number of searches $C = n^2 - n$, having pair-wise searches $A + B$ and $B + A$ (with A and B being topics of the list). This is necessary as the SERP list of $A + B$ is not the same as $B + A$. Also, the search query $A + B$ returns 100 pages that need to be crawled to get the texts. In our experiment, this results in 16Gb of data, having 38.000 texts of 20 topics with pair-wise searches, where the metric has to be derived for each text. The required storage grows exponentially with the number of topics. The length of the resulting topic list of educational recommender systems can be limited in general, thus it is not a problem, but it is important to limit the list first, before finding the optimal order to avoid the need for large storage and high computational capacities. Besides, using the first 10 results of the SERPs instead of 100 reduces the crawling budget as well as computing time, but makes the approach less robust.

In our experiment, we conclude that commercial popularity and the estimated search amount are no indicators for a good topic sequence. Independently from the intention of the paper, using popularity is a helpful metric to get insights into trends about what people are searching for. Online course suppliers can use this information to create online courses for a large audience, those sizes can be estimated with the search popularity. As data-driven approaches, e.g. AI-related decisions require lots of participants, offering online courses that are of high interest can help to get the required number of participants to have enough training data for AI methods. From the researchers' perspective having popular courses is of high interest to obtain AI decisions with a high statistical significance. Sources like the Semantic Web do not provide this additional information.

As this is ongoing research, the next step is to create a comparison of the identified cluster sequences with sequences that can be derived using the semantic web as proposed by Toman & Weddell [20]. This real-world experiment can show the applicableness in the field of education. If this method results in similar sequences, we recommend using an already existing semantic network and in case of missing concepts, we can use our method as a fallback.

Observing the overlap of expert sequences, we can see that they are quite diverse. Finding an "optimum in education" is mostly a trade-off between different opinions of experts. We used the sequences to detect partial sequences that are similar across all experts. In the future, all topics should have a description of the taught contents to reduce the variety of sequences. Examining the detected partial sequences, we can see that these topics have a semantic connection and some topics have knowledge dependencies. In a future scenario, we recommend finding clusters of topics first and then use a text complexity metric like the GFI to get the optimal order. Otherwise, there might be a switch of topics, those order is good while looking at the complexity only, but could be confusing on a more global view. From the didactical perspective, switching between different topics in the learning path that have little semantic coherence is not recommended.

In this paper, we focused on AI-related topics to present our research at an early stage. It is of high interest to compare our approach to data from another domain. We assume that the GFI as a complexity metric can be used as an indicator for a useful order as well. But it is important to note, it remains possible that GFI randomly happened to give a good result. Thus extending the experiment to different domains is necessary to give a final and scalable recommendation.

Besides, we assumed that using text difficulty metrics will result in nearly the same order as their task is identical. Observing the results, we can see that there are major differences in the resulting order. The GFI is used to estimate how many years of formal education the reader needs to understand the text on the first reading [16]. In our case, it was the best and most practical metric. Looking at Figure 2, the Flesch-Reading-Ease is also of high importance but failed to create the optimal order of our three clusters (Table 2). Comparing the GFI with FRE, both metrics are based on syntactical features. The GFI is enriched with contextual features like "easy words". This enrichment could be a reason why this index works best in our experiment. Besides, other textual metrics need to be taken into account for testing. Semantical features could be used as well as text entailment. In the future, combining these metrics can be beneficial, e.g. at training a neural network with all metrics to use non-linear dependencies, that were not examined in this paper yet. Textual metrics must be used carefully as they are "just" formulas for judging the complexity of texts [21]. The methods cannot be used to judge the appropriateness of contents or whether the content is correct. Thus, selecting learning material of high quality is important and the metrics are not useful in the selection process.

The proposed approach depends on the SERPs of Google. Having a high fluctuation of rankings within the SERPs could change the feature's importance. As Google regularly updates their algorithms within a core update twice a year, rankings may change [22]. As we use the first 100 results we assume that the approach is robust because there are only minor changes if we consider the set of the first 100 pages. It is debatable that high-ranking Google results contain web pages of high authority, it can be discussed whether the first 100 resulting pages are a good resource for educational purposes and whether they are trustworthy. Instead, they are likely to be optimized for search engines, e.g. by search engine optimizers that create contents with ingoing links of high authority web pages aiming to have high rankings. There is the problem, that often texts of competitors are re-written for new pages to rank for similar terms. Thus, many texts with similar contents can be found. Besides, the SERP came from multiple contributors, they may include low-quality texts from commercial sources and web pages that block search engines are systematically excluded.

We use Google as a proxy to get access to the web pages that contain the texts that we are working with. The same can be done with other search engines. Alternatively, being limited to resources those contents are created by editors of publishing houses for education may be biased as the complexity of texts also depends on the writing style of authors. Using a resource like the first 100 texts results in a more robust view to avoid this bias due to averaged data. It can be discussed whether Google is a good source for characterizing academic terms because SERPs might be too inclusive and therefore noisy. Based on our experiment we could see that a text difficulty average of the gathered data can be a good indicator. Whether this is the case, in general, has to be examined

in further experiments. Besides, we could use educational materials from publishing houses. In general, they are not publicly accessible, which increases the costs if we want to use them. Further research can examine whether resources like Wikipedia or Web of Science can be used with similar metrics to determine the optimal order.

Limiting the approach to the header of courses could generally lead to wrong conclusions if the courses do not cover the topic that was given in the headline. In our experiments, we used topics as keywords only. Using the course description or the course(ware) content itself to obtain more rich information for having richer keywords could be beneficial, that will be addressed in further experiments. Besides, we did not consider synonyms, which should be observed in future studies because using different words (even synonyms) results in different SERPs.

6. CONCLUSION

In this paper, we propose different strategies to use texts that we got using a search engine to find the optimal order of online course topics. The pre-study has shown that the optimal topic sequences differ among experts. But we can also observe that there are partial topics that have the same order in all expert sequences. We identified them to define a gold standard and to check for the practical usefulness. The sequences derived by our approaches were compared to the expert ones and the order of the partial topics. The commercial popularity, that can be derived by searches in search engines is not an indicator of a good topic sequence. Searching for pair-wise topics and comparing the text complexity of the SERPs' web pages' texts can be used as an indicator for creating a plausible order of taught topics within online courses.

We identified the Gunning Fox Index as the most robust metric for topic sequencing. We can conclude that this feature helps to find the optimal sequence for automatic composed online courses to personalize them ethically without using students giving them randomized learning paths that could impair their learning experience as well as their learning outcome.

Targeting Design-Loop Adaptivity

ABSTRACT

Recent work describes methods for systematic, data-driven improvement to instructional content and calls for diverse teams of learning engineers to implement and evaluate such improvements. Focusing on an approach called "design-loop adaptivity," we consider the problem of how developers might use data to target or prioritize particular instructional content for improvement processes when faced with large portfolios of content and limited engineering resources to implement improvements. To do so, we consider two data-driven metrics that may capture different facets of how instructional content is "working." The first is a measure of the extent to which learners struggle to master target skills, and the second is a metric based on the difference in prediction performance between deep learning and more "traditional" approaches to knowledge tracing. This second metric may point learning engineers to workspaces that are, effectively, "too easy." We illustrate aspects of the diversity of learning content and variability in learner performance often represented by large educational datasets. We suggest that "monolithic" treatment of such datasets in prediction tasks and other research endeavors may be missing out on important opportunities to drive improved learning within target systems.

Keywords

Design-loop adaptivity, deep knowledge tracing, Bayesian knowledge tracing, mastery learning, learning engineering.

1. INTRODUCTION

Recent work calls on researchers and developers, including teams of learning engineers [14, 26], to focus on "explanatory" models of learners [25] and "design-loop adaptivity" processes [1, 15] to practically improve learning systems. While researchers describe specific examples of how explanatory learner models and design-loop adaptivity can be used to drive improvements to instruction, less (if any) attention has been paid in the literature to the practical problem of how content developers and learning engineers target and prioritize content for improvement.

We focus on cases in which a target system has a large portfolio of content, elements of which must be prioritized and targeted for improvement given finite learning engineering and software development resources. We present a case study using a data set that is among the largest considered in the literature on knowledge tracing and related methods [9, 18, 22], comprised of middle school and high school student work over an academic year on several hundred mathematics topics, each generally completed by thousands of students, generating several hundred million data points tracking student actions. We motivate, describe, and illustrate two approaches to targeting content for improvement within this portfolio, focusing primarily on what Aleven et al. [1] call "design-loop adaptation to student knowledge," relying on large-scale data to find similarities amongst learners we might leverage to redesign instructional content for better learning.

One targeting method is based on a measure of the extent to which learners tend to struggle with particular pieces of content, and we contrast it with an approach based on the relative prediction performance of deep learning models (i.e., Deep Knowledge Tracing; DKT [18, 22]) compared to traditional Bayesian Knowledge Tracing (BKT; [9]) models.

The first method targets content students struggle to learn, relying on measures of knowledge component (KC [19]; or skill) mastery that are internal to the target intelligent tutoring system (ITS). In contrast, the second method is roughly motivated by the idea that identifying content in which there is a large difference in performance between deep learning and traditional Bayesian approaches may suggest areas in which deep learning can leverage statistical regularities in students' performance that could point to improvements in the KC models that are used to drive adaptation with BKT. Such performance differences may suggest a particular focus area for KC model improvements. Relative DKT performance versus BKT performance also provides an instance of a metric that is perhaps less dependent on how the run-time ITS has "set the bar" for success in terms of KC mastery.

In exploring these two approaches, we illustrate the variability in learning content and experiences within widely deployed systems like Carnegie Learning's MATHia (formerly Cognitive Tutor) [23]. While different facets of variation may at times call for different approaches to content improvement (e.g., variation in student motivation could call for redesigns that discourage "gaming the system" [3]), our present work explores how to guide learning engineers' "attention" to particular pieces of content to then consider specific improvements via processes for design-loop adaptivity [1, 15].

Original contributions of this work are two-fold: (1) We describe a novel problem in the literature related to how to target

Stephen Fancsali, Hao Li, Michael Sandbothe and Steven Ritter "Targeting Design-Loop Adaptivity". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 323-330. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

instructional content improvement or design-loop adaptivity and explore two targeting approaches, and (2) we shed light on opportunities in treating large-scale educational datasets that may be missed by treating such datasets as "monolithic" targets for data-intensive approaches. Treating datasets in a "monolithic" way, though not a universal practice (e.g., [4-5, 10]) may inhibit practical progress in learning engineering.

In addition to considering one of the largest-scale applications of DKT (and BKT) modeling in the literature, we illuminate avenues for research at the intersection of educational data science and learning engineering at scale in a widely-deployed adaptive learning platform for K-12 mathematics. We seek to amplify extant calls for a more nuanced approach to work on performance prediction [15, 25] while illustrating solutions to practical problems in learning engineering and product improvement.

2. DESIGN-LOOP ADAPTIVITY

2.1 Background

A recent survey of adaptive instructional technologies [1] describes three categories along which learners' experience can be varied, including "step-loop adaptivity," "task-loop adaptivity," and "design-loop adaptivity." Step-loop adaptivity and task-loop adaptivity roughly correspond to "inner" and "outer" loop adaptive functionality in ITSs distinguished by VanLehn (e.g., [28**]**), respectively. We briefly describe step-loop and task-loop adaptivity before considering design-look adaptivity.

Step-loop or inner-loop adaptivity enables an adaptive instructional system or ITS to provide support to learners *within a particular learning task* based on their performance (e.g., providing context-sensitive hints or just-in-time feedback within a math problem based on learner responses). Task-loop or outer-loop adaptivity enable an instructional system to *choose the next appropriate task for a learner* based on a model of student learning and evolving estimates of a learner's mastery of underlying competencies, skills, or KCs [19] based on a learner's performance. Extensive educational data mining (EDM) literature considers, for example, variants of and data-driven parameter optimizations for BKT (e.g., [18]), which can be used to select tasks for learners as their mastery of KCs evolves.

In their recent survey, Aleven and colleagues describe design-loop adaptivity as involving

> data-driven decisions made by course designers before and between iterations of system design, in which a… system is updated based on data about student learning, specifically, data collected with the same system… [1].

They go on to describe goals toward which design-loop adaptations might be made, including adaptations to student knowledge, affect and motivation, student strategies and errors, and self-regulated learning, providing examples of each. Canonical examples of design-loop adaptivity or adaptation to student knowledge, the goal of our present targeting and prioritization endeavor, generally involve situations in which content within tutoring systems or online courses are improved by refining the fine-grained KC models that drive the adaptive experience of learners using a combination of data and human expertise [17, 20, 27].

Design-loop adaptivity for motivation and affect might drive content or system design and redesign to discourage off-task behavior [4] and "gaming the system" [3], wherein students attempt to make progress in a system by taking advantage of system features like hints, rather than making genuine attempts to master content. Aleven et al. [1] suggest that an approach to modeling gaming the system behavior based on a large-scale survey of the extent to which gaming the system [3] manifests across topics (what we will refer to as "workspaces") in an intelligent tutoring system like MATHia provides a foundation for future design-loop adaptivity investigations. One important facet of this work (and related work on off-task behavior [4]) is its appreciation of the extent to which there is variability in how learning occurs across different (types of) content within adaptive instructional systems. Appreciating and surveying this variability is vital to ascertaining where, within large portfolios of content, to target design-loop adaptivity efforts and related data-driven, instructional improvement efforts.

2.2 A Process for Design-Loop Adaptivity

Huang et al. [15] describe a systematic approach to design-loop adaptivity or data-driven instructional redesign and improvement. They suggest three general goals for such redesign efforts. For a particular piece of content in an ITS or similar adaptive instructional system with a KC model, the goals are: (1) refine the KC model for the target content, (2) redesign the content, and (3) optimize individualized learning within the content. Existing EDM methods and novel analyses are then described to achieve each of these goals, targeting an "Algebraic Expressions" unit of content within the Mathtutor ITS [2]. For example, KC models can be refined using data-driven, computationally intensive methods like Learning Factors Analysis (LFA; [8]) or a simpler approximation of such an approach that uses regression techniques called "difficulty factor effect analysis" by Huang et al. [15]. Human expertise also plays an important role in such refinements, including in setting up data-driven analyses to produce meaningful results, interpreting these results for inclusion in potential task redesigns, and often in providing suggested refinements for target tasks.

Huang et al. [15] demonstrate that redesigned content improves learning as measured by pre-tests and post-tests. Broadly, these goals align with on-going, data-driven content improvement efforts pursued by learning engineers working with MATHia. Nevertheless, the process of design-loop adaptivity generally requires extensive human and computational resources to be carried out in ways that will drive improved instructional effectiveness. The present work seeks to illustrate how EDM techniques might help improve targeting this process.

3. MATHia

3.1 Learning Platform

Carnegie Learning's MATHia [23] is an ITS used by hundreds of thousands of learners each year, mostly in middle and high school classrooms as a part of a blended math curriculum that combines collaborative work guided by instructors and Carnegie Learning's *MATHbook* worktexts (60% of instructional time in recommended implementations) with individual work in MATHia (40% of instructional time). Nevertheless, usage of MATHia, contexts in which it is used, and other implementation details vary across a diverse, nationwide user-base.

Grade levels of content in MATHia (e.g., Grade 7, Algebra I) are organized into a series of "modules," each of which is comprised of a series of "units." Units are composed of a series of "workspaces." Workspaces represent the underlying unit of learner progress to mastery in MATHia. Each workspace presents

a set of problems associated with a set of KCs; student progress within the system is determined by students' achievement of mastery of all of the KCs associated with a particular workspace, estimated by MATHia using BKT (see §3.2). Learning experiences vary substantially between workspaces with respect to design patterns, content areas, types of practice and instruction provided, (quality of) KC models intended to practice such content (e.g., some the result of years of iterative refinements, others introduced more recently), BKT parameters, and other parameters that drive task selection and mastery judgment.

Consider the problem solving task illustrated in Figures 1 and 2. Figure 1 illustrates the workspace "Modeling the Constant of Proportionality." In this workspace, students are provided with a word problem and several associated questions (left pane; Figure 1). On the right-hand side of Figure 1, tools are presented to solve the problem's "steps." There is a worksheet or table in which they can provide units of measurement, responses to questions, and fields in which to write expressions to model the problem's scenario. After they have completed entries in the worksheet, students work with a graphing tool. Each problem-step in the ITS can provide context-sensitive hints upon request as well as just-in-time feedback that tracks errors that students often make. Most problem-steps are mapped to KCs, for which MATHia provides an evolving mastery estimate to adapt problem selection to the individual student's needs (see §3.2).

Contrast the learning experience of the problem in Figure 1 with that of Figure 2. "Modeling the Constant of Proportionality" (Figure 1) involves substantive reading, modeling the problem scenario via algebraic expressions, working through concrete instances of these expressions, and using a graphing tool. Figure 2 illustrates problem-solving in a menu-based equation "solver" workspace, "Solving with the Distributive Property Over Multiplication." Here the student is tasked with solving for x in the equation $65 = 10\,(x + 6)$. There is little reading and no context provided for the equation, but hints and just-in-time feedback are available. Learners' progress toward mastery is tracked for a different set of KCs. The menu-based solver constrains possible student actions at various points in the equation-solving process compared to the typed-in input that students provide in the worksheet in Figure 1. Far from an exhaustive list, we seek to illustrate a few from among substantial differences in types of content provided, design patterns, interaction modalities, underlying KC models, and tools available, even within the relatively constrained domain of math, any of which may have important impacts on inferences that might be drawn from data or the ability of different methods to predict performance and learning within such content. While any of the features in these examples might reasonably be refined as a part of the design-loop adaptivity or content improvement process, we leave to future work the data-driven targeting of specific improvements within a workspace. We consider how to target specific "workspaces" for design-loop adaptivity improvements.

3.2 Knowledge Tracing & Mastery Learning

BKT [9] posits a binary (i.e., "mastered" or "unmastered") knowledge state for each independently modeled KC and can be formalized as a four-parameter hidden Markov model. One parameter represents the probability that a learner has already mastered a KC before their first opportunity to practice it. A second parameter represents the probability that a learner transitions from the unmastered to the mastered state at any particular KC practice opportunity. Two parameters link the knowledge state to observable outcomes at any KC practice opportunity: the probability that a student is in the unmastered state and responds correctly ("guessing") and the probability that a student is in the mastered state and answers incorrectly ("slipping"). Extensive EDM literature has explored the data-driven fitting of BKT parameters as well as individualized (e.g., [30]) and more sophisticated variants of this approach (e.g., [18]).

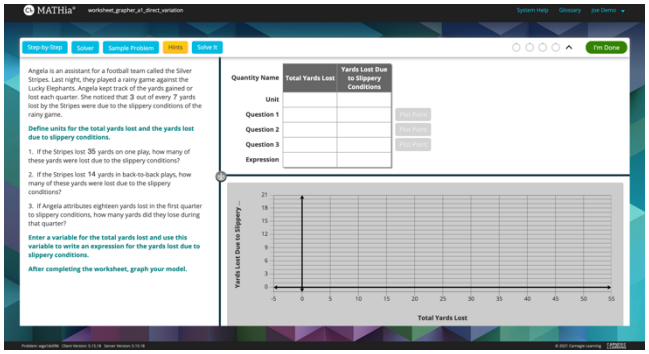

Figure 1. Problem-solving screenshot from a MATHia workspace called "Modeling the Constant of Proportionality."

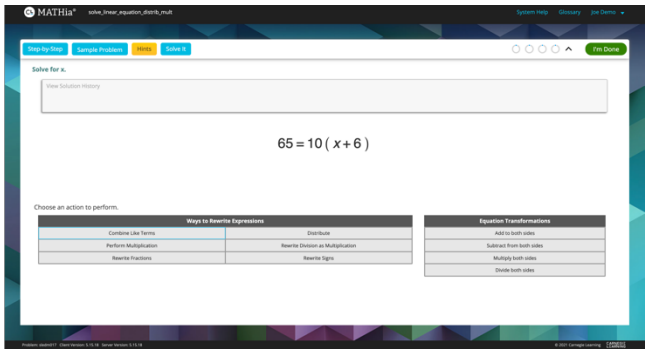

Figure 2. Screenshot from the MATHia workspace "Solving with the Distributive Property Over Multiplication."

Based on parameter settings and performance data collected as a student practices each KC, the system can use BKT to infer and update estimates of the probability that a student is in the "mastered" state for any particular KC. Typically, systems set a threshold for mastery (often 0.95, as in MATHia); if the system's estimate that the probability a student has mastered a particular KC is above the threshold, then the system considers the KC mastered for that student.

Relying on evolving estimates of learner KC mastery, instructional systems can use knowledge tracing frameworks like BKT to drive "task-loop" (or "outer loop") adaptivity [1, 28] and mastery learning [7, 24]. After a student completes a problem (or task; like the problems illustrated in Figures 1-2), the system can select the next problem based on KCs that a student has yet to master. In this way, systems can adapt to the student's evolving mastery of KCs, providing (ideally) just enough practice for students to master KCs and avoiding cases in which the system provides too little or too much practice.

Implementing self-paced mastery learning [7, 24], MATHia provides practice to a student until they have either mastered all KCs associated with a particular workspace or they have reached the maximum number of problems that designers have specified for a particular workspace. Once the student masters all of the KCs in a particular workspace (or reaches the max number of problems), they are moved on to the next workspace in an

assigned content sequence. Teachers are alerted when students reach the max number of problems in a workspace without reaching mastery. Setting a max number of problems ensures that students do not endlessly struggle unproductively within a piece of content [11].

3.3 Data

We consider data from 252,036 learners who used MATHia during the 2018-19 academic year and completed at least one of 308 workspaces that track KC mastery across math content for Grades 6-8, Algebra I, Algebra II, and Geometry. These data account for approximately 3.8 million workspace completions. Models are learned over subsets of 267,419,999 student actions (i.e., first-attempts, including hint requests) at problem-steps mapped to KCs. Over the 308 workspaces, MATHia tracks 2,152 KCs. Table 1 provides summary statistics.

Table 1. Summary statistics for 308 MATHia workspaces in 2018-2019; "KCs" = # KCs tracked; "Comps." = # student-workspace-completions; "Actions" = sum across all students completing workspace of count of first attempts (including hint requests) at problem-steps within workspace problems.

	Min.	Q1	Med.	Q3	Max.
KCs	2	5	6	9	15
Comps.	167	4275	9414	18801	51097
Actions	5530	197757	489159	1278325	7191034

When working with large, complex datasets, it is essential to focus learning engineering efforts on the portions of the system for which improvements can be most impactful. Rather than consider such a broad dataset as a single monolithic target, especially for performance prediction modeling in §4.2, we learn models for each workspace within the dataset; input data are sequences of correctness labels for learner actions (e.g., binary correct or incorrect, where incorrect includes both errors and hint requests) and labels for KCs mapped to each action.

4. METRICS FOR TARGETING IMPROVEMENTS

As illustrated in Figures 1 and 2, workspace-to-workspace variability in learning experiences is substantial. Types of practice vary (e.g., equation solving, graphing, etc.), and developers make a plethora of design choices in creating content. Some workspaces require more reading; KC models vary in complexity, and some have been iteratively refined over the course of nearly two decades while others are newly deployed in a given year. Given this variation and the nature of grade-level content standards, there is also variability in the extent to which learners find particular content difficult.

Learner difficulties manifest at the problem-step level in the form of problem-solving errors and hint requests and at the workspace level in at least two ways: (1) that some learners require a greater number of problems to achieve mastery of all KCs, and (2) that some learners reach the maximum number of problems set by designers without having achieved mastery of all KCs. These latter students are moved along within their curriculum sequence without mastery. Teachers are alerted of this failure to reach mastery via reporting analytics available to them as well as in the LiveLab teacher companion app to MATHia. Some students fail to reach mastery in a workspace because of genuine difficulty with presented math content, but relatively frequent instances of such failure to reach mastery often indicate that content improvements (i.e., design-loop adaptivity) is called for to enhance experiences for learners.

Prior research considers MATHia's workspace level as a unit of analysis. Researchers have focused on associations between characteristics of Cognitive Tutor "lessons" (MATHia's workspaces) and learners' affective states like confusion and frustration [10] as well as the extent to which students go off-task [4] and game the system [5]. In what follows, we adopt an approach similar in spirit to this literature by considering a large corpus of MATHia data as broken down into workspaces rather than treating the entire dataset in a monolithic fashion.

The first metric we consider helps identify content that is instructionally ineffective in ways that manifest as difficulty for learners to successfully complete the content. In considering the second metric, we explore one example where the metric may be providing some insights into places where content is not "difficult" (i.e., measures of difficulty do not "raise flags" about improvement needs) but where design-loop adaptivity improvements might drastically improve student learning.

4.1 Proportion of Failures to Reach Mastery

The first design-loop adaptivity targeting metric we consider is the proportion of learners who fail to reach mastery of at least one of the KCs associated with a workspace before reaching the maximum number of problems set by content designers. Figure 3 provides a histogram showing the overall distribution of this proportion across workspaces. The median workspace has 4.3% of students fail to reach mastery of all its KCs (minimum = 0%; Q1 = .7%; Q3 = 12.1%; maximum = 77.7%).

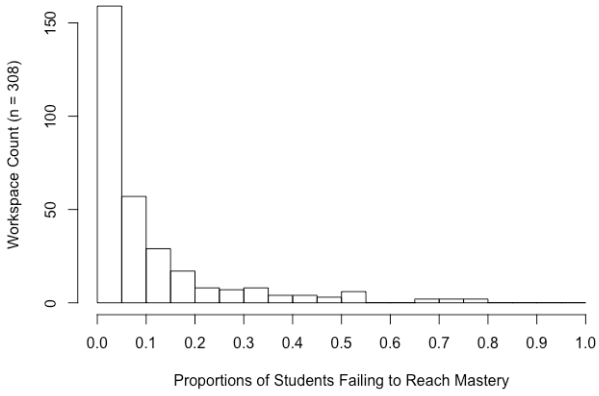

Figure 3. Histogram illustrating the distribution of the proportion of students failing to reach mastery of all KCs associated with 308 workspaces in the 2018-19 academic year.

Fancsali et al. [11] argue that students' failure to achieve mastery at a level of aggregation like that of a workspace is an important outcome for predictive modeling, mostly overlooked in the literature on so-called "wheel spinning" (e.g., [6]), which tends to develop models to predict whether students will master particular KCs in a tutoring system, ignoring other elements of how instructional content is presented. Fancsali et al. argue that, given the clustering of KCs within problems, the clustering of problems within workspaces, and the fact that workspaces are the unit at which learners make progress in ITSs like MATHia, reporting outcomes like the count and percentage of KCs that student fail to master (a la Beck and Gong [6]) is of dubious practical value.

Since design-loop adaptivity improvements are likely to often involve redesign of instructional content, we similarly contend that measures closely aligned to instructional delivery are likely to be helpful in targeting this process. Large proportions of students failing to master instructional content are likely to be important in determining what learning content to improve with limited resources. This metric serves as a foil to a second approach.

4.2 DKT vs. BKT Prediction Performance

Extensive recent literature (e.g., [12, 18, 22]) considers deep learning approaches to the problem of predicting student performance at fine-grained opportunities to demonstrate mastery of KCs in learning systems like ASSISTments [13]. DKT [22] has been compared (e.g., [12, 18] to BKT and logistic regression approaches to the same type of prediction task [21]. Early work demonstrated that DKT generally had superior prediction performance compared to BKT [22], but subsequent literature also suggests that variations of BKT (e.g., modeling "forgetting") and logistic regression approaches can bridge some, if not most, of the gap in prediction performance (e.g., [18, 29]).

Nevertheless, we seek to better understand the extent to which DKT out-performs BKT when considered workspace-by-workspace across a large dataset from MATHia, which presents a wide variety of learning experiences. We find that, for a variety of workspaces, classic BKT's performance is often comparable to DKT even without accoutrements added in the work of Khajah et al. [18]. Further, in keeping with our primary concern in the present work, we explore the extent to which observed differences in performance between the two approaches, especially examples of DKT's far superior prediction performance, might serve as a metric for targeting improvement work for MATHia workspaces, possibly indicating an especially flawed KC model.

4.2.1 Modeling Approach

We rely on the Khajah et al. [18] implementation of DKT with long short-term memory (LSTM) recurrent units.[1] We use Yudelson's *hmm-scalable*[2] implementation of classic BKT parameter fitting using expectation maximization [30]. We learn DKT and BKT models for each of the 308 workspaces, splitting the data for each workspace into training and test sets with a 80%-20% student-level split and calculate the AUC (area under the receiver-operating characteristic curve) on the test set following methods in Khajah et al. [18]. BKT and DKT models are trained and tested on the same datasets. AUC is a measure of the extent to which a model can "discriminate" between or predict students' correct and incorrect responses in the held-out test set. An AUC value of 0.5 indicates "chance" ability to discriminate between two classes; a value of 1.0 indicates perfect discrimination.

4.2.2 Results

Table 2 provides summary statistics for AUC performance for DKT, BKT, and AUC differences of these methods over all workspaces. As expected, DKT generally provides superior prediction performance to classic BKT over the 308 workspaces. However, there is substantial variability, with classic BKT in some cases, albeit many (but not all) with relatively small sample sizes, even out-performing DKT. While there is a modest, statistically significant positive correlation between the AUC difference in DKT and BKT and sample size (i.e., the number of student-sequences available for training and testing) ($r = .2$; $p < .001$), BKT performs comparably to DKT on a number of workspaces with tens of thousands of students' data, and BKT only underperforms DKT by approximately .07 AUC units for the median workspace. The Q1 value for this difference (the greatest difference over 77 workspaces) is approximately in line, in terms of AUC units, with a value (.03 AUC units) declared comparable by Khajah et al. [18] for BKT "variants" compared to DKT.

The difference in AUC between DKT and BKT is uncorrelated with the proportion of students who fail to reach mastery ($r = -.05$; $p = .4$) and is thus not an indicator of the relative difficulty of particular workspaces, regardless of the source of difficulty.

Table 2. Summary statistics for AUC performance over 308 workspaces of DKT and BKT models and of the difference between DKT and BKT performance (Δ); negative minimum value indicates better BKT performance for some workspaces.

AUC	Min.	Q1	Med.	Q3	Max.
DKT	.5852	.7839	.8331	.8783	.9763
BKT	.5150	.7045	.7456	.7854	.9563
Δ	-.0802	.0361	.0676	.1281	.3073

4.2.3 Practical Promise

We consider two observations relating to workspace design patterns that emerge from considering workspaces with the largest differences in terms of DKT's (generally better) prediction performance compared to BKT. First, we consider the design of a particular workspace as a prime target for design-loop adaptivity to student knowledge, motivation, and affect. Second, we consider more general design patterns in workspaces on which DKT and BKT performance differences are greatest, suggesting more "macro-level" design-loop adaptivity that may affect broader categories of workspaces.

4.2.3.1 Example Workspace

The second greatest observed difference in AUC occurred for the workspace "Checking Solutions to Linear Equations" (DKT AUC = .968; BKT AUC = .684). A mere 0.2% of students fail to master all KCs in this workspace, suggesting that it may not be "flagged" for design-loop adaptivity improvements based on difficulty. Nevertheless, careful inspection of the workspace yields several areas for improvement.

This workspace presents students with problems (See Figure 4) like: "Jordan solved the equation $-3u - 8 = 10$. She calculated $u = -6$. Use the Solver to check Jordan's solution." The student is then presented with a menu-based equation solver. Work with the equation solver should involve the student substituting in the solution value from the problem presentation and checking whether the result is a balanced equation. After choosing "Substitute for variable" from the menu, the student then must input a value on the left-hand side of the equation (see Figure 5).

Problems in this workspace present both correct and incorrect cases, but the KC model does not distinguish between correct and incorrect cases, making problems with a correct solution targets for possible gaming the system. For example, in the problem in Figure 5, the student might enter *10* to complete "*10 = 10*." This response may not reflect having correctly carried out the variable substitution to arrive at this solution. KCs in this workspace are also not currently mapped to work in the solver; the solver provides hints and just-in-time feedback on errors, but it is not instrumented to track KC mastery. Once the student has entered

[1] https://github.com/mmkhajah/dkt

[2] https://github.com/myudelson/hmm-scalable

the appropriate value, two questions appear on the left of the screen (see Figure 6), and student responses to these questions trigger updates to two KCs at a time.

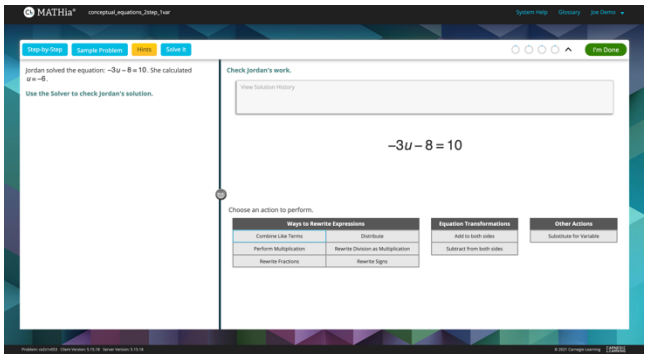

Figure 4. Screenshot in the MATHia workspace "Checking Solutions to Linear Equations."

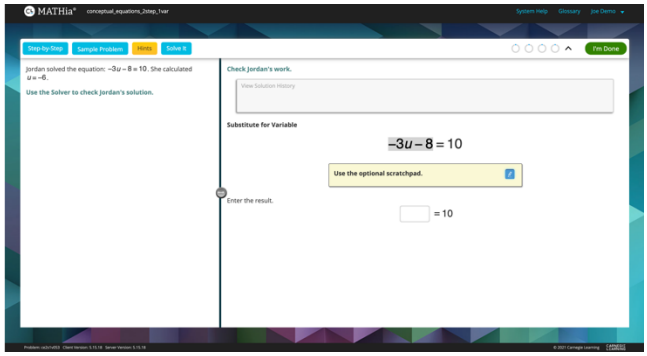

Figure 5. Screenshot after the student has selected "Substitute for variable" from the equation solving menu (see Figure 4).

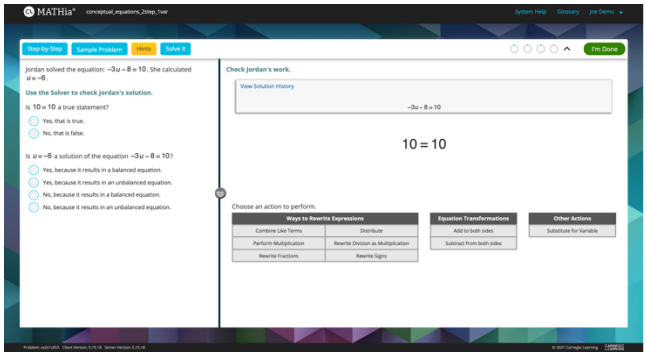

Figure 6. Screenshot after the student has entered the value 10 on the left-hand side of the equation (see Figure 5).

Following design-loop adaptivity steps laid out by Huang et al. [15], we have identified (1) where the KC model can be refined, and (2) areas for task redesign. The third step would involve fitting a BKT model using the hypothetical re-mapping of KCs to steps within problems in existing data to determine whether the hypothesized, refined KC model fits the data better than the existing KC model. Future work will experimentally test workspace redesigns to "close the loop" (cf. [16, 25]) between this data-driven approach and empirical learning outcomes.

4.2.3.2 Prominent Design Patterns

Patterns emerge in comparing the performance of DKT to BKT over 308 workspaces. In the top twenty workspaces in which DKT outperforms BKT, differences in AUC units range from .307 to .212, and all provide constrained input mechanisms relative to broader MATHia content. Fourteen workspaces (70%) involve equation solving, and the others are split between those that involve placing values on a number line and those in which problem input is provided via drop-down menus.

Gervet et al. raise questions about explanations for observed properties of DKT in predicting student performance. Can DKT, for example, "better pick up on local patterns of student behavior like gaming the systems" [12]? While far from conclusive, DKT's performance for the workspace "Checking Solutions to Linear Equations" could exemplify this phenomenon. Workspaces with more constrained inputs may provide examples where DKT "picks up" on local patterns that BKT does not. Future work ought to investigate whether these particular types of relatively constrained input mechanisms are easy to "game" or whether and how DKT learns local performance patterns.

Equation solver and number line workspaces are widespread in the top workspaces in which DKT outperforms BKT. "Checking Solutions to Linear Equations" has readily apparent flaws, suggesting that our approach may be promising in targeting instructional improvement work. Systematic review of these results remains future work.

5. DISCUSSION

There are numerous questions for future research. That differences in AUC between DKT and BKT are uncorrelated with an important measure of instructional ineffectiveness, combined with DKT's ability to find regularities in data that are not found by BKT suggests that this difference may be signaling important workspace characteristics. Analysis of a particular workspace (§4.2.3.1) suggests that DKT-BKT differences may signal inadequacies in the KC model. These findings can be compared to the results of data-driven search for better KC models [8]. Improvements can be made to the workspace, and A/B tests can "close the loop" and establish more effective approaches.

Systematic analysis of instructional content and prediction performance differences in DKT and BKT might follow work that explores a space of properties and features of particular tutor "lessons" to determine which predict students' affect, gaming the system, and off-task behavior [4-5, 10]. Comparisons to logistic regression methods (e.g., [12]) are also needed.

Naïve learning engineering may focus on reducing students' mastery failures. Such an approach could lead to "over-simplified" tasks that don't produce failure because they don't require much knowledge. Large differences between DKT and BKT may help identify over-simplified workspaces that provide opportunities for students to game the system [3, 12]. To what extent do gaps in modeling techniques' performance indicate unproductive patterns of "local" behavior in particular workspaces? What else drives differences? What other behavior patterns indicate ways to target improvement?

Methodologically, our "non-monolithic" analysis of a large educational data set treats component instructional experiences as units for analysis. Such analytical decomposition is vital to practical learning engineering to improve instructional systems and large portfolios of content used by learners every day.

ABSTRACT

Knowledge tracing algorithms are embedded in Intelligent Tutoring Systems (ITS) to keep track of students' learning process. While knowledge tracing models have been extensively studied in offline settings, very little work has explored their use in online settings. This is primarily because conducting experiments to evaluate and select knowledge tracing models in classroom settings is expensive. To fill this gap, we introduce a novel way of using machine-learning models to generate simulated students. We conduct experiments using agents generated by the Apprentice Learner Architecture to investigate the online use of different knowledge tracing models (Bayesian Knowledge Tracing, the Streak model, and Deep Knowledge Tracing). An analysis of our simulation results revealed an error in the initial implementation of our Bayesian knowledge tracing model that was not identified in our previous work. Our simulations also revealed a more fundamental limitation of Deep Knowledge Tracing that prevents the model from supporting mastery learning on multi-step problems. Together, these two findings suggest that Apprentice agents provide a practical means of evaluating knowledge tracing models prior to more costly classroom testing. Lastly, our analysis identifies a positive correlation between the Bayesian knowledge tracing parameters estimated from human data and the parameters estimated from simulated learners. This suggests that model parameters might be initialized using simulated data when no human-student data is yet available.

Keywords

Computational Models of Learning, Simulated Students, Knowledge Tracing

1. INTRODUCTION

Intelligent Tutoring Systems (ITS) are used within K-12 education to improve learning outcomes. In addition to providing students with scaffolding and feedback, tutors utilize an approach called *knowledge tracing* to estimate what students know and do not know [2]. When combined with a problem selection policy [16], knowledge tracing enable tutors to support mastery learning and to focus students practice where it is most needed (i.e., on the skills they do not yet know rather than the skills they already know). While many studies have explored knowledge tracing for offline evaluation (fitting knowledge tracing models to existing data sets), there is comparatively little work on evaluating these algorithms in online settings (evaluating how well these algorithms estimate students' mastery from just a few data points and decide when to stop giving them additional problems).

We aim to understand which knowledge tracing models yield the greatest mastery learning efficiency in online settings. Additionally, we want to find out how the parameters for knowledge tracing models can be selected before human data is collected. To meet our need for multiple experiments to investigate our knowledge tracing questions, we introduce a novel way of using computational models of learning, or simulated student models that learn from interactions with a tutor just like human students do, to simulate our knowledge tracing experiments. We use the Apprentice Learner architecture [10], a machine-learning framework that aims to model how humans learn from examples and feedback to generate simulated students and conduct experiments.

To explore the feasibility of this approach, we conducted experiments to compare Bayesian Knowledge Tracing (BKT)[2] to the Streak model [7] and Deep Knowledge Tracing (DKT) [15]. Our simulations show that both BKT and Streak stop before giving all the problems, but that BKT is slightly more aggressive than Streak and seems to assume students have mastered skills a bit earlier than expected. Upon further inspection, our analysis revealed a bug in our underlying implementation of BKT (which we fixed for this study). Further, we found that DKT exhibits strange behavior that makes it unusable in certain cases of mastery learning and problem selection. This limitation of DKT for mastery learning has not been identified in prior work. These findings demonstrate that simulation students might serve a valuable role in testing knowledge tracing models before more costly classroom deployments.

We also explore the use of simulated data from these experiments to estimate initial parameters for the BKT model. Prior to collecting human data, knowledge tracing parameters are often set to reasonable hand-picked defaults. A better approach is to run a pilot study with human students

Qiao Zhang and Christopher MacLellan "Going Online: A simulated student approach for evaluating knowledge tracing in the context of mastery learning". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 331-337. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

to collect data for model training, which requires additional time and labor. Our analysis identifies a positive correlation between the BKT parameters estimated from the simulated data and those estimated from human data, suggesting simulated data might be used to initialize parameters.

2. BACKGROUND

2.1 Knowledge Tracing

The main purpose of knowledge tracing is to track students' skill mastery and predict their future performance based on their past activity. Knowledge tracing uses labels of the skills needed for each step, which we call Knowledge Components (KCs), and students' first attempt correctness (correct or incorrect) to predict whether the students will correctly solve a new problem containing the same KC.

2.2 Bayesian Knowledge Tracing

BKT [2] is a well-known knowledge tracing algorithm that can estimates whether students have learned a particular skill given their past performance on opportunities to practice that skill. It models student knowledge using a Hidden Markov Model, where the hidden state is estimated from observations of students' correctness on each step. For each skill, a student can be in one of the two possible knowledge states: "unknown" or "known". A binary response (correct or incorrect) is generated at each opportunity a student practices a skill [5]. Although, BKT supports the ability to model forgetting, it is typically assumed that students never forget what they have mastered [16]. If a student reaches 95% probability of being in the known state for a skill, the skill is marked as being mastered by the student. With these assumptions, the BKT model has four parameters.

- P(L_0): initial probability of mastery ("known").
- P(T): probability of learning the skill ("learn").
- P(G): probability of guessing the answer ("guess").
- P(S): probability of making a mistake ("slip").

Researches have created variants of the BKT model. Yudelson et al. [20] introduced an individualized BKT model that can take student differences in initial mastery and skill learning probabilities into account. Nedungadi et al. [13] created PC-BKT (Personalized and Clustered), which has individual priors for each student and skill, and dynamically clusters students based on learning ability. This prior work aims to improve predictive performance over original BKT. Despite the quantity of research on BKT models, there is relatively little evaluation in online settings.

2.3 Streak Model

Another knowledge tracing approach that is popular for use within mastery learning is the Streak model. Also known as "three-in-a-row" [7], it is a relatively simple and intuitive model since it only has one parameter, how many correct answers in a row equates to mastery. It was first applied in ASSISTments and the key idea was to keep giving the student questions until some proficiency threshold was reached. The default setting was "three correct in a row" but this could be manipulated by teachers.

2.4 Deep Knowledge Tracing

DKT [15] is a knowledge tracing model that has been receiving increasing attention. This model leverages information about students sequence of steps and correctness on those steps to predict performance on subsequent steps. Additionally, DKT leverages information about performance on one skill to improve predictive performance on other skills. DKT uses a long short-term memory (LSTM) architecture, which is a kind of recurrent neural network that allows for the modeling of non-Markovian processes. Recent work evaluating DKT [6, 8] suggests that DKT often outperforms BKT in terms of predictive performance. Despite this promising finding, there has been very little work exploring the use of DKT within online knowledge tracing (e.g., for mastery learning within a tutor). Beyond the original DKT work [15], which explores the use of DKT for next step recommendation, we are unaware of any research programs that currently uses DKT in this way.

Finally, it is worth noting that knowledge tracing is not strictly necessary for tutoring systems. Many tutors either use a fixed problem sequence or present a fixed number of problems in a random order. However, we hypothesize that knowledge tracing in conjunction with mastery learning component is one of the main components of tutors that makes tutors effective.

2.5 Computational Model of Learning

The Apprentice Learner Architecture is a framework for modeling human learning from demonstrations and feedback in educational environments [10]. We use an Apprentice model previously developed in prior work; see [11] for a complete description of the model. Most work in the field of educational data mining focuses on building mathematical, predictive models of learning. In contrast, the Apprentice models actually perform the task (not just predict performance). They induce task-specific knowledge from the demonstrations and feedback they receive. Apprentice models are ideal for the current study because they do not require prior human data to operate. They can predict learning and behavior based solely on the task structure.

3. METHODOLOGY

We created 30 simulated students (Apprentice agents) to solve problems in a fraction arithmetic tutor (tutor presented in [14]). The tutor had three different types of problems: Add Different (AD), add fractions with different denominators; Add Same (AS), add fractions with same denominators; Multiplication (M), multiply two fractions.

3.1 Experiment Design

Our study had six conditions: Random, Streak, BKT_default, BKT_random, BKT_human and DKT_random. There were four types of conditions: Random, BKT, Streak, and DKT, which differ in the way they select the next problem to give to a simulated student. In the Random condition every problem was assigned only once in random order and the training ends when problems run out. Since Random gives the most training, it produces the highest correctness prediction by the end of practice. We use Random as a baseline for evaluating other models.

The other conditions use the respective knowledge tracing approaches for mastery learning and problem selection. During problem selection, each knowledge tracing model randomly chooses a problem with at least one unmastered skill

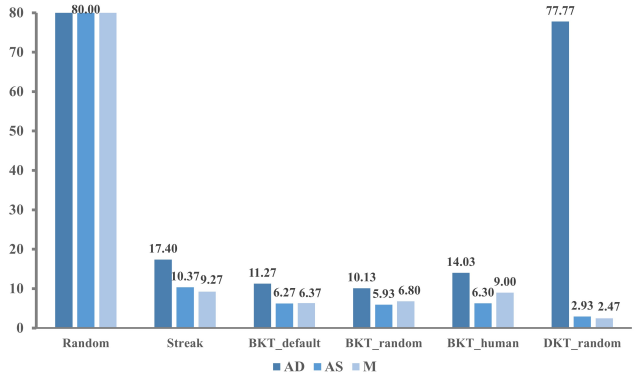

Figure 1: Num. problems given in each condition (by type).

and updates the student's mastery level based on the result. The training ends once the proficiency threshold is reached (95% in all cases but Streak, where it was 3 in a row).

The parameters in BKT_default were manually set based on our prior experience with BKT. We set P(L_0) to 0.1, P(T) to 0.05, P(G) to 0.05 and P(S) to 0.02. These parameters are identical for each KC. The BKT_random and BKT_human parameters were estimated using the BKT module on LearnSphere [9]. The human-based parameters were obtained from fitting BKT to the "Fraction Addition and Multiplication" dataset accessed via DataShop (Koedinger et al., 2010). The random-based parameters were obtained from fitting BKT to the log data generated from simulated students in the Random condition.

To support the use of DKT within online master learning, we created our own implementation using PyTorch's LSTM module.[1] Based on prior work [8], the model has 200 nodes in the hidden layer, uses a dropout of 0.4 during training, and uses a batch size of 5 (our sequences were longer than those in prior work, so a smaller batch size works well). This implementation supports the ability to fit DKT to data presented in standard DataShop [9] format. Trained models have a simple interface for use in online knowledge tracing settings. Similar to BKT, we fit DKT to the log data generated from simulated students in the Random condition to estimate model parameters.

3.2 Simulation Studies and Evaluation

During the experiment process, we created 30 simulated students for each of the six conditions and analyzed the data that they generated. For these experiments, we created a KC model that labels each step as a combination of "Problem Type" and "Selection". There are 14 unique KCs in our analysis, 8 for Add Different, 3 for Add Same and 3 for Multiplication. As the Additive Factors Model (AFM) is often used to examine learning curves from existing data [1], we used pyAFM [12] (a python implementation of AFM) to predict the probability that students will get a next step with the respective skill correct at the end of their practice. This provided an independent means for us to estimate how well each knowledge tracing approach did at appropriately recognizing when students had achieved mastery.

[1]Open-source code for the model is available here: https://gitlab.cci.drexel.edu/teachable-ai-lab/dkt_torch.

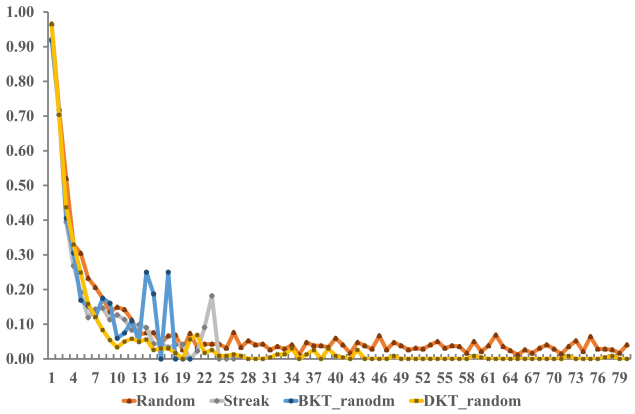

Figure 2: Learning curves for four conditions.

The AFM model assumes that performance monotonically converges to zero error in the tail. However, both humans and simulated students have non-zero error in the tail of their learning curve. This violation of the AFM model's assumption causes the model to estimate lower learning rates in order to accommodate non-zero error in the tail. We found that because the simulated students sometimes get a much larger number of practice opportunities than human students (e.g., 80 vs. 30 practice opportunities), the bias in AFM's learning rates was non-trivial. To address this challenge, we utilized the Additive Factors Model + Slip (AFM+S) approach [12], which explicitly models non-zero error rates in the tail using additional "slipping" parameters for each KC. The AFM+S model better fit the simulated student data from all six conditions than the AFM model (three fold cross-validated RMSE = 0.240 vs. 0.257). Qualitatively, we found that the AFM+ S learning curves seemed to better fit the data, particularly for slopes at the beginning of difficult to master skills.

4. SIMULATION RESULTS

4.1 Online Knowledge Tracing Results

Figure 1 shows the numbers of problems administered by the tutoring system in each condition. Random always gives all 80 problems each type. Streak gives around 17 problems for AD, 10 problems for AS and 9 problems for M. BKT_default gives around 11 problems for AD and 6 problems for AS and M. BKT_random has the similar statistics to the BKT_default, while BKT_human gives around 14 AD problems, 9 M problems and around 6 AS problems. DKT_random gives around 78 AD problems, almost as many as Random; however, it gives less than 3 problems in AS and M. The number of problems given by BKT_human is slightly higher than those given by BKT_random. We hypothesize that this is because the BKT_random parameters were fit specifically to the simulated students, so when used for knowledge tracing they provide better estimates of mastery than the the BKT_human parameters.

To get a better sense of the overall differences between Random, Streak, BKT (BKT_random), and DKT, we plotted the overall learning curves for the data from these conditions, see Figure 2. We can see from this figure that BKT

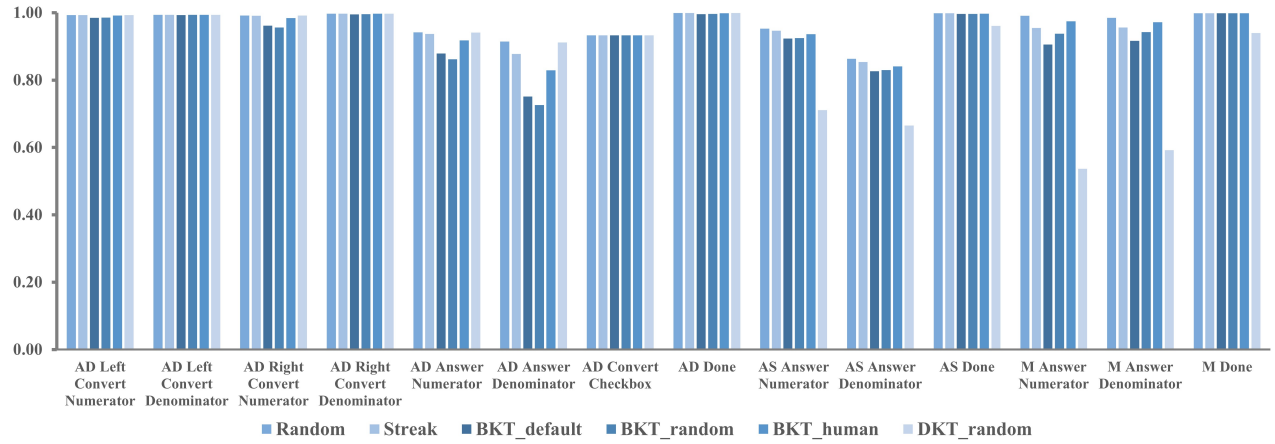

Figure 3: The AFM+S predicted probability at the end of training for each KC averaged over all students.

stops giving practice earlier than Streak, which subsequently stops giving practice earlier than Random and DKT. We observe higher variance in the tail of the learning curves for BKT and streak because the total number of students is decreasing as each student reaches mastery.

We applied the AFM+S model to predict performance on a hypothetical next opportunity for each KC and student. Figure 3 shows the average predicted correctness (across students) after the final practice opportunity for each skill. For most KCs, the prediction is higher than 95%, which suggests that mastery has been obtained in these KCs. Unfortunately the KC "AD Answer Denominator" has the lowest overall next-step correctness prediction in all six conditions. Figure 4 displays the learning curve for this skill across all six conditions and the number of students that have not yet mastered the skill at each point. This graph shows that there is a high slipping rate for this particular skill (see green line), indicating that there is a ceiling on the best possible AFM+S prediction that can be achieved.

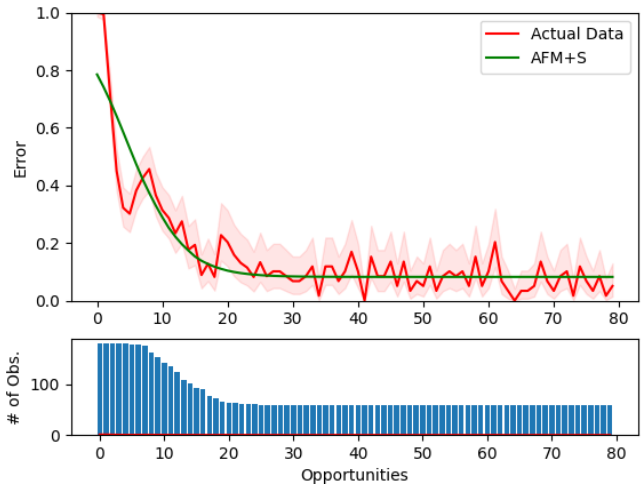

Figure 4: Learning curve for "AD Answer Denominator" and number of unmastered students at each opportunity.

Conditions	AD Average	AS Average	M Average
Random	0.01	0.01	0.01
Streak	0.06	0.11	0.12
BKT_default	0.09	0.16	0.16
BKT_random	0.10	0.17	0.15
BKT_human	0.08	0.16	0.12
DKT_random	0.01	0.30	0.31

Table 1: Model efficiency scores across six conditions.

To evaluate how well each approach handles the trade off between maximizing student's performance while minimizing the amount of practice, we computed a metric that we call "efficiency", see Table 1. To compute the score, we divided the AFM+S predictions at the end of training by the number of opportunities the student received for each student and KC. We then averaged over students to get a score for each KC. Finally, we averaged over KCs within each problem type. This produced, 3 model efficiency scores for each of the six models. Bigger value refers to a more efficient model. The efficiency score complements accuracy and provides more information for selecting the best model.

Although Random gives the highest prediction in Figure 3 among all KCs, it is the least efficient one as it gives all the problems during training. BKT_random has lower predictions than Streak, however the model efficiency suggests that it is more efficient. DKT_random yields the same efficiency as Random in AD problems. However, for AS and M problems, it appears to have the highest efficiency across all six models since it takes the least practice, but still achieves a moderate correctness prediction.

4.2 Simulated vs. Human BKT parameters

To validate the feasibility of generating BKT parameters using simulated student data, we did a correlation analysis of the BKT_random and BKT_human parameters. Figure 5 shows that there's a positive correlation of around 0.65 in the "Learn" parameter, which means the simulated students generated by Apprentice Learner have a similar learning rate as human students. We argue that this is one of the

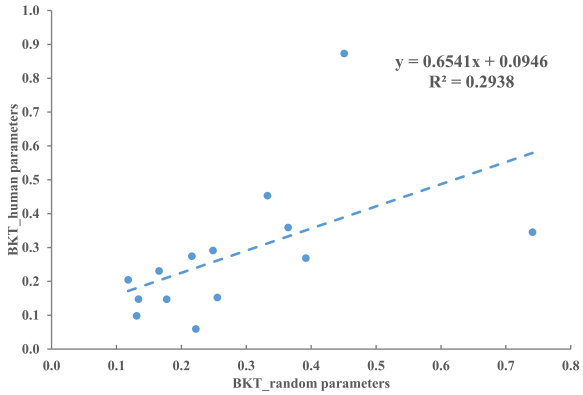

Figure 5: Positive correlation in the BKT "Learn" parameter values estimated from simulated and human data.

harder parameters to set. The "Known" parameter ($P(L_0)$) was near 0 for all skills in the simulated data because all agents start off without any prior knowledge. In human data, this parameter will vary based on the learning context. The "Guess" and "Slip" parameters based on the simulated data were reasonable (both greater than 0), but exhibited no notable correlation with the human guess and slip values. Taken together, we argue that this approach is a promising way to identify initial parameter values for BKT, but more research is needed to explore and generalize this idea.

4.3 Knowledge Tracing Sequence Analysis

Next, we take a closer look at the estimates of several knowledge tracing approaches for different sequences. Figure 6 shows the correctness sequence of a single student on "AD Answer Denominator" KC. This student was taken from the BKT_random condition. We added the mastery predictions generated by BKT, Streak and DKT given this sequence. For BKT and Streak, only the correctness on this skill was used. For DKT, the model was given the entire student sequence for all KCs, but only the predictions for this KC are shown. Predictions were taken at where the student just finished the problem that contained the target KC.

For BKT, the estimates trend towards increased mastery over the course of practice, but sometimes the probability decreases when it gets an item wrong. For Streak, each correct response yields a 33% increase in the mastery prediction, accumulating to 100% by the third correct response in a row. The DKT models predictions tend to jump around, but generally do not seem to be increasing despite getting the problem correct multiple times in a row. For example, the model's probability of correct jumps to 100% before returning to and staying close to 0%.

Correctness		✗	✗	✗	✓	✓	✓	✗	✓
BKT Mastery	0%	13%	16%	16%	72%	97%	100%	99%	100%
Streak Mastery	0%	0%	0%	0%	33%	67%	100%	0%	33%
DKT Mastery	36%	0%	0%	100%	0%	0%	0%	2%	0%

Figure 6: Different Model Predictions on "AD Answer Denominator" given student correctness sequence.

To figure out why the DKT model has such erratic behavior and why it gives so many AD problems, we fed a complete sequence from one student into the DKT model (student from BKT_random condition). Figure 7 shows the prediction of mastery for each KC after the student has completed each problem (problem type shown on the x-axis). It seems that the student never masters the "AD Answer Numerator" or "AD Answer Denominator", which explains why the DKT tutor is giving almost all the AD problems to the students.

Upon further investigation, we discovered that the DKT model has a fundamental issue that makes it difficult to use for mastery learning. The issue is caused by using the DKT predictions between problems when the mastery learning system is determining which KCs are mastered before picking another problem. Unfortunately, for multi-step problems some KCs cannot be correctly applied on the first step. DKT correctly predicts these KCs will have near 0% correctness (any attempts will be incorrect). However, this has the side effect of confusing the mastery learning system into thinking that the KC is unmastered. When the DKT model actually reaches a step where the KC can be correctly applied, then its predicted probability jumps to a more realistic estimate of the mastery. This problem was not identified in previous work on mastery learning with DKT (e.g., [15]) because the prior work only looked at problems with a single step, so this issue never occurred. However, most problems within tutoring systems are multi-step. Future work should explore how to correct this issue within DKT so it can be used for mastery learning.

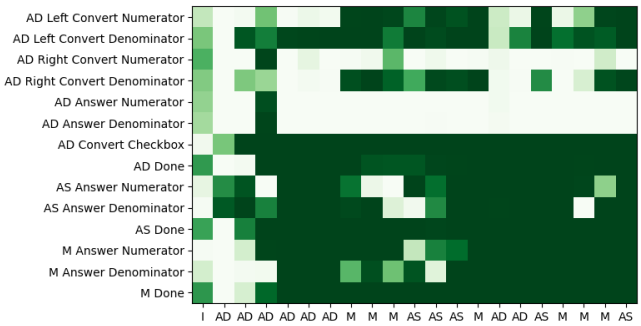

Figure 7: DKT predictions for each KC after each problem.

5. SUMMARY OF KEY FINDINGS

Our first key finding is that simulated students can successfully evaluate online knowledge tracing models. Our simulations indicate that Streak works well for mastery learning and has reasonable efficiency; although the model gives a bit more practice than strictly necessary (e.g. the average number of steps to master all AD KCs is around 17 in Streak and 10 in BKT_random). Still, Streak is very simple to operate, implement, and modify and it behaves reasonably well.

BKT also work well for mastery learning and generally seems to have the best efficiency of the approaches we compared (although DKT seems to be more efficient for AS and M problems). However, it seems to stop a little early in some cases, resulting in under practice. Figure 3 shows that the BKT_random model gets 86% correctness prediction for the KC "AD Answer Numerator", 73% for "AD Answer Denom-

inator" and 83% for "AS Answer Denominator". To some extent, it reveals that these KCs might be more difficult for both simulated students and human students to master, and more practice is required to obtain mastery. Our work suggests that it is important to look at multiple factors when evaluating knowledge tracing approaches in online settings. In particular, it is important to look at both student mastery and the amount of practice that is administered. To explore this trade off, we proposed the efficiency metric. We believe that this metric (or ones like it) might be useful for evaluating knowledge tracing approaches in online settings.

Multiple studies [18, 17] suggest that the DKT model has good predictive performance in offline setting. However, we found that it does not seem to work properly for online knowledge tracing, particularly in cases of multi-step problems. Yeung & Yeung [19] identified that DKT's predictions for KCs are not consistent across time-steps, which we believe is related to the issue we encountered. Even when a student performs well on a KC, DKT's predicted performance for that skill may drop. In general, DKT's predictions fluctuate drastically over time, so *when* its predictions are sampled has a big impact on its accuracy. The core issue is that DKT generates predictions for every KC at every step, but its loss function only constrains predictions that are likely to occur next. Yeung & Yeung suggested some possible modifications to the DKT objective function to mitigate this problem, but implementation and testing of these was beyond the scope of the current study.

In preliminary analysis, BKT estimated students reached mastery even though their error rates were still high. Further inspection revealed an error in our BKT model that was causing it to incorrectly estimate student mastery. Multiple researchers across multiple labs have used this open-source implementation. Despite wide use, we uncovered issues that had not been previously uncovered. Although we corrected these issues for the current study, we argue that this is a positive outcome for our simulated student approach. This finding reinforces the idea that simulated students can be used to test and improve knowledge tracing approaches before running more costly human studies.

Our second key finding is that researchers might use data generated by simulated students to initialize knowledge tracing parameters when human data is not available. To evaluate the feasibility of this idea for BKT, we conducted a correlation analysis between the random-based BKT parameters and human-based parameters. We found a strong correlation between the learning rate parameters suggesting that initializing BKT parameters using simulated student data might be an informed, but cost-effective approach.

6. RELATED WORKS

The closest work to ours is the simulation studies conducted by Doroudi et al. [4, 3], which investigates different knowledge tracing approaches using simulated students. They argue that it is important to evaluate knowledge tracing under various assumptions about how students learn. One of the major differences between their approach and ours is that they use statistical models that predict correctness to simulate students rather than computational models of learning that actually learn and perform the task, as we do with Apprentice agents. Apprentice agents are more complex than the knowledge tracing approaches that are being used to evaluate them. It would be interesting to explore the use of Apprentice agents as another kind of student model for the knowledge tracing evaluations proposed by Doroudi et al.

7. CONCLUSIONS AND FUTURE WORK

We were able to successfully apply simulated students to test different knowledge tracing models. When we compared the three knowledge tracing models (BKT, Streak, and DKT) to a no-knowledge-tracing baseline (Random), we found that BKT gave the fewest problems, Streak gave the second fewest, Random gave the most and DKT gave almost as many as Random in one problem type and the least in the other two. In general, we found that BKT seemed to be the most efficient approach, but streak gave reasonable results despite its simplicity. Through the use of simulated students, we also discovered a number of issues with our BKT implementation as well a fundamental issue with DKT. Despite widespread use of the BKT implementation and a lot of recent investigation into the DKT model, these issues had not been discovered in prior work. Together, these results support our primarily claim that simulated students are an effective tool for investigating and evaluating online knowledge tracing approaches.

Our analysis also found evidence to support the idea that simulated student data might be used to initialize BKT parameters when no human-student data is available. In particular, we found that BKT learning rates estimated from simulated data have a significant correlation to the learning rates estimated from human data. While these initial results are promising, more work is needed to further explore these ideas. In particular, we would like to try running human-subject experiments to compare BKT models initialized using simulated student data to those with default parameters. One surprising finding is how well BKT_default performs; despite somewhat arbitrary parameters, it was more efficient than Streak. Future work should explore how to manually pick robust default values for BKT.

We have a number of additional future directions we would like to explore. We intend to individualize the Apprentice models to make them better mimic the behaviors of different kinds of learners (e.g., high vs. low performing students), students with different motivation in learning, and those who suffer from learning disabilities. We should also explore variations of DKT that address concerns we have identified and enable its use in online mastery learning. Finally, we should move beyond simulation and explore how well our simulated students predict which knowledge tracing approaches will yield the best learning for human students.

8. ACKNOWLEDGMENTS

We would like to thank Danny Weitekamp and Erik Harpstead, who developed much of the framework for testing the Apprentice agents within the fractions tutors. We also thank Anna Raffery for creating the framework for applying knowledge tracing to simulated students and developing the initial version of Bayesian Knowledge Tracing that we used. We also thank Adit Gupta for reading earlier drafts and providing suggestions for improvement.

ABSTRACT

Knowledge tracing algorithms such as Bayesian Knowledge Tracing (BKT) can provide students and teachers with helpful information about their progress towards learning objectives. Despite the popularity of BKT in the research community, the algorithm is not widely adopted in educational practice. This may be due to skepticism from users and uncertainty over how to explain BKT to them to foster trust. We conducted a pre-registered 2x2 survey experiment (n=170) to investigate attitudes towards BKT and how they are affected by verbal and visual explanations of the algorithm. We find that ostensible learners prefer BKT over a simpler algorithm, rating BKT as more trustworthy, accurate, and sophisticated. Providing verbal and visual explanations of BKT improved confidence in the learning application, trust in BKT and its perceived accuracy. Findings suggest that people's acceptance of BKT may be higher than anticipated, especially when explanations are provided.

Bayesian Knowledge Tracing, Data Visualization, Explainable AI

1. INTRODUCTION

Knowledge tracing can offer students and teachers a real-time understanding of what students have already learned and what they are still struggling with [7]. It provides actionable insights that can lead to better educational outcomes [16]. Among many types of knowledge tracing algorithms, Bayesian Knowledge Tracing (BKT) has been established and researched most extensively, as evidenced by the 114,000 Google Scholar results for "Bayesian Knowledge Tracing," 17,500 of which published since 2020. BKT has been tested to help students self-monitor their learning progress [4, 23], to help teachers understand what students have not learned yet [22], and to enable adaptive learning technologies that let students skip over the content they have mastered [18]. In contrast to the abundance of research on BKT, including hundreds of articles devoted to incremental enhancements of the original model [20], there are not many real-world applications that use BKT in practice. Some of the most widely used K-12 learning platforms like ASSISTments and Khan Academy decided against using BKT in favor of simpler models such as N-Consecutive Correct Responses (N-CCR) [13]. This raises questions about barriers to adopting knowledge tracing algorithms in educational practice. In particular, how much is the relative complexity and opacity of BKT responsible for its slow adoption? Platform providers may be concerned that educators and learners will not trust a model that cannot easily be explained to them [13, 12, 24, 25, 1].

The Technology Acceptance Model (TAM) posits that a user's acceptance and adoption of new technology is based on its perceived usefulness (PU) and perceived ease of use (PEOU) [9]. PU and PEOU are beliefs that can be influenced by external factors, such as providing additional information about a technology. According to TAM, learners' and educators' PU and PEOU are essential factors in the adoption of BKT in practice. Improving their perceptions could therefore increase the acceptance and adoption of BKT in real-world applications. Moreover, a better understanding of the mechanisms behind the acceptance of BKT is expected to inform the presentation of other knowledge tracing algorithms as well.

A large number of knowledge tracing algorithms have been developed over the years that could benefit from empirical evidence on how to explain them to users. Recent advances in artificial intelligence have inspired research into more complex algorithms such as deep knowledge tracing (DKT), which uses neural networks [17, 11]. With more complex algorithms that provide less insight into their inner workings, it becomes more important to understand how people's trust in the algorithm and its perceived accuracy might influence perceptions of usefulness and usability of a learning application [1]. Besides BKT and DKT, which are suitable for modeling understanding and sense-making, there are also logistic learning models, such as Additive Factor Models and Performance Factor Analysis [5, 19, 20], which model memory and fluency [20]. These two types of models can also be integrated into one [15]. While there are many types of models that can be examined, we choose BKT as an example knowledge tracing algorithms that is relatively simple and popular among researchers.

This research contributes causal evidence to address three important research questions. First, do people prefer to learn with BKT or N-CCR (N-Consecutive Correct Responses) in an ostensible high-stakes test scenario? Second, how is their preference related to specific attitudes, including their confidence in the learning system to do well on a test, their trust in the algorithm, and the perceived accuracy of the algorithm? And third, how do verbal and/or visual explanations affect people's attitudes and preferences over knowledge tracing algorithms? We answer these research questions with data collected from a pre-registered 2x2 factorial survey experiment.

2. BACKGROUND

One of the simplest knowledge tracing algorithms is N-CCR. It assesses student mastery by evaluating the number of consecutive correct responses for a particular skill. For example, the model determines that a student has learned fractions after correctly answering three fraction questions in a row. Although N-CCR is easy to understand, its simplicity can sometimes make it less accurate than BKT. Still, N-CCR has been used in popular platforms, including ASSISTments and Khan Academy [13], and there is mixed evidence as to whether BKT outperforms N-CCR at modeling student learning [8, 10, 13, 21]. Nevertheless, the scientific community shows a clear preference for BKT (and other more complex knowledge tracing algorithms) based on the allocation of research attention.

BKT is a two-state Hidden Markov Model where the unobserved hidden state being modeled is student learning, and for a given knowledge component, a student has a state of either learned or not learned [6, 17, 11]. Although BKT is already more sophisticated than N-CCR, critics have suggested that BKT is too simple of an algorithm for modeling human learning. They point to deep (neural network) learning models to better represent all factors that go into student learning [17, 11]. Mao and colleagues [17] found that deep learning models outperformed BKT on some learning tasks. However, they also acknowledge that these gains in performance might not be worth the loss in model interpretability. While researchers tend to consider BKT as one of the simpler and more explainable algorithms for knowledge tracing, practitioners and learners who are the end-users may not share this view.

The explainability of an algorithm, which is partly determined by how transparent, understandable, interpretable it is, can play an essential role in its adoption into applications. Barredo Arrieta and colleagues [1] identified these and other reasons for making algorithms more explainable: most relevant to the work on BKT are trustworthiness, confidence, causality, and accessibility. Prior research on algorithms in education has echoed this finding. Kizilcec [14] found that increasing transparency by providing users with additional information about an algorithm made users trust the algorithm more (though too much information can erode trust). Other studies have more specifically examined the interpretability of BKT in learning applications. Yeung [24] explored the use of Item Response Theory to make BKT and deep learning models more explainable, but they have not examined how users react to it. Zhou and colleagues [25] examined BKT explainability by creating visualization "explainables." They then designed an experiment to determine the effectiveness between a static and interactive visualization and found that the static explainable led to a better understanding of the BKT algorithm. More generally, research on Open Learning Models (OLMs) has advanced an understanding of how to visualize and explain learning models [3, 2]. OLMs provide users with interactive visualizations that grant them insights into learning algorithms, along with the ability to adjust the algorithm. This study will add to OLM research by expanding knowledge on how to explain and visualize information to foster positive attitudes.

The current study provides a foundational understanding of how individuals perceive BKT compared to N-CCR along several attitudinal dimensions, and how much verbal and visual explanations of BKT can improve those perceptions. Our review of prior work informed the following two hypotheses:

H1. Verbal and visual explanations of BKT lead participants to prefer it over N-CCR.

H2. Verbal and visual explanations of BKT will positively increase participants attitudes about the BKT algorithm.

3. METHODS

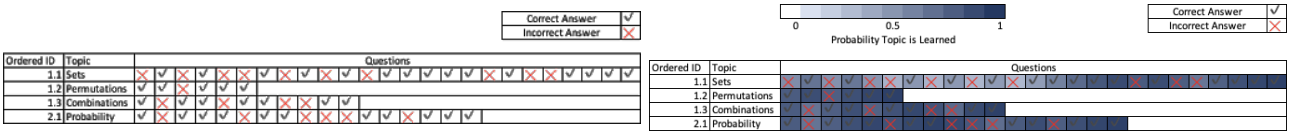
The study design, materials, measures and analysis approach are pre-registered with the Open Science Foundation: https://osf.io/7c5zt/. To refine the study design, measures, and analysis plan, we ran a pilot study with 26 participants and used both descriptive and inferential statistical analyses to build our analysis plan. We first used descriptive analysis to estimate survey completion time, ensure we had enough variance in responses, and check that the information provided to participants was enough information for them to evaluate the algorithms. We used respondents' answers and an open-ended question at the end of the survey in which we asked participants for any feedback to improve the survey. We took the results from this pilot study to alter the visualizations and information provided to participants and rephrase some questions to improve clarity. We removed the open-ended feedback question from the survey after the pilot.

3.1 Participants

Participants were recruited from Amazon Mechanical Turk and received $1.70 for completing a 10-minute survey. The study was advertised as seeking input on test preparation applications. To determine our target sample size of 170, we used G*Power to conduct a power analysis. Our analysis goals were to obtain 95% power to detect a medium effect size of 0.25 at the standard 0.05 alpha error rate with six repeated measures and four groups. While we had 170 participants who took the survey, 34 participants either failed to answer all of the comprehension questions correctly (29) or had prior experience with BKT (4) or both (1). Analyses were conducted on the remaining 136 respondents. Table 1 describes the sample demographics for the sample.

3.2 Procedure

To contextualize the study, participants were provided the following narrative with pictures of two sample questions taken from the ASSISTments platform:



(a) Simple visualization

(b) Detailed visualization

Figure 1: Two versions of a visualization of student performance on questions shown to participants depending on their condition assignment.

Table 1: Sociodemographics of Participants included in the study.

		n	%
Gender	Woman	79	58.1
	Man	54	39.7
	Transgender Man	1	.7
	Gender Variant/Non-Conforming	2	1.5
Ethnicity	Hispanic	10	7.4
	Not Hispanic	126	92.6
Race	White	100	73.5
	Black or African American	10	7.3
	American Indian or Alaska Native	2	1.5
	Asian	16	11.8
	Not Listed	5	3.7
	Multiracial	3	2.2
Age	18-24	27	19.9
	25-34	52	38.2
	35-44	37	27.2
	45-54	8	5.9
	55-64	11	8.1
	Above 65	1	.7

As an admissions requirement for a university program that you are applying for, you are preparing to take a general knowledge exam. The test is important to you and you need to do as well as possible to get accepted.
You have decided to use a test preparation app to help you study for the test.
A key feature of the test prep app is that it ***personalizes*** *the learning experience to help you study efficiently. The app shows you* ***only questions about topics that you have not already learned.***
The system keeps track of your answers to each question and ***automatically moves to the next topic once it determines that you have learned the previous topic.*** *To determine if you have learned a topic, the app uses an algorithm. Once the* ***algorithm determines you learned a topic****, it will stop giving you study questions about it. Thus, it also determines the speed at which you progress in your test prep.*
We would like to get your opinions about the ***two different algorithms*** *to understand which one you find more accurate and trustworthy.*

On the next page, participants answered three multiple-choice comprehension questions: (1) How does the test prep app determine what questions to give you? (2) What determines how quickly you are going to be done with test prep? (3) What happens when the system determines that you have learned a topic? We pre-tested these questions to ensure that an attentive reader would have no problems answering them correctly.

Next, participants saw a short description of the N-CCR algorithm, which we labeled as 3 Right in a Row (3RR): "A topic will be considered learned once a student correctly answers three questions in a row." A simple table depicting a sample student's progression for four topics (table rows) and questions for each topic (table columns) accompanied the description. The table looked like Figure 1a. Each cell contained an X or a ✓depending on if the student answered the question correctly. True to the 3RR algorithm, each topic was considered learned once three consecutive questions were answered correctly. At the bottom of the page, participants answered several questions about their attitudes towards the 3RR algorithm (see Measures).

At this point, participants were randomly assigned to conditions based on a 2x2 factorial design. There were 33 participants in the No BKT Explanation/BKT Simple Visualization condition in the final sample, 34 in the No BKT Explanation/BKT Detailed Visualization condition, 38 in the BKT Explanation/BKT Simple Visualization condition, and 31 in the BKT Explanation/BKT Detailed Visualization condition.

The following page mirrored the structure of the previous one but for BKT, providing a description and sample learning progress visualization based on the experimental assignment, followed by the same set of attitudinal questions about the algorithm. Next, on the final page of the survey, participants were asked to compare the two algorithms.

3.3 Experimental Manipulations

In the no BKT explanation condition, participants received this one-sentence description of the BKT algorithm: "A topic will be considered learned once the algorithm estimates with a high probability that a student has learned the topic based on their responses up to that point." In the BKT explanation condition, participants additionally received the following information about the BKT algorithm:

After every question you answer, the Bayesian Knowledge Tracing algorithm estimates the probability that you have now learned a topic using a probabilistic model that accounts for the following data:
– an initial probability that you have learned the topic based on your first answer: it is higher if you answered correctly
– a correct guess probability: e.g., 50% for a true/false question
– a slip probability for answering incorrectly even though you already learned the topic

– the difficulty of questions you have answered based on how many people have answered them incorrectly
– performance data such as the number of hints that you asked for and the time it took you to answer the question

Using all of this information, the algorithm estimates the probability that you have learned a topic. If the probability is above 95%, the algorithm moves you on to the next topic.

In the BKT simple visualization condition, participants received a simple table depicting a sample student's learning progress mirroring the one shown in the 3RR algorithm (Figure 1a). In the BKT detailed visualization condition, the same table was enhanced to show the estimated probability of having learned the topic using a color scale (Figure 1b). To make the visualizations realistic, we ran a BKT algorithm over a sample of ASSISTments data and used a 95% probability to determine mastery.

3.4 Measures

We measured participants' attitudes towards each algorithm using six items rated on 5-point unipolar response scales ('Not at all', 'Somewhat', 'Moderately', 'Very', 'Extremely'):

Confidence: "How confident are you that the test prep app with this algorithm will prepare you to do very well on the test?"
Understanding: "How well do you understand how this algorithm determines if you have learned a topic?"
Sophistication: "How complex is this algorithm for determining if you have learned a topic?"
Accuracy: "How accurate is this algorithm at determining if you have learned a topic?"
Trust: "How much do you trust this algorithm to determine what you have learned?"
Speed: "How quickly do you learn the materials for the test using this algorithm?"

At the end of the survey, participants rated their general preference over the two algorithms in response to the following question: "Now that you have learned about the 3 Right in a Row (3RR) and Bayesian Knowledge Tracing (BKT) algorithms, which one would you prefer to use for your test prep?" Response options were on a 7-point bipolar scale: 'Strongly prefer 3RR', 'Moderately prefer 3RR', 'Slightly prefer 3RR', 'Neither prefer 3RR nor BKT', 'Slightly prefer BKT', 'Moderately prefer BKT', 'Strongly prefer BKT'. Participants were invited to provide a rationale for their preference using an open-ended question: "Please tell us why you prefer the algorithm that you choose above."

3.5 Analytical Approach

We used the pilot study data to finalize our analysis plan by developing our inferential analysis. For H1, we decided to use linear regression to understand if the conditions had an association effect on the participants' overall preference. We used the conditions as the predictor variables and the preference as the outcome variable. We next decided to use multiple linear regression to understand the association between the attitudinal constructs and algorithm preferences. This analysis used the attitudinal constructs as the predictor variables with preference as the outcome variable. The last planned analysis evaluated H2 by running a linear regression on each attitudinal construct with the conditions as the predictor variables and the attitudinal construct as the dependent variable. While the interpretation of linear regression output is clear and familiar, we acknowledge that our measures are ordinal and not strictly continuous. We confirmed that analysis by ordinal logistic regression yields equivalent results.

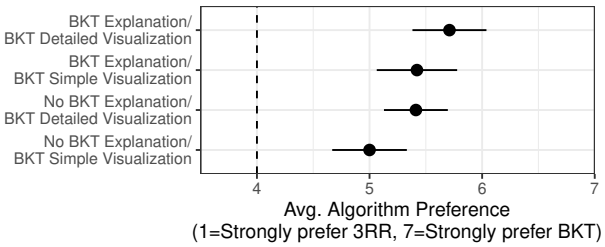


Figure 2: Average algorithm preference by condition.

For the open-ended question asking participants why they choose their preferred algorithm, we planned to use simple thematic coding. While we used the pilot data to create our analysis plan, we did remove all pilot data from the final dataset.

4. FINDINGS

First, we examine which algorithm participants preferred overall. Figure 2 shows their average preference in each condition, which varied between 5 (i.e. Slightly prefer BKT) and 6 (i.e. Moderately prefer BKT). While there is a suggestive pattern that providing more explanation for BKT strengthens the preference for BKT, this pattern was not statistically significant (linear regression: $F_{3,132} = 0.7455, p = 0.5268$). This means the data do not support H1.

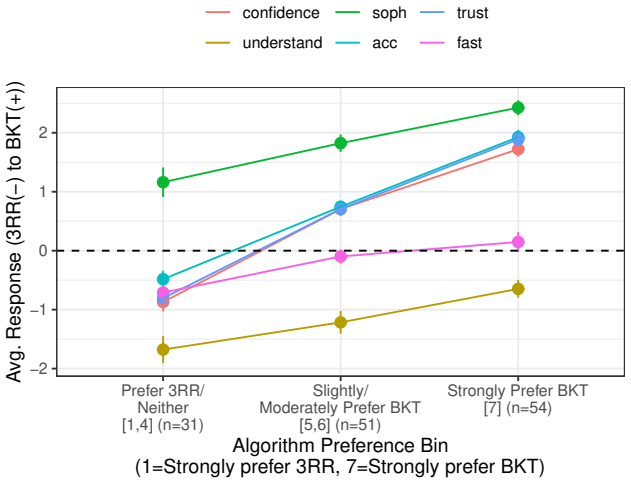

Figure 3: Average response on each measure at three levels of preference: Prefer 3RR to Neither, Slightly and Moderately Prefer BKT, and Strongly Prefer BKT. We choose these groupings because each group represents approximately 1/3 of the sample.

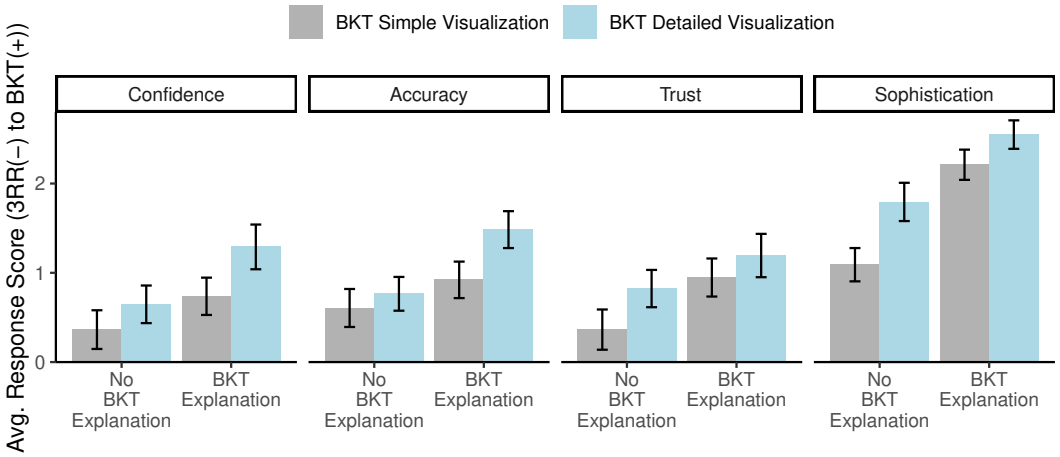

Figure 4: Average differences (BKT score - 3RR score) in significant attitudinal constructs as a function of the randomly assigned conditions. Positive scores indicate a higher score for BKT.

Next, we examine how algorithm preference is related to the six attitudinal measures: confidence in the learning system, the sophistication of the algorithm, trust, understanding, accuracy, and speed. We use the repeated measures design of our study by computing the difference score for each question: subtracting the participant's 3RR response from the BKT response. Figure 3 shows the average response on each measure at three levels of preference: Prefer 3RR to Neither, Slightly and Moderately Prefer BKT, and Strongly Prefer BKT. We choose these grouping because each group represents approximately 1/3 of the sample. All measures are positively correlated with preference as evidenced by their positive slopes (all Pearson's $r > 0.325, p < 0.0001$), but accuracy, confidence, and trust are correlated more strongly ($r > 0.739$). This highlights the importance of these three constructs in determining people's preference over the algorithms. In fact, the six measures explain 66.7% of the variance in preferences (multiple linear regression: $F_{6,129} = 43.07, p < 0.0001$).

Lastly, we examine how the provision of verbal and/or visual explanations influenced participant attitudes about BKT. Figure 4 shows the average response in each condition for the four measures that were significantly affected by the intervention (i.e., relative understanding and speed did not change significantly at $p < 0.1$). We find that confidence in the learning application with BKT (relative to 3RR) improved when both a detailed explanation and visualization were provided ($F_{3,132} = 2.88, p = 0.03844$). Likewise, the perceived accuracy of BKT improved with both types of explanation provided ($F_{3,132} = 3.28, p = 0.02305$). Trust in BKT improved by providing a detailed explanation, especially when complemented with the detailed visualization ($F_{3,132} = 2.346, p = 0.07575$). Finally, and not surprisingly, the more detail was provided, the more sophisticated BKT was perceived to be ($F_{3,132} = 11.17, p < 0.001$). This provides evidence in support of H2.

In all of our analyses, we tested for the presence of demographic heterogeneity in results. However, no significant demographic sources of variation were found in our sample.

5. DISCUSSIONS

This study investigated people's attitudes towards BKT relative to a more straightforward knowledge tracing algorithm and tested the effect of additional information via explanations and visualizations on their attitudes. Understanding how students might perceive the algorithms used in their learning applications is a crucial issue for the adoption and usability of these tools [9]. The results provide evidence supporting our second hypothesis that additional explanations improve key attitudinal measures of confidence, perceived accuracy, trust, and sophistication. Qualitative data from participants echo this result:

> For something high stake, I'd only trust the methods that employs a variety of learning modalities. The analytics for such should match the complexities of my learning process as well as the nature of the material I'm learning. The BKT would put me more at ease than the quick route of the 3RR approach. (Participant assigned to BKT Explanation and BKT Detailed Visualization who had high confidence, sophistication, accuracy, and trust in BKT relative to 3RR)

Surprisingly, we did not find a significant increase in people's preference for BKT (H1), even though we found that algorithm preference is explained largely by people's perceptions of accuracy, trust, and confidence. This preference for BKT regardless of experimental condition is furthered explained by the qualitative responses from participants:

> I don't believe the 3RR algorithm is at all beneficial to the student attempting to learn the topic. If the student just happens to get 3 exceptionally easy questions in a row, the algorithm will assume that the student has learned the topic which is likely not entirely true. (Participant assigned to No BKT Explanation and BKT Simple Visualization who Strongly Preferred BKT)

Nevertheless, participants generally preferred to use the BKT algorithm regardless of the experimental treatment.

Since confidence, trust, and accuracy are important to a user's preference for BKT, it was notable that those three measures were affected by the experimental manipulations. Consistent with prior studies of explainability and transparency in algorithmic systems, we also found that when more information about an algorithm is presented to people, they believe the algorithms to be more trustworthy and accurate, leading the user to have more confidence in the algorithm [1, 14]. This confidence can, in turn, increase the use of applications shown to improve educational outcomes. Our results further highlight the importance of OLM to provide more transparency to gain user trust and confidence. In addition, future educational applications using complex knowledge tracing algorithms should include detailed verbal and visualization explanations of the algorithm to improve confidence and trust in the application.

Frankly, we did not expect to find such strong support for BKT going into this study. Many learning platforms that have the capacity to implement BKT or even more complex algorithms have opted not to do so. Our informal understanding was that this was largely due to concerns that users, such as math teachers who use ASSISTments to assign homework, would not understand BKT and not trust it and lose confidence in the platform. This understanding led us to expect that participants would report a preference for the simpler algorithm and report that they find it more trustworthy and have more confidence in a system that uses it. Therefore, we are surprised by our positive findings for BKT and propose future research directions to follow up on these results.

Future work in this area should explore different participant populations and scenarios. We are planning to run this study with student samples to see if we can replicate the results. While we asked our participants to put themselves in the shoes of a student needing to prepare for a high-stakes test, running this experiment on a student population might make the scenario more realistic to the participants. Additionally, given that many tasks on Mechanical Turk involve subjects annotating machine learning datasets, this group of participants may have more favorable attitudes to algorithms. Another area for future work includes changing the scenario. We ran the study from the viewpoint of a student. However, we acknowledge that intelligent tutoring systems deployed in classrooms also need the trust and confidence of the teachers administering the applications. We plan to rewrite the scenario to allow participants to take on the role of a teacher.

ABSTRACT

We explore how different components of an Automatic Short Answer Grading (ASAG) model affect the model's ability to generalize to questions outside of those used for training. For supervised automatic grading models, human ratings are primarily used as ground truth labels. Producing such ratings can be resource heavy, as subject matter experts spend vast amounts of time carefully rating a sample of responses. Further, it is often the case that multiple raters must come to a census before a final ground-truth rating is established. If ASAG models were developed that could generalize to out-of-sample questions, educators may be able to quickly add new questions to an auto-graded assessment without a continued manual rating process. For this project we explore various methods for producing vector representations of student responses including state-of-the-art representation methods such as Sentence-BERT as well as more traditional approaches including Word2Vec and Bag-of-words. We experiment with including previously untapped question-related information within the model input, such as the question text, question context text, scoring rubric information and a question-bundle identifier. The out-of-sample generalizability of the model is examined with both a leave-one-question-out and leave-one-bundle-out evaluation method and compared against a typical student-level cross validation.

Keywords

ASAG, Assessment, SBERT, Generalizability

1. INTRODUCTION

Automatic Short Answer Grading (ASAG) is an emerging field of research, as the education community has started to embrace the use of technology to assist students and education professionals. It has been shown that the use of open-ended (OE) questions helps facilitate learning [7], but educators are often deterred from their use because grading requires much more time than that for multiple choice [12]. In addition, human ratings may contain bias and vary in consistency, as rating choices are often subjective [28]. ASAG systems may be an important tool for educators, allowing more frequent use of OE questions, and more objective ratings for both formative and summative assessments.

A key challenge with supervised automatic grading models is gathering a large enough sample of labelled data for training. While some labeling tasks for supervised learning may be straightforward such as identifying an image as either a dog or a cat, others such as rating student responses require careful consideration. In high-stakes assessment scenarios, two or more ratings by different experts are often necessary to form a reliable consensus rating. Thus, obtaining labelled data to train an ASAG system can be arduous. It follows that quickly introducing new questions to an existing system may not be feasible if a data collection as well as the meticulous rating of new responses is necessary. Further, a new model would have to be trained and tuned with the newly collected responses. If we create more generalizable ASAG models, educators may have the flexibility to add new questions to an existing assessment with very little effort, thus increasing the practical use of the ASAG system.

We hypothesize that the inclusion of extra question related information within the model input may improve both the classification performance, and the generalizability of the model. For the purposes of this project, we formally define the generalizability of an ASAG model as the capacity to classify responses from out-of-training-sample questions.

This research contributes to the field of automatic grading in three related ways. We focus on classification performance and generalizability of the supervised grading model in terms of 1) the textual representation type, 2) the content of the input and 3) the classification model. We compare three different representation types, including those of state-of-the-art models: Sentence-BERT, Word2Vec, and Bag of Words. In terms of input content, we experiment with including previously untapped resources relating to the questions in the model input. Such resources include a question-bundle identifier, the question stem text, question context text, and rubric information. Extra input content is vectorized (if the source is textual) and concatenated to the response vectors

Aubrey Condor, Max Litster and Zachary Pardos "Automatic short answer grading with SBERT on out-of-sample questions". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 345-352. https://educationaldatamining.org/edm2021/

to be used as input to the classification model. Finally, we compare a non-neural model (a multinomial logistic regression) and a simple neural (a three layer feed forward network) model.

In order to examine the generalizability of the model for each experiment, we use a leave-one-question-out evaluation procedure where we train the model on N-1 questions, and use the one left-out question data as our test set. Thus, during training, the model has not yet seen responses from the question for which we use solely to evaluate the model. We go one step further in testing the generalizability of the model with a leave-one-bundle-out evaluation procedure where we train the model on M-1 question bundles (groupings of questions that are related in context), and use the questions for the left-out bundle as the test set. We conceptualize the leave-one-bundle-out method as a more extreme test of the model's ability to classify out of sample questions because even questions that are related in context have not been seen by the model during training. Additionally, we compare results of our experiments against and a typical student level cross validation. Results from a majority class classifier are included as well for a baseline comparison.

2. RELATED WORK

This section outlines notable work relating to ASAG and the more general use of NLP for education. For this project, we build on the previous literature by considering lessons learned in preceding research, and employing novel approaches that, to our knowledge, have not yet been explored.

2.1 ASAG work

A systematic review of trends in ASAG [3] illustrates an increasing interest in the field of automatic grading for education. Unsupervised methods have been explored such as concept mapping, semantic similarity, and clustering to assign ratings. For example, Mohler and Mihalcea [19] compared knowledge based and corpus based semantic similarity measures for automatic grading, Klein et al. [14] implemented a latent semantic analysis approach, and Basu et al. [2] used clustering to provide rich feedback to groups of similar responses. In addition, many types of supervised classification methods have been utilized for ASAG. Noteable examples include Hou and Tsao [13] who incorporated POS tags and term frequency with a Support Vector Machine classifier, and Madnani et al. [16] who made use of simple features such as a count of commonly used words and length of response with a logistic regression classifier.

More recent ASAG research exploits deep learning methods. Noteable work includes Zhang et al. [31] who used a combination of feature engineering and deep belief networks, Liu et al. [15] who employed multi-way attention networks, and Yang et al. [30] who considered a deep autoencoder model specific to Chinese responses. Additionally, Qi et al. [21] created a hierarchical word-sentence model with a CNN and Bi-LSTM model and Tan et al. [25] explored the use of a graph convolutional network (GCN) to encode a graph of all student responses.

Further, much of the newest ASAG work makes use of state-of-the-art transformer based models, including Gaddipati et al. [11] who evaluated four different types of response embeddings, ELMo, GPT, BERT, and GPT-2 for their performance on an ASAG task, Camus and Filighera [4] who compared the performance of transformer models for ASAG in terms of the size of the transformer and the ability to generalize to other languages, and Sung et al. [24][23] who examined the effectiveness of pre-training BERT, including further pre-training the model on relevant domain texts.

2.2 NLP for Education

Literature addressing the general application of natural language processing (NLP) for various uses in field of education has grown quickly in recent years as well. For example, Fonseca et al. [10] used NLP to automatically classify the programming assignments for students within given academic context, Thaker et al. [26] incorporated textual similarity techniques to recommend remedial readings to students, and Arthurs and Alvero [1] examined bias in word representations for college admissions essays. Additionally, Xiao et al. [29] employed NLP and transfer learning methods for problem detection in peer assessments, Venant and d'Aquin [27] utilized a concept graph to predict semantic complexity of short essays by written by English language learners, and Chen et al. [6] leveraged a variety of textual analysis methods to predict student satisfaction in the context of online tutorial dialogues.

We build on the previous literature by incorporating state-of-the art representation methods such as Sentence-BERT and a neural classification model. The novel contribution of this project includes both our focus on the generalizability of the model to out-of-training-sample questions, as well as the leveraging of previously untapped, question related information as input to the model.

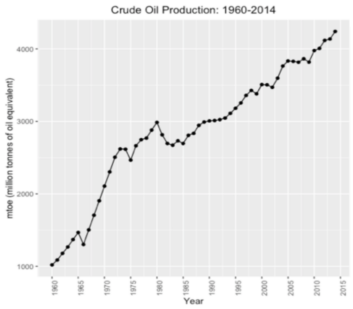
3. DATA SET

The data we will use for this project was sourced from a 2019 field test of a Critical Reasoning for College Readiness (CR4CR) assessment [17] created at the Berkeley Evaluation and Assessment Research (BEAR) center. The data consists of 5,550 student responses from 558 distinct students to 33 different items. The field test included other items that were multiple choice, but these questions were filtered out of the data for our use. The mean number of responses per question is 179 with the minimum being 128 and the maximum being 313. Most of the items belong to an item bundle - a grouping of items that are related in context and/or share a common question context. Additionally, the items were administered in four different test forms, where some items were included in multiple forms. The items all relate to four constructs about student understanding of algebra.

An example of one of the items, labelled 'Crude Oil 4ab' is included in Figure 1. For this item, students are presented with two images relating to oil production - one being a line graph and the other, a table. With the given context, students are presented with a choice between the graph or the table for which would be better to represent the historical patterns, or change over time of the oil production. The correct answer for this question is the graph, and students are expected to provide reasons why this is the right choice.

An example of a student response to the Crude Oil 4ab question (shown in Figure 1) rated at the highest (most correct)

The following graph and table show annual crude oil production in million tonnes of oil equivalent (mtoe) from 1960 to 2014.



Year	Oil Produced (mtoe)	Year	Oil Produced (mtoe)	Year	Oil Produced (mtoe)
1960	1,020	1980	2,986	2000	3,507
1961	1,087	1981	2,814	2001	3,504
1962	1,179	1982	2,695	2002	3,470
1963	1,267	1983	2,671	2003	3,595
1964	1,369	1984	2,732	2004	3,763
1965	1,467	1985	2,695	2005	3,833
1966	1,301	1986	2,807	2006	3,828
1967	1,503	1987	2,835	2007	3,816
1968	1,705	1988	2,945	2008	3,864
1969	1,904	1989	2,991	2009	3,817
1970	2,106	1990	3,026	2010	3,976
1971	2,303	1991	3,011	2011	4,006
1972	2,505	1992	3,023	2012	4,117
1973	2,619	1993	3,046	2013	4,136
1974	2,615	1994	3,111	2014	4,240
1975	2,465	1995	3,181		
1976	2,663	1996	3,254		
1977	2,747	1997	3,357		
1978	2,769	1998	3,426		
1979	2,880	1999	3,380		

[a] For a group project, you and your classmates have to present the overall historical patterns of annual oil production as a poster. Due to limited space, only one of the following representations can be included in the poster: a table, a graph, or a set of equations. Which representation should you use?

[b] Briefly explain your answer choice in [a].

Figure 1: An example of an item from the data set.

score category is shown: *"the graph easily displays patterns over time whereas the table and equations require more analyzing."* In contrast, a student response to the same question rated at the lowest (most incorrect) category is shown: *"the table is more clear, the information is seen in the table."*

Responses were rated from 0 (fully incorrect) to 4 (fully correct) by multiple researchers and subject-matter experts at the BEAR center. The quality and consistency of ratings were evaluated by an inter-rater reliability score, and when a high percentage of rating mismatches between raters existed, incongruous ratings were discussed until a consensus was reached by the raters.

4. METHODS

In this section, We briefly introduce the representation methods and model classes that we include in our experiments. Additionally, we describe the question related information, beyond that of the responses, that are used as inputs to the model. Further, we outline our experiments in detail including methods for evaluation and comparison.

4.1 Input Representations

We chose to include three distinct, yet commonly used, representation types in our experiments: A count-based method that elicits the distinct vocabulary of our data (Bag of Words), a simple neural method that utilizes pre-trained word vectors (Word2Vec), and a state-of-the-art, contextual neural method (Sentence-BERT). A short description of each representation type is included.

4.1.1 Sentence-BERT

Sentence-BERT (SBERT) is a modification of the BERT network that utilizes siamese and triplet network structures to create semantically meaningful sentence embeddings [22]. SBERT fine-tunes the BERT network on a combination of the SNLI dataset and the Multi-Genre NLI datasets, totaling about 1 million sentence pairs. Although sentence embeddings can be derived from the original BERT model using methods such as averaging the BERT output layers or using the [CLS] token embedding, it has been shown that such methods yield poor sentence embeddings [20]. In comparison, SBERT sentence embeddings outperformed other state-of-the-art methods such as InferSent [8] and Universal Sentence Encoder [5] on the SentEval [8] benchmark, which gives an idea of the quality of sentence embeddings for various tasks such.

4.1.2 Word2Vec

Word2Vec (W2V) ma13, is a neural model that creates vector representations of words that have been shown to be semantically meaningful and useful in different NLP tasks [22]. We use an extension of the previously introduced Skip-gram model [18] that incorporates sub-sampling of frequent words during training in order to speed up training, and improves accuracy of representations of less frequent words. For this project, we use the Google News corpus of pre-trained word embeddings. Vectors of size 300 are created for each word, and in order to construct response embeddings from the individual word vectors, we employ a simple but popular method: averaging the vectors of all words in the response.

4.1.3 Bag-of-words

The bag-of-words (BOW) model represents a document as a vector, or "bag," of length equal to the number of unique words in the entire corpus and values of the vector equal to the frequency with witch its corresponding word occurred in the document. In our application, the bags are student short answers and additional question information.

4.2 Input Content

In an item design context, there are various untapped sources of information relating to a particular question that may be useful to include as input to a classification model. We explore the use of four different sources of information, outside that of the response itself. A brief description of the such sources are included below.

4.2.1 Question Text

The question text consists of the direct question stem. As in the example item provided in Figure X, the question text would be: *"Briefly explain your answer choice in [a]."*

4.2.2 Question context

The question context includes any textual information beyond that of the question stem that is related to the question, and might be useful for the respondent to produce a response. In the question example in Figure 2, the question context would include: *"The following graph and table show annual crude oil production in million tonnes of oil equivalent (mtoe) from 1960 to 2014. For a group project, you and your classmates have to present the overall historical patterns of annual oil production as a poster. Due to limited space, only one of the following representations can be included in the poster: a table, a graph, or a set of equations. Which representation should you use?"* We note that not all of the included items have question context text beyond that of the question text itself. For such items, it was not possible to include question context as part of the input.

4.2.3 Rubric Text

Level	Description	Example Response
4	Student provides a fully correct positive and negative justification for ...	"The graph best illustrates the visual trend of oil production. The table or the equation won't provide an overall ..."
3	Student provides a fully correct positive justification for selected representation ...	"The table cannot show a trend in the oil production effectively. "
2	Student provides a partial/general positive justification for selected ...	"The graph helped me with more questions."
1	Student provides incorrect justification for selected representation.	"Because the graph gives us better projections."
0	Student makes no attempt to provide a justification for selected representation.	"I am not sure why."

Figure 2: An example of a scoring rubric corresponding to the item in Figure 1.

As part of the assessment cycle as previously mentioned, an important step in a measurement process is defining the outcome space for each item through a scoring guide, which is essentially a rubric. The scoring guide includes a detailed description of the reasons for which a response would be rated at a certain score, and is used as a guide for human raters. In addition, the scoring guide often includes example responses for each rating level. An example of a scoring guide for the 'Crude Oil 4ab' item in Figure 1 is included shown in Figure 2. When the rubric text is included in the input text, we include both the level descriptions as well as the example response(s).

4.2.4 *Bundle Identifier*

As described above in the data section, most of the questions belong to a bundle of questions - those that are linked based on a similar image, or context text. As a question bundle identifier, we concatenate a one-hot vector to the input vectors. Although items within the same bundle will often share the same context text, we include the one-hot bundle identifier within our extra input text experiments so that we can infer whether the model makes use of semantics within the context text, or rather just a general indication of similar questions.

4.3 Classification Models

We compare a multinomial logistic regression model with a simple neural network classification model. We chose these classification methods representing a linear transformation of the feature space to a label (regression) and a non-linear transformation (neural network). A brief overview of each model is included.

Multinomial logistic regression (MLR) is a classification model that predicts probabilities of different outcomes for a categorical dependent variable. In order to generalize to a K-class setting, the model runs K-1 independent binary logistic regression models where one outcome is chosen as a "pivot" and other K-1 outcomes are separately regressed against the pivot outcome. We use the Limited-memory Broyden-Fletcher-Goldfarb-Shannon (LBfGS) algorithm for optimization [9], and incorporate L2 regularization.

Additionally, we use a simple feed forward neural network on a categorical cross entropy loss function with 2 hidden layers of size 100, using rectified linear unit (ReLU) activation functions for both hidden layers. We include dropout of 0.4 and utilize Adam optimization. We train the model for 16 epochs and use a batch size of 36.

4.4 Evaluation and Model Comparison

In this section, we enumerate our experiments and the evaluation methods chosen for comparison.

4.4.1 *Experiments*

As input to our model, we experiment with 8 different combinations of content to vectorize and concatenate to the response vectors before training our classification models:

1) response
2) question + response
3) question context + response
4) scoring rubric + response
5) bundle one-hot + response
6) question + scoring rubric + response
7) bundle one-hot + question + scoring rubric + response
8) bundle one-hot + question + question context + scoring rubric + response

For each of the 8 combinations listed above, we create three different vector representations with the aforementioned methods: 1) Sentence-BERT, 2) Word2Vec, and 3) Bag-of-words, resulting in 24 distinct input types. We fit a classification model for each of the input types, for both of our classification models. Thus, we compare 48 separate versions of an ASAG model with three types of evaluation.

4.4.2 *Leave-one-question/bundle-out Evaluation*

In order to assess the generalizability of the ASAG model to out-of-training-sample questions for each of the 48 experiments, we average the results of N (where N is the number of questions) independent models. For each of the N models, we train the classifier on data from N-1 questions, and test on data exclusive to the left-out-of-training question. In the case of the leave-one-question-out results, it is important to note that although the model has not seen data specific to the left-out question, it has seen questions that are part of the same question bundle and are therefore related.

To expand our evaluation of generalizability further, we include a leave-one-bundle-out metric for each experiment. For such, we average the results from M (where M is the number of bundles) independent models where we train the classifier on data from M-1 bundles, and test on data exclusive to the left-out-of-training questions which belong to a single bundle. So, these results give us an idea of whether the model can successfully rate responses from questions that have not been used for training, and when the model has not seen questions related by context during training.

4.4.3 *Evaluation Metrics*

We report our results in both multilabel accuracy, and weighted F1 score because multilabel accuracy is both widely used and easy to interpret, and the weighted F1 score captures both the precision and recall and accounts for class imbalance.

Multilabel accuracy represents the degree to which our model classifications agree with the ground truth labels (for this

Table 1: Experiment Results: Multilabel Accuracy

project, human ratings). It is calculated simply as the number of correct predictions divided by the number of total number of examples. The F1 score for a certain class is the harmonic mean of its precision and recall, where precision is calculated as true positives divided by false positives and true positives, and recall is calculated as true positives divided by false negatives and true positives. In order to account for class imbalance, we specifically use the weighted F1 score. This metric calculates the F1 score for each class independently, and the overall score for all the classes is the average weighted by class size.

5. RESULTS

Results of our experiments are detailed in Table 1, reported in multilabel accuracy. For column and row averages, the weighted F1 score is presented as well. In the left-most half of the table, an x is present for a given row if the information type, indicated by the column header, is included in the model input. For example, results in the first row represent an input of only the response text and results in the second row represent an input of both the Bundle ID and the response. Additionally, the top half of the table results are those from the multinomial logisitic regression classifier, and the bottom half of the table results are those for the neural network classifier (as indicated by the leftmost column). For each of our evaluation methods, random holdout, question holdout, and bundle holdout, we present results for the three textual representation methods: SBERT, W2V, and BOW.

In terms of the general performance of our classification models, we consider the random holdout evaluation method. Overall, SBERT representations performed best when averaging across the classification methods and input combinations, followed by the BOW representations (accuracy of 0.621 for SBERT compared to 0.575 and 0.605 for W2V and BOW, respectively). Additionally, the neural network achieves higher accuracy than the logistic regression in general. Both SBERT and BOW perform notably well when the input includes the question text, or the question content.

To assess the generalizability to grading answers to questions unseen in the training set, we focus on the question holdout and bundle holdout results. Across the board, we see much lower accuracy for the question and bundle holdout experiments than that of the random holdout, with the bundle holdout being the lowest. This is in line with what one might expect because for the question holdout, the model has not yet seen responses for the particular question in the test set and for the bundle holdout, the model has not seen questions even related to the test set question.

Similar to the random holdout experiments, we see the same overall pattern for the question and bundle holdout experiments: SBERT is generally superior, followed by BOW and W2V, respectively. One notable difference for the question holdout experiments compared to those of the random holdout is that we see increased performance when we include multiple extra sources of information. For example, with SBERT and bundle holdout, we achieve 0.365 accuracy with the neural network classifier when we include the rubric text, question text, and bundle ID. We might explain this result as, when the model is lacking previous information about the test question from training, extra input information might provide guidance for the model.

For the question and bundle hold out experiments, the addition of the rubric text improves performances particularly well with the use of BOW representations, for both the logistic regression and neural network classifiers. With SBERT, the addition of the question text seemed to help the generalizability of the model as well. Interestingly, we do not see the same pattern between the classification models for the question and bundle holdout methods: where the neural net was clearly superior in the random holdout experiments, results are more similar between the logistic regression and neural network for the bundle and question holdout experiments.

We see from the row averages in the right most columns of the table that across all experiments and text representation types, the response and question text, as well as the response and context text achieve the highest evaluation scores. Additionally, the column averages further confirm that the SBERT representations perform best.

Further, we include results from a majority class classifier on the top row for a baseline comparison. We emphasize that, across all random holdout experiments, the classification models outperform the majority class classifier significantly. However, this is not the case for the question holdout and bundle holdout experiments. For the question holdout experiments, many of the SBERT experiments out-

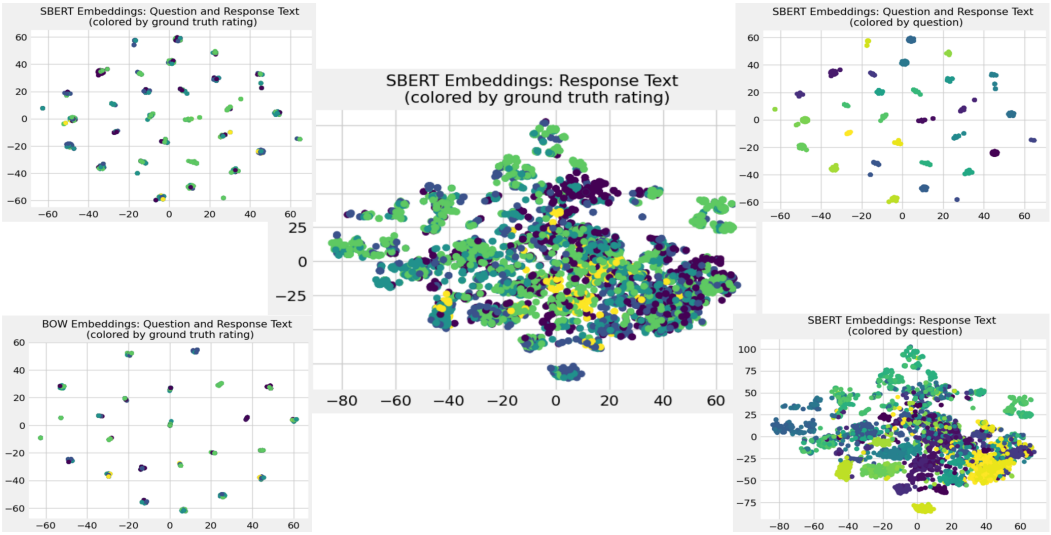

Figure 3: 2D visuals of input vector representations. Plots vary by representation type, input content, and color labeling.

performed the majority class classifier, but on average, the W2V and BOW experiments performed a bit worse than majority class. For the bundle holdout experiments, on average, SBERT performs slightly better than majority class, but the W2V and BOW experiments do not.

Further interpretations can be made from Figure 4, which includes two dimensional, t-distributed Stochastic Neighbor Embedding (TSNE) reduced vector representations. The center image includes SBERT embeddings of only the response text and the colors represent the ground truth ratings. From the top left and right images, as well as the bottom left image we can see very distinct question clusters with the inclusion of question text. However, from the bottom right image, we can visualize question specific clusters, but they are not as distinct as the representations that include the question text.

Thus, we conclude that in terms of question holdout, the model can generalize to out-of-sample questions with only slight improvement over majority class, with a state-of-the-art representation method like SBERT. Certain extra pieces of input information aid our models more than others like question text and the best performing models use the neural network classifier.

6. DISCUSSION

Although our results are not promising for the generalizability of autograding models to unseen questions, we emphasize the importance of finding more generalizable models to decrease time spent on the laborous task of creating ground-truth human ratings. Our intention is that this work will influence researchers to consider further innovative methods to increase the generalizability of ASAG models. Further, because we did find that including certain question-related text may improve model performance, it may be of use to the ASAG research community to continue to explore how extra sources of information about a question may be incorporated into an ASAG system.

As is evident in our literature review, there has been increased adoption of state-of-the-art textual representation methods such as SBERT, and transformer-based models such as BERT and XLNet, within the field of NLP in Education. Our results support that such models may achieve superior performance for certain tasks.

To build on this work further, we could consider other methods, beyond that of concatenation to the input text, to include the extra question information in our model. We could further pre-train a transformer-based model such as BERT or XLNet with the extra textual information by either tuning the existing weights or altering the existing architecture with an extra encoder layer of weights trained on our text alone. Moreover, we may focus more closely on how the classification model itself might be altered such that it might better generalize to out-of-training-sample questions, instead of only focusing on the input content.

We believe that beyond model performance, the practical utility of an ASAG system must be considered in order for educators to continue to adopt new technologies that employ advanced methods in artificial intelligence. Recent years have seen vast improvements in the field of machine learning and language processing. Embracing such technologies for applications in education may be pivotal to provide the assistance that both educators and learners need. However, we do not suggest that machine learning systems such as ASAG should be used to replace human judgements in education, especially in high stakes testing scenarios. We emphasize the ASAG systems should be used to support educators, not replace them. This project represents a continued effort to explore the ways in which we can make use of new technologies to improve learning.

ABSTRACT

Sentiment Analysis is a field of Natural Language Processing which aims at classifying the author's sentiment in text. This paper first describes a sentiment analysis model for students' comments about professor performance. The model achieved impressive results for comments collected from student surveys conducted at a private university in 2019/20. Then, it applies the model to different scenarios: (i) in-person classes taught in 2019 (pre-COVID); (ii) the emergency shift to online, synchronous classes taught in the first semester of 2020 (early-COVID); and (iii) the planned online classes taught in the second semester of 2020 (late-COVID). The results show that students acknowledged the effort professors did to keep classes running during the first semester of 2020, and that the enthusiasm continued throughout the second semester. Furthermore, the results show that students evaluated professors' performance for online courses better than for in-person courses.

Keywords

sentiment analysis, BERT, online classes, in-person classes

1. INTRODUCTION

The systematic evaluation of a Higher Education Institution (HEI) provides its administration with valuable feedback about several aspects of academic life, such as the reputation of the institution and the individual performance of faculty. In fact, in some countries, it is mandatory that HEIs implement self-evaluation committees, whose members are elected by the various segments of the community and whose duties include the preparation of annual reports assessing the performance of the institution on predefined aspects.

In particular, student surveys are a first-hand source of information that help assess professor performance and course adequacy. Such surveys are typically organized as a questionnaire with *closed-ended* questions, which the student answers by choosing predefined alternatives, and *open-ended* questions, which the student answers by freely writing comments on the topic of the question. Albeit interesting and useful, the analysis of open-ended questions poses challenges, such as how to summarize the comments and how to determine the sentiment of the comments.

The primary goal of this paper is to introduce a sentiment analysis model for students' comments in the context of questionnaires designed to assess professor performance, and to evaluate the model using data from student surveys applied at Brazilian University in 2019 and 2020.

Studying this particular period of time is interesting because, in early 2020, the COVID-19 pandemic forced the Brazilian University to move all classes online, taught with the help of a videoconferencing software and a Learning Management System (LMS), and they so remained throughout 2020. This change in instructional model offers the unique opportunity to compare the in-person classes in 2019 (pre-COVID scenario), with the emergency shift to online, synchronous classes in the first semester of 2020 (early COVID scenario), and with the planned online classes in the second semester of 2020 (late-COVID scenario). Therefore, the second goal of this paper is to apply the sentiment analysis model developed to the case study data to compare the overall sentiment of the students' comments about professor performance in these different scenarios.

The results reported in this paper indicate that the sentiment analysis model developed achieves good performance in the classification of the sentiment expressed by the students' comments about professor performance. This model was separately applied to the different scenarios covered by the case study data. The results show that students acknowledged the effort professors did to keep classes running during the first semester of 2020 (early-COVID sce-

Haydée Guillot Jiménez, Anna Carolina Finamore, Marco Antonio Casanova and Gonçalo Simões "Sentiment Analysis of Student Surveys - A Case Study on Assessing the Impact of the COVID-19 Pandemic on Higher Education Teaching". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 353-359. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

nario), and that the enthusiasm continued throughout the second semester of 2020 (late-COVID scenario). These conclusions are justified by the peak in positive comments observed in the first semester of 2020, as compared with the other semesters. Furthermore, the results show that students evaluated professor performance for online classes better than for in-person classes. To a large extent, these remarks are consistent, for example, with the findings of a random-sample survey, conducted in late May 2020, involving more than 1,000 US college students whose classes moved from in-person to completely online in early 2020 [13]. However, they have to be cross-checked with other surveys conducted in 2019/2020 at the Brazilian University and elsewhere.

The remainder of this paper is organized as follows. Section 2 summarizes related work. Section 3 presents the case study used in the paper. Section 4 details the model for sentiment analysis. Section 5 describes the results obtained with the case study data. Section 6 contains the conclusions and directions for future work.

2. RELATED WORK

Sentiment Analysis (SA), also known as Opinion Mining, is a field of natural language processing (NLP) where the main focus is to automatically analyze people's opinions and sentiments [11]. According to Pang and Lee [15], for most of us, the decision-making process takes into consideration "what other people think". Based on this assertion, it is easy to understand why SA is very popular in several domains, such as tourism, restaurants, movies, music, and, more recently, education.

Chaturvedi et al. [5] addressed the essential task of eliminating "real" or "neutral" comments that do not express a sentiment. The article reviewed hand-crafted and automatic models for detecting subjectivity in the literature, comparing the advantages and limitations of each approach. Ahuja et al. [1] addressed the analysis of comments from one of the most popular Twitter platforms. As the comments are not structured, they used six techniques to pre-process the comments. They then applied two techniques (TF-IDF and N-Grams) to classify comments, and concluded that the TF-IDF word level of sentiment analysis is 3-4% higher than the use of N-characteristics. Prusa et al. [17] also concentrated on Twitter data. They analysed the impact of ten filter-based feature selection techniques on the performance of four classifiers. Nazare et al. [14] analyzed about 1,000 Twitter comments using various machine learning approaches, separately or in combination, to classify the comments. Unlike other articles with traditional approaches to analyze the sentiment of short texts, Li and Qiu [10] did not consider the relationship between emotion words and modifiers, but they showed how to mitigate these problems through the sentiment structure and rules that captured the text sentiment. The results of an experiment with microblogs validated the efficacy of their approach.

Analyzing comments from sales Web sites is important to detect if users are praising or criticizing the products they consume. Bansal and Srivastava [4] used the word2vec model to convert comments into vector representations using CBOW (continuous bag of words), which were fed to a classifier. Experimental results showed that Random Forests using CBOW achieved the highest precision. Khoo and Johnkhan [9] analysed comments from the Amazon Web site, using a new general-purpose sentiment lexicon, called WKWSCI Sentiment Lexicon, and compared it with five existing lexicons. Akhtar et al. [2] used classification algorithms, like Conditional Random Filed (CRF) and Support Vector Machine (SVM), to classify comments from different Indian Web sites.

Zhou and Ye [22] reviewed journal publications between 2010-2020 in SA applied to the education domain and, among others future research directions, they pointed out: (i) the need to explore SA in the learning cross-domain; (ii) consider a combination of text mining and qualitative answers (questionnaires or interviews) to understand the psychological motivation behind learning sentiment; (iii) explore the association between sentiment, motivation, cognition, and also demographic characteristics to regulate the emotions of learners. Santos et al. [19] studied SA in online students' reviews to identify factors that influence international students' choice for a HEI. They also suggested aspects that HEI managers may have to consider to attract more international students, such as: online information about (HEI) offerings, students' comments about their experiences, international environment, courses taught in English, and support to students' accommodation or expenses. Sindhu et al. [20] proposed an aspect-oriented SA system based on Long Short-Term Memory (LSTM) models. They considered two datasets with students' comments, namely: the Sukkur IBA University and a standard SemEval-2014. They suggested that the evaluation of teaching performance would have to consider six dimensions: teaching pedagogy, behavior, knowledge, assessment, experience, and general. We previously created a tool for the analysis of student comments [8] but it was limited to a fixed, manually created dictionary, which might therefore not take into account some relevant words.

The choice of a university to enroll in is a difficult decision and, at the same time, the information available on the internet is overwhelming. To address these issues, Balachandran and Kirupananda [3] proposed an aspect-based sentiment analysis tool to evaluate the reputation of universities in Sri Lanka from users' comments in Facebook and Twitter, using the StanfordCoreNLP library to perform sentiment analysis. Lytras et al. [12] built the Learning Analytics Dashboard for E-Learning (LADEL) tool to monitor different sources, such as student blogs, social networks and Massive Open Online Courses (MOOC) in search of comments that express satisfaction, anxiety, efficiency, frustration, abandonment. LADEL is composed of four modules: collection, cleaning, word cloud and sentiment of opinion. Sivakumar and Reddy [21] extracted students' comments using the Twitter API and tried to analyze the relations between word aspects and phrases of student opinion. They used a sentiment package available in R to find the polarity of the sentences and then applied k-mean clustering and naïve Bayes for the sentiment analysis classification.

de Oliveira and de Campos Merschmann [6] analyzed the combination of NLP pre-processing tasks (tokenization, POS tagging, stemming, among others) with three classifiers (Ran-

dom Forest, Support Vector Machine, and Multilayer Perceptron), and discussed their predictive performance. They evaluated these tasks in five Portuguese datasets related to sentiment analysis, encompassing comments, news and tweets. They analyzed some combinations of preprocessing tasks and classifier

This paper focuses on identifying students' sentiments expressed in comments about professor performance in Higher Education. It uses the pre-trained model called Bidirectional Encoder Representations from Transformers (BERT) [7] for the sentiment analysis task. BERT-style models are the current state-of-the-art in several NLP tasks, including entity recognition and sentiment analysis. BERT's architecture is based on multi-layered transformers, which are particularly optimized to be trained on GPUs and TPUs with significant amounts of data. For this reason, a recipe for success with these models is to pre-train them with large datasets (in the order of millions of documents) on general tasks such as masked language models or next sentence predictions [7]. This pre-training allows the model to learn a lot about some language patterns (that are independent of the task we care about) and make it easier to train them specifically for other language tasks even without the need for large amounts of annotated data. Our corresponding code is available at GitHub[1].

3. CASE STUDY

3.1 Course Survey Data

In the rest of this paper, we use *course* to denote "a series of lectures in a particular subject", and *class* to describe "a particular instance of a course". Therefore, students enroll in a class of a course. We assume that classes run on a per semester basis, and use <year>.1 and <year>.2 to denote the first and second semesters of the calendar year, respectively.

Since 2005, at the Brazilian University used in the case study, students are invited, at the end of each semester, to answer a questionnaire for each class they took in the semester. Students' participation in the survey is not mandatory. The questionnaire has a set of closed-ended questions about the professor that taught the class, and a separate set of closed-ended questions about the course the class is an instance of. For each closed-ended question, the student chooses a score from a Likert scale (1-5). The questionnaire also has one open-ended question which invites students to write as many sentences as they like to express their evaluation of the professor that conducted the class, and likewise for the course the class is an instance of. The comments are in Portuguese and the sentences are often ungrammatical. We are interested in the sentiment analysis of the students' comments about the professor performance, which we will refer to as the *comments* for brevity.

The purpose of the case study is to analyse comments collected from the questionnaires applied in the first and second semesters of 2019 and 2020. However, we also use the comments collected from the questionnaires applied in both semesters of 2018 for pre-training (see Section 5). The reason for using comments from 2018 for pre-training is that we wanted to make sure that no comment used in the analysis step has been observed before in the pre-training step. Using the 2018 data is possible because it has been observed that the vocabulary students use to write comments has not changed significantly over the years. Table 1 presents the number of comments for the 2018, 2019 and 2020 student surveys.

[1]https://github.com/hguillot/Sentiment-Analysis-of-Student-Surveys-with-BERT

Table 1: Number of comments about professor performance in classes.

Semester	#Comments
2018.1 and 2018.2	10,077
2019.1	3,182
2019.2	1,910
2020.1	3,492
2020.2	2,219

Table 2: Structure of the professor questionnaires.

Year	Class Mode	#Closed-ended Questions	#Open-ended Questions
2018	in-person	10	1
2019	in-person	16	1
2020	online	20	1

As far as professor evaluation is concerned, the questionnaires varied slightly from 2018 to 2019. Also, in early 2020, the COVID pandemic forced the university to move all classes online, taught with the help of a videoconferencing software and a Learning Management System (LMS), and they so remained throughout 2020. The questionnaire, used for classes taught in 2020.1 and 2020.2, was then modified accordingly. Table 2 summarizes the structure of the various questionnaires that the case study is concerned with.

Given this new reality, forced by the COVID pandemic, it is reasonable to ask if the professors were prepared for online classes and if this would affect the students' evaluation of the professor performance at the end of 2020.1 (the early-COVID scenario).

As a simple answer to this conjecture, consider the last closed-ended question incorporated in the 2019/20 surveys: *"O: Overall evaluation of the professor"*. Figure 1 depicts the distribution of the scores of Question O per semester, grouped as 1 and 2, for "negative", 3, for "neutral", and 4 and 5, for "positive", considering only questionnaires with a non-empty comment about professor performance. Figure 1 shows that students in fact evaluated the overall professor performance better in 2020.1 (again, the early-COVID scenario) than in the other semesters.

But the question remains if the overall sentiment of the comments about professor performance points in the same direction.

3.2 Use of the Course Survey Data

This section describes how the course survey data were used to construct models for the sentiment analysis of comments about professors performance (recall that each questionnaire

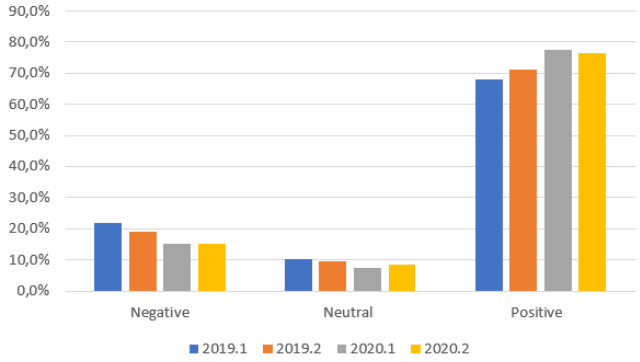

Figure 1: Distribution of the scores of Question O per semester (considering only questionnaires with a non-empty comment about professor performance).

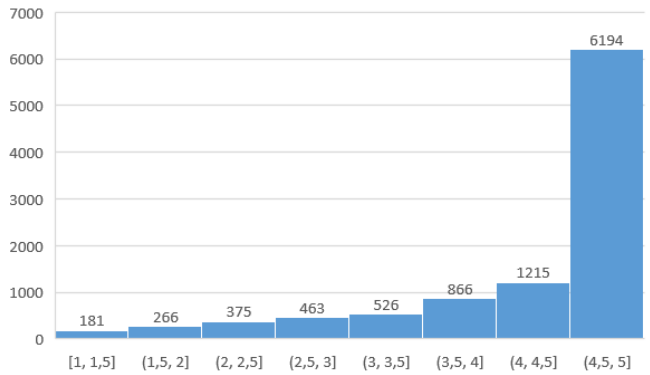

Figure 2: Distribution of the average score of all questions of a questionnaire from 2018.

has only one such comment).

We first observe that no text pre-processing was necessary, as in the Twitter sentiment analysis reported in [16], since the students' comments do not significantly depart from written Portuguese, albeit they often contain ungrammatical sentences.

The models used manually annotated comments, obtained as follows. From the course surveys of the two semesters of 2019, 800 questionnaires with non-empty professor comments were randomly chosen, using the following criteria: 5 samples were chosen for each of the Likert scale scores (1-5) for each of the 16 closed-ended questions (5 * 5 * 16 = 400) in each of the semesters (400 * 2 = 800). The comments of the selected questionnaires were manually classified into 3 categories: *positive*, when the comment only praised the professor; *negative*, when the comment only criticized the professor; and *neutral* when the comment expressed no opinion or when the comment both praised and criticized the professor. Table 3 shows the number of comments in each of these classes.

The pre-training step (see Section 5) used data from the 2018 student surveys as follows. We considered a dataset with all questionnaires with non-empty comments from the 2018 student surveys. But, since the questionnaire applied in 2018 had no overall professor evaluation (Question O), we used the average score $s_{avg}[q] \in [1, 5]$ of all questions of a questionnaire q to induce a label $c[q] \in \{$"*negative*", "*neutral*", "*positive*"$\}$ for the comment as follows: if $s_{avg}[q] < 3$ then $c[q] =$ "*negative*"; if $3 \leq s_{avg}[q] < 4$ then $c[q] =$ "*neutral*"; and if $s_{avg}[q] \geq 4$ then $c[q] =$ "*positive*". Figure 2 shows the distribution of the average scores obtained.

4. A SENTIMENT ANALYSIS MODEL

In the paper, we focus on the *polarity classification* task, whose focus is to classify comments, which express opinions or reviews, into "positive", "negative" or "neutral", or even into more than these three classes. We neither consider *subjectivity classification*, i.e., the task of verifying the subjectivity and objectivity of a comment, nor *irony detection*, i.e., the task of verifying whether the comment is ironic or not.

Table 3: Distribution of the number of questionnaires per class of comment about professor performance, using the manual classification and the automatic classification induced by the score of Question O (considering 800 questionnaires with a manually classified comment about professor performance).

Year	Classification	Positive	Negative	Neutral
2019.1	Manual	107	220	73
	Automatic	187	150	63
2019.2	Manual	119	203	78
	Automatic	201	138	61

We use BERT [7], which achieves outstanding results on a number of NLP tasks. The core of the architecture has been pre-trained on a very large amount of unlabeled data. The model is then fine-tuned on small supervised datasets, designed for the task in question.

For our case study, BERT encodes each comment into a 768-dimensional embedding and, then, a dense layer transforms the embeddings into a three-dimensional vector for each comment that indicates the probability that the comment belongs to each of the three classes - "positive", "negative" or "neutral". We adopted the BERT-Base, Multilingual Cased version[2] (for 104 languages, with 12-layer, 768-hidden, 12-heads, 110M parameters), which is required since the comments are written in Portuguese. In order to significantly speed up the training and inference with our model, we limited the size of each input comment to 64 tokens, which is enough to cover the vast majority of the comments. Any comment with less than 64 tokens was padded with the '[PAD]' symbol already allocated in BERT's vocabulary and any comment with more than 64 tokens was truncated.

Finally, the model was implemented using KERAS and running on GPU's.

5. EXPERIMENTS AND RESULTS

We started our experimental setup by executing a pre-training step that aims at getting the model used to the style of stu-

[2]Available at `https://github.com/google-research/bert/blob/master/multilingual.md`

Table 4: Results of the experiments.

Experiment	Accuracy	Precision	Recall	F1
Zero-shot	50.2±2.3	54.2±2.2	51.8±2.8	53.0±2.4
From scratch	86.3±1.8	**84.5±2.3**	83.0±3.1	83.7±2.4
Fine-tuned	**87.5±2.0**	84.6±2.0	**84.8±2.0**	**84.6±2.5**

dent's comments through non-annotated data. In order to do that, we used the set of comments from the 2018 student surveys, and the scores they assigned to the professor as a proxy to the labels, as explained in Section 3.2. We started the pre-training experiment with the multilingual BERT checkpoint that is publicly available and trained for 10 epochs, resulting in a newly trained checkpoint which we call from this point on the *pre-trained checkpoint*.

After the pre-training step, we proceeded to experiment with three setups, using a 5-fold cross-validation strategy, applied to the set of 800 manually classified comments. Therefore, each round of cross-validation used 640 comments for training and 160 comments for testing. The three setups we used were as follows:

- *Zero-shot*: this experiment does not perform any training with the manually classified comments. Instead, it performs inference directly using the pre-trained checkpoint that resulted from the pre-training step on the test set. If this model's performance was good, then it would show that manually annotating comments would not be necessary.
- *From scratch*: this experiment does not use the pre-trained checkpoint that resulted from the pre-training step. Instead, it starts with the multilingual BERT checkpoint and uses the manually classified comments to train and evaluate the model. The objective of this experiment is to understand if the pre-training step is necessary to obtain top-quality results.
- *Fine-tuned*: this experiment uses the pre-trained checkpoint that resulted from the pre-training step and then uses it as the starting point when training with the manually classified documents. This experiment aims at evaluating if combining pre-training and manually annotated comments helps in obtaining top-quality results.

Table 4 shows the results of the 5-fold cross-validation (each cell indicates the average and the standard deviation over the 5 rounds). Observe that the fine-tuned model obtained the best results, which indicates that combining pre-training and manually annotated comments helps in obtaining top-quality results.

We have also computed the Fisher-Irwin test [18], to examine the hypothesis that Fine-tuned model does not have an equivalent classification performance when compared to both Zero-shot and From scratch. For this purpose, we computed the Fisher-Irwin test twice. In the first test, our null hypothesis (*Fine-tuned classifier has a proportion of correct classifications equivalent to the proportion of correct classifications from Zero-shot classifier*) was tested against the alternative hypothesis (*Fine-tuned classifier has a proportion of correct classifications superior to the proportion of correct classifications from the Zero-shot classifier*), and the null hypothesis was rejected for the usual levels of statistical significance (5% and 10%). The same happened in our second test where our null hypothesis (*Fine-tuned classifier has a proportion of correct classifications equivalent to the proportion of correct classifications from From scratch classifier*) was tested against the alternative hypothesis (*Fine-tuned classifier has a proportion of correct classifications superior to the proportion of correct classifications from the From scratch classifier*). Based on this, we can conclude that our results are statistically significant, since our null hypotheses were both rejected for the usual levels of statistical significance (5% and 10%), leading us to accept alternative hypotheses.

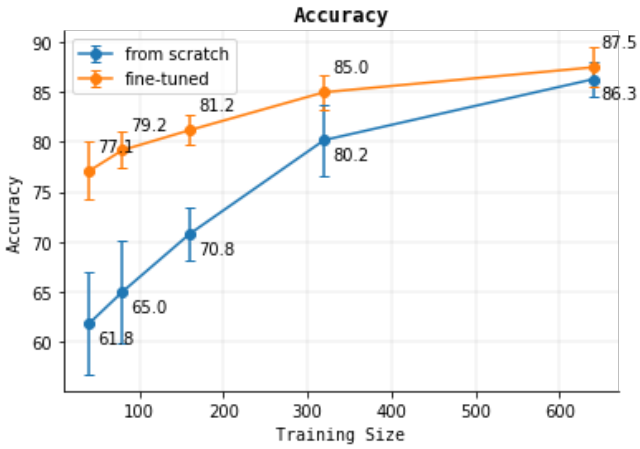

Figure 3: Accuracy for *From scratch* and *Fine-tuned* using train set of 40, 80, 160, 320 and 640 comments.

An important question that arises is about the number of comments that must be manually annotated to achieve an acceptable level of accuracy. To address this question, we ran the following cross validation experiment, with a decreasing number of manually annotated comments used for training. We divided the 800 manually annotated comments into 5 sets of 160 comments each. Let $G_1, ..., G_5$ denote these sets and $\overline{G_i}$ denote the 640 comments not in G_i. For each $i = 1, ..., 5$, we computed the accuracy and the F1-score of the from-scratch and the fine-tuned models, using G_i for testing and subsets of $\overline{G_i}$, of sizes 640, 320, 160, 80, and 40, for training. Finally, for each cardinality of the training sets, we computed the average accuracy and the average F1-score of each model. Figures 3 and 4 depict the results.

Figure 3 shows that, using 640 manually annotated comments for training, the fine-tuned model achieved an average accuracy of 87.5% and the from-scratch model achieved 86.3%, and so on for the other training set cardinalities (320, 160, 80 and 40). Therefore, based on the level of accepted accuracy, one can balance the effort to manually annotate the comments.

Figure 3 also shows that: (i) using just 40 manually annotated comments for training, the fine-tuned model achieved an average accuracy of 77.1%, while the from-scratch model

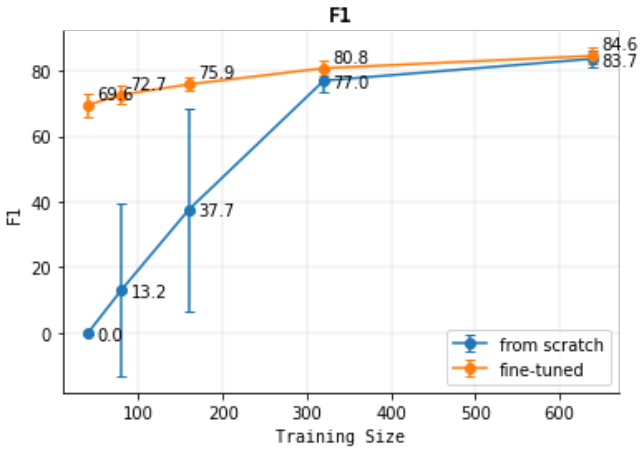

Figure 4: F1 for *From scratch* and *Fine-tuned* using train set of 40, 80, 160, 320 and 640 comments.

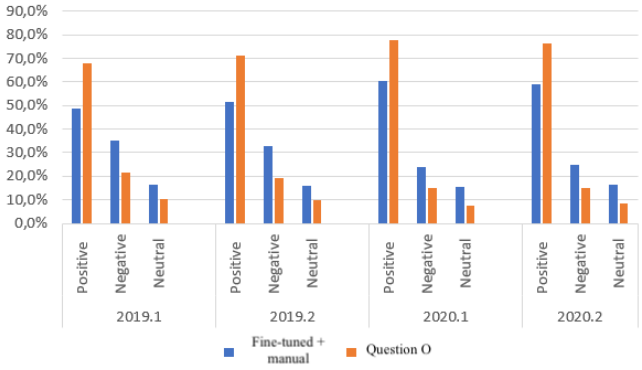

Figure 5: Distribution of the final classification of the comments from all surveys, using the fine-tuned model, added to the manually classified comments from 2019.1 and 2019.2 (shown in blue), and the classification of the comments from all surveys, using the score of Question O (shown in orange).

only achieved an accuracy of 70.8%, when trained with 160 comments, that is, 4 times as much comments; (ii) the fine-tuned model, again trained with just 40 comments, achieved a much better accuracy than that of the zero-shot model, shown in the first line of Table 4 (the zero-shot model is the equivalent to training the fine-tuned model with 0 comments); (iii) the pre-trained check-point had a positive impact, since the fine-tuned curve is always above the from-scratch curve; (iv) the fine-tuned model achieved a standard deviation smaller than that of the from-scratch model, which means that this technique is more stable and less susceptible to changes due to the samples. These observations reinforce that, with an adequate pre-training strategy, we may achieve good results without the need to manually annotate a large amount of data.

Finally, we used the fine-tuned model to classify the full set of comments from the 2020.1 and 2020.2 surveys, and the set of comments from 2019.1 and 2019.2 that were not manually classified. Then, we added the manually classified comments from 2019.1 and 2019.2 to obtain the final distributions for the four semesters, as shown in Figure 5.

For comparison purposes, Figure 5 includes the distributions of the comment classifications induced by the score of Question O as explained in Section 3.1. Note that Question O induces a classification biased towards positive comments, when compared with the classification based on the fine-tuned model. This is also observed when just the manually classified comments are considered.

In conclusion, the distributions of the students' comments sentiment and of the scores of Question O indicate that students evaluated the professor performance better in 2020.1 (the early-COVID scenario) than in the other semesters, which seems to indicate that students acknowledged the effort professors did to keep classes running during 2020.1, and that the enthusiasm continued throughout 2020.2 (late-COVID scenario). Furthermore, students evaluated the professor performance better in 2020.1 and 2020.2 (online classes), by a margin of nearly 10%, when compared with 2019.1 and 2019.2 (in-person classes), respectively.

6. CONCLUSIONS

This paper first described a sentiment analysis model for students' comments about professor performance. The model is based on BERT and has achieved good results when applied to a case study with students' comments about professor performance, obtained in 2019/20.

Then, the paper applied the model to compare the overall sentiment of the students' comments about professor performance in different scenarios: in-person classes in 2019.1 and 2019.2 (pre-COVID scenarios); the emergency shift to online, synchronous classes in 2020.1 (early COVID scenario); and the planned online classes in 2020.2 (late-COVID scenario). The results show that students acknowledged the effort professors did to keep classes running during 2020.1, and that the enthusiasm continued throughout 2020.2. Furthermore, the results show that students evaluated professor performance for online courses better than for in-person courses, by a margin of nearly 10%, which seems to indicate that students favor online classes.

This paper also discussed the number of comments that must be manually annotated to achieve good results. Future experiments can take advantage of this discussion to reduce the manual annotation effort, even with datasets obtained from other universities.

The stability of the models was also investigated, indicating that the fine-tuned model achieved a lower standard deviation, which means that this technique leads to more stable results. The fine-tuned model also achieved a higher performance, when compared to both the zero-shot and from-scratch models, in terms of the proportion of correct classifications, and the difference was statistically significant.

We plan to extend the analysis to past student surveys, which go back to 2005, and to the student survey to be applied at the end of 2021.1, when classes will still be online. We also plan to cross-check these preliminary findings with other surveys conducted in 2019/20 at the Brazilian University and elsewhere.

ABSTRACT
Influenced by Covid-19, online learning has become one of the most important forms of education in the world. In the era of intelligent education, knowledge tracing(KT) can provide excellent technical support for individualized teaching. For online learning, we come up with a new knowledge tracing method that integrates mathematical exercise representation and association of exercise(ERAKT). In the aspect of exercise representation, we represent the multi-dimensional features of the exercises, such as formula, text and associated concept, by using ontology replacement method, language model and embedding technology, so we can obtain the unified internal representation of exercise. Besides, we utilize the bidirectional long short memory neural network to acquire the association between exercises, so as to predict his performance in future exercise. Extensive experiments on a real dataset clearly proved the effectiveness of ERAKT method, they also verified that adding multi-dimensional features and exercise association can indeed improve the accuracy of prediction.

Keywords
Knowledge tracing. Context-aware. Exercise representation.

1. INTRODUCTION
As one of the key technologies of adaptive learning, knowledge tracking has become a research hotspot in adaptive education. The main task of knowledge tracking is to automatically track students' acquisition knowledge level with time according to their historical learning trajectory, so as to accurately predict their performance in future learning. In actual teaching, teachers can adjust teaching plan dynamically by predicting the result, improve teaching quality and teaching efficiency, and help teachers to achieve accurate teaching goal.

Knowledge Tracing method (KT) was first proposed by Atkinson. Bayesian knowledge tracing method (BKT) [1] is one of the most popular knowledge tracing methods in the early stage. BKT assumes that students will never forget a knowledge concept once they have mastered it, which is not in line with the actual teaching situation. Later, with the continuous development of deep learning, more and more scholars combined knowledge tracing tasks with deep learning methods, among which Deep Knowledge Tracing (DKT) [2] is the most popular and commonly used one. DKT partly solves the assumption error problem in BKT which does not conform to the actual teaching situation, and can more accurately represent the concept proficiency of learners. However, the assumption of concept state represented by a hidden layer in DKT is inaccurate, making a student's mastery level difficult to track. Furthermore, Jiani Zhang et al. proposed Dynamic Key-Value Memory Networks for Knowledge Tracing (DKVMN) [3] based on memory neural networks, and DKVMN is significantly better than BKT and DKT in terms of performance effect. In recent years, the University of Science and Technology of China team proposed some methods which integrated exercise records and exercise materials into KT based on the existing KT methods, such as EKT[11], qDKT[12], etc., which has stronger explanatory power and gradually improved performance effect.

However, most of the traditional knowledge tracing methods only consider the exercises records of students, using the covered concepts to index the exercises, ignoring the influence of exercise formula, text or concepts on a student's knowledge state. In fact, besides exercise interaction records, the multi-dimensional information of exercises has an important impact on a student's performance. Therefore, in order to solve the above problems, we propose a mathematical knowledge tracing method that integrates the representation and association of a student's exercises, so as to solve the problem of information loss caused by ignoring multi-dimensional representation and association of exercises in traditional knowledge tracing and improve accuracy of the method. Contributions of ERAKT are as follows:

(1) We propose a new context-aware knowledge tracing method that can automatically learn and predict a student's performance in the next exercise.
(2) We propose an exercise representation method that integrates multi-dimensional information, including text, formulate and associated concept.
(3) We propose a sequential question association mining method based on a bidirectional neural network to acquire association content between exercises.

2.1 Semantic representation
In the domain of text processing, the most important task is to transform text into a vector form which could be understood and processed by computers, that is, semantic representation. There are

Tao Huang, Mengyi Liang, Huali Yang, Zhi Li, Tao Yu and Shengze Hu "Context-aware Knowledge Tracing Integrated with The Exercise Representation and Association in Mathematics". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 360-366. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

many ways to get semantic representation, such as Word2vec, TextCNN, FastText, Bert etc.

Word2Vec[4] was proposed by Google's Mikolov team. It is the preliminary application of neural networks in semantic representation. Word2Vec conducts fixed-dimensional vectors to represent words. For sentences, the Doc2Vec method [5] is derived, which establishes a model by means of a neural network structure. Paragraph vectors are obtained during the training of the model. Both of them are typical unsupervised text representation methods. Compared with the traditional bag-of-words method, they can better integrate the internal information of exercise, such as context, semantics and word order.

Yoon Kim modified the input layer of traditional CNN. In 2014, he proposed a text classification method named TextCNN[6], which has a simpler network structure, smaller amount of calculations and faster speed of training. So compared with traditional CNN method, TextCNN performs better in field of semantic representation. Another method to get semantic representation is FastText [7]. FastText can train word vectors by itself without requiring pre-trained word vectors, which speeding up training and testing while maintaining high accuracy.

The Bert [8] method was also proposed by the Google team to solve the semantic representation problem. To deal with the effects of polysemous words in sentences, Bert exploits the transfomer model with Self-attention and Multi-Headed Attention mechanisms [9], which combines the context of the sentence to determine the specific semantics. Bert has a two-way function, allowing for more accurate results and adaptive learning in a multi-tasking environment.

2.2 Knowledge tracing considering multi-dimensional characteristics of exercises

With the rapid development of deep learning, more and more scholars exploit different deep learning methods to represent exercises in order to complete the knowledge tracking task and attempt to comprehensively consider the impact of different features of the exercises on knowledge tracing tasks. The multi-dimensionality mainly include textual materials and concepts involved in the exercises.

Therefore, the majority of existing KT methods utilize concepts to index exercises to avoid over-parameterization. For example, both DKT and DKVMN treat all the exercises covering the same concept as a single one. Compared with the former, the key-value matrix in DKVMN extends the hidden feature representation of the exercises, but it still does not take advantage of the characteristics of other dimensions. The Prerequisite-driven deep knowledge tracing(PDKT) [23] method integrates the structural information between concepts with the help of the Q matrix in the cognitive diagnosis theory, and specifically considers the contextual relationship between concepts. The self-attentive knowledge tracing (SAKT) [24] method exploits concepts to index exercises and introduces a self-attention mechanism to consider the degree of relevance between concepts. The Context-Aware Attentive Knowledge Tracing method(AKT) [13] utilizes a novel monotonic attention mechanism that relates a student's future responses to assessment exercises to their past responses; attention weights are computed using exponential decay and a context-aware relative distance measure, in addition to the similarity between exercises. Moreover, AKT utilizes the Rasch model to capture individual differences between exercises. The Graph-based Knowledge Tracing(GKT) [25] also introduces concepts to index exercises, at the same time constructs a graph method to represent the association between concepts, updates the student's knowledge status through the GRU mechanism.

The exercise materials which KT methods consider are mainly text materials and the concepts covered. EERNN (Exercise-Enhanced Recurrent Neural Network) [10] and qDKT(Question centric Deep Knowledge Tracing)[12] predict a student's performance only by making full use of his practice records and text of exercises. EKT (Exercise-aware Knowledge Tracing for Student Performance Prediction) [11] is an improved method based on EERNN. It is the first method to comprehensively consider the influence of a student's practice records and exercise materials (concepts and text contained) on his performance. But it is worth noticing that in EKT exercise text is represented by LSTM, due to its internal structure problem, LSTM can't parallel computing, resulting in dealing with text slower, so the effect is not very satisfactory. Exploring Hierarchical Structures for Recommender Systems (EHFKT)[21] make full use of concepts, difficulty, and semantic features to represent exercises. The first two are embedded using TextCNN, and semantic features are extracted using Bert. The Introducing Problem Schema with Hierarchical Exercise Graph for Knowledge Tracing(HGKT) [22] method exploits a hierarchical graph neural network to learn the graphical structure of the exercises. It also introduces two attention mechanisms to better mine knowledge state of learners, and utilizes the K&S diagnosis matrix to obtain the diagnosis result.

3. PROPOSED METHOD

The student's knowledge mastery is tracked by observing his interactive information in different exercises. It is a supervised learning sequence prediction problem in the field of machine learning. In this section, we will first define the problem and then describe the proposed method in detail.

3.1 Problem Definition

Assuming that each student does exercises separately, we define the student sequence $s = \{(e_1, r_1), (e_2, r_2), \dots\dots, (e_T, r_T)\}$, where e_T belongs to exercises sequence E, which represents the exercises done by the student at time T. Usually, 0 or 1 is applied to mark whether his answer is correct, i.e. 1 means correct, 0 means wrong. In the ERAKT method, we add the text content of each exercise into the student's exercise sequence E, because we mainly focus on knowledge tracing task in mathematics, which generally contain not only words but also specific mathematical elements, so the text is represented as $e = \{w, f\}$, where $w = \{w_1, w_2, \dots\dots, w_M\}$ represents the words in the exercise, and $f = \{f_1, f_2, \dots\dots, f_M\}$ represents the mathematics components. Furthermore, the corresponding concept is a key information in KT task, $k = \{k_1, k_2, \dots\dots, k_M\}$, which is summarized into a concepts matrix for embedding, and the student sequence after embedding turns into sequence $s = \{(e_1, k_1, r_1), (e_2, k_2, r_2), \dots\dots, (e_T, k_T, r_T)\}, s \in S$.

The ultimate goal of our ERAKT method is to track a student's knowledge status through hidden layers to predict his performance in future exercise, that is, his response to exercise e_{T+1} at the next moment T+1. Besides, we take into account the student's record of exercises, the text content of the exercises and the concepts included. The ERAKT framework is shown in Figure 1. The method includes three major parts: exercise representation module, exercise association module and the performance prediction module.

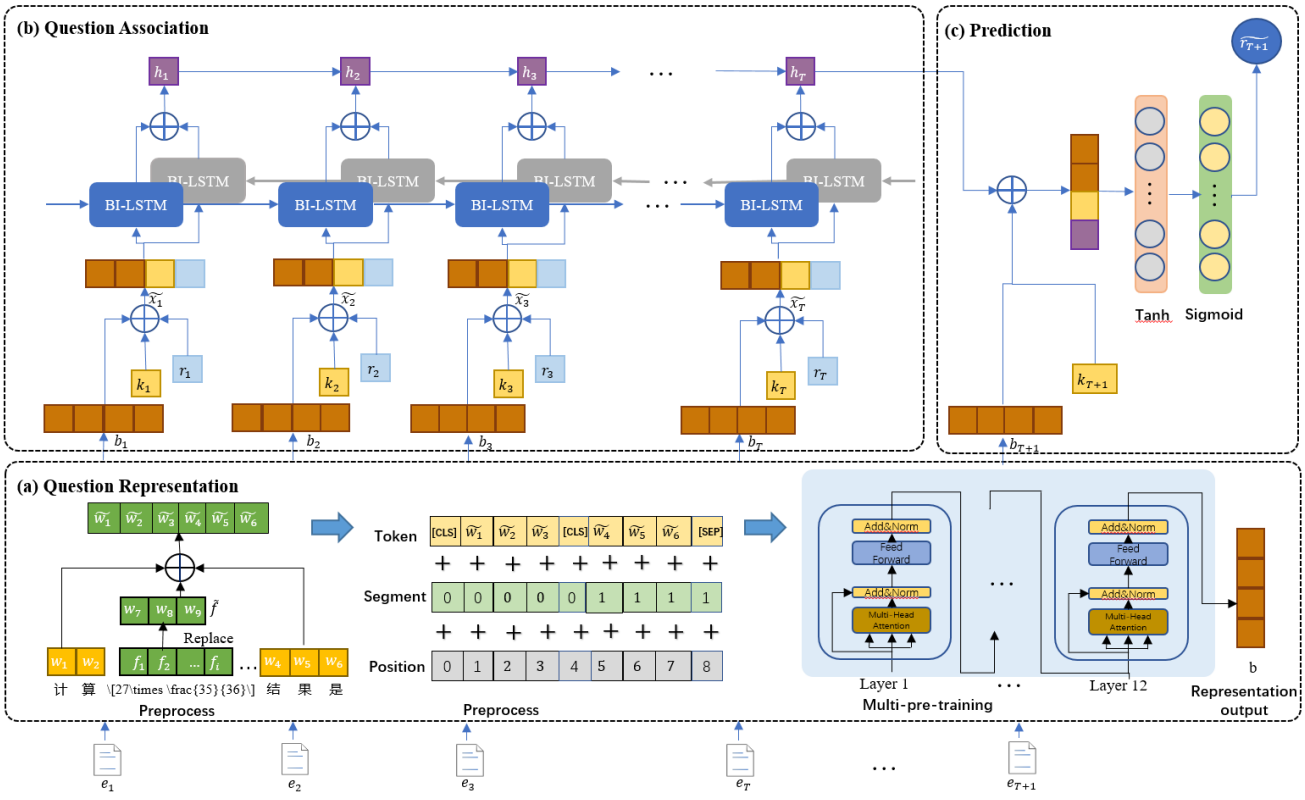

Figure 1. ERAKT framework. (a) The process of obtaining the exercise representation. After the replacement of the formula, we splice the formula with the original text, and the final exercise representation vector is obtained through 3 embedding layers and 12 layers of encoder. (b) Combine the exercise representation vector with the knowledge concepts and student response corresponding to the exercise, and input them into the Bi-LSTM network together to obtain the student's hidden state representation. (c) The student response prediction part, which predicts the student's response to the exercise at time T+1.

3.2 Exercise Representation Method

The information of the exercise includes the material itself and the concepts associated with it. To realize the unified representation of mathematics exercises, firstly, we need to construct the different dimension features in the exercises to represent the material itself and its associated concepts, and then integrate the feature representations of multidimensional exercises into a unified feature vector.

3.2.1 Preprocessing of exercise formula

Mathematical exercises involve text and formulas, which are represented by LaTex, and we need to convert formulas into unified text expressions in advance. Since the LaTeX formula in the exercises follows a set of unified coding rules, we first replace LaTeX formulas uniformly through ontology replacement method, then perform unified preprocessing together with other text.

In the unified preprocessing of the formula text, the entities and attributes in the exercises are identified and replaced from entities to attributes. During the replacement process, the replaced entities or attributes and the replaced forms are saved in a dictionary. , That means, replace these formula texts $f = \{f_1, f_2, \ldots\ldots, f_M\}$ to obtain $\tilde{f} = \{\widetilde{f_1}, \widetilde{f_2}, \ldots\ldots, \widetilde{f_M}\}$. The partial replacement relationship is shown in Table 1.

Table 1. Formula replacement table.

f	$\tilde{f}$
complement	补集
sqrt	根式
^	幂
+	加号
cm	厘米
pi	圆周率

After the replacement, splice $\tilde{f}$ with the text $w = \{w_1, w_2, \ldots\ldots, w_M\}$ according to the original position, and get the text representation of the exercise $\widetilde{w}$.

$$\widetilde{w} = w \oplus \tilde{f} \quad (1)$$

For exercise representation $\widetilde{w}$, we apply python's Chinese word segmentation package Jieba for word segmentation. Jieba has three segmentation modes: precise mode, full mode and search engine mode. Here we utilize precise mode to accurately segment a complete sentence into independent words according to the segmentation algorithm. Then use a self-built stop word list to delete some words that cannot express specific meanings. This specific process is shown in Figure 2.

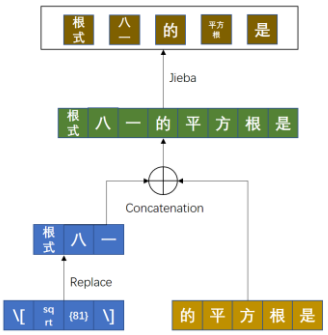

Figure 2. Example diagram of exercise formula preprocessing.

3.2.2 *Vector representation of multi-dimensional exercise*

In view of the superiority of Bert in the field of natural language processing, we exploit Bert to conduct self-supervised learning and training on the text features of exercises. We employ three embedding layers and a 12-layer encoder to pre-train the exercise representation. As shown in the question representation part in Figure 1, it includes three layers. The function of the token embedding layer is to convert each word segmentation into a 768-dimensional vector, then the segment embedding layer distinguishes differences between the vectors of two sentences, the position embedding layer can help understand the order of words. When all the embedding processes are done, we add the results of each layer element by element to get the input of the Bert encoder layer. After encoding by the 12-layer encoder, we can get the final text vector representation b_T.

$$b_T = e_{Token} + e_{Segment} + e_{Position} \quad (2)$$

In this way, semantic information of exercises can be obtained automatically without any extra expert manual coding.

3.2.3 *Representation of concepts*

In the dataset, each exercise will be marked with concepts involved, $k = \{k_1, k_2, \dots\dots, k_M\}$. With reference to EKT, we select the first concept k_1,which is also the most relevant one to represent the concept involved in exercise, then all the concepts of exercises are encoded into a vector of length |E| through one-hot vector encoding, E is the set of exercises, |E| represents the number of exercises, the encoded vector is adjusted by a layer of sigmoid activation function into the concepts representation c_T.

After getting the text representation and concepts representation, we concatenate them together as the final exercise embedded matrix.

$$x_T = b_T \oplus c_T \quad (3)$$

$\oplus$ means concatenate two vectors in a certain dimension, and the length of vector obtained after concatenating is |E|+768.

3.3 Exercises association modeling

After obtaining the final merged exercise embedding matrix, we need to model the entire exercising process of each student and obtain his hidden state at each step, it will be affected by both the history exercises sequence and his responses.

3.3.1 *Student response embedding*

First of all, we combine the student's response with each exercise representation. Specifically, at each step t,we combine exercise embedding x_T with the corresponding score r_T as the input to the recurrent neural network.

We first extend the score r_T to a feature vector $0 = (0, 0, \dots, 0)$ with the same dimensions of exercise embedding x_T and then learn the combined input vector $\widetilde{x_T}$ as:

$$\widetilde{x_T} = \begin{cases} x_T \oplus 0 & r_T = 1 \\ 0 \oplus x_T & r_T = 0 \end{cases} \quad (4)$$

After the concatenating, the student sequence becomes $s = \{\widetilde{x_1}, \widetilde{x_2}, \dots\dots, \widetilde{x_T}\}$.

3.3.2 *One-way time series knowledge tracing*

Like the original DKT method, a hidden layer is applied to track changes in student's knowledge status, the formula is as follows:

$$i_T = \sigma(W_i \cdot [h_{T-1}, \widetilde{x_T}] + b_i) \quad (5),$$

$$f_T = \sigma(W_f \cdot [h_{T-1}, \widetilde{x_T}] + b_f) \quad (6)$$

$$o_T = \sigma(W_o \cdot [h_{T-1}, \widetilde{x_T}] + b_o) \quad (7)$$

$$\widetilde{c_T} = tanh(W_c \cdot [h_{T-1}, \widetilde{x_T}] + b_c) \quad (8)$$

$$c_T = f_T \cdot c_{T-1} + i_T \cdot \widetilde{c_T} \quad (9)$$

$$h_T = o_T \cdot tanh(c_T) \quad (10)$$

Where c_T is the long-term state at time T, i_T, f_T, and o_T are the input gate, forget gate, and output gate in LSTM respectively. tanh represents the tanh activation function, $tanh(z_i) = (e^{z_i} - e^{-z_i})/(e^{z_i} + e^{-z_i})$, σ represents sigmoid activation function, $\sigma(z_i) = 1/(1 + e^{-z_i})$.

3.3.3 *Bidirectional time series knowledge tracing*

In order to better obtain the association between the exercises, we introduce a bidirectional long and short-term memory neural network [14] to obtain the hidden state representation of the students, because Bi-LSTM can make full use of the exercises representation in both forward and backward directions [15], it can obtain the association between the exercises. Specifically, after getting $s = \{\widetilde{x_1}, \widetilde{x_2}, \dots\dots, \widetilde{x_T}\}$, we set the input of the first layer of LSTM to $\overrightarrow{\boldsymbol{h}}^{(0)} = \overleftarrow{\boldsymbol{h}}^{(0)} = \{\widetilde{x_1}, \widetilde{x_2}, \dots\dots, \widetilde{x_T}\}$, at each time T, the forward hidden state of each layer $(\overrightarrow{h_T^{(l)}}, \overrightarrow{c_T^{(l)}})$ and backward hidden state $(\overleftarrow{h_T^{(l)}}, \overleftarrow{c_T^{(l)}})$ updates with the input from previous layer from each direction. The specific formula is as follows:

$$\overrightarrow{h_T^{(l)}}, \overrightarrow{c_T^{(l)}} = \text{LSTM}\left(\overrightarrow{h_T^{(l-1)}}, \overrightarrow{h_{T-1}^{(l)}}, \overrightarrow{c_{T-1}^{(l)}}; \overrightarrow{\theta}_{\text{LSTM}}\right) \quad (11)$$

$$\overleftarrow{h_T^{(l)}}, \overleftarrow{c_T^{(l)}} = \text{LSTM}\left(\overleftarrow{h_T^{(l-1)}}, \overleftarrow{h_{T+1}^{(l)}}, \overleftarrow{c_{T+1}^{(l)}}; \overleftarrow{\theta}_{LSTM}\right) \quad (12)$$

The association between exercises can be captured by Bi-LSTM. Since the hidden state of each direction only contains the association of one direction, it is beneficial to combine the hidden state of both directions together to obtain the final student hidden state representation:

$$H_T = \text{concatenate}\left(\overrightarrow{h_t^{(L)}}, \overleftarrow{h_t^{(L)}}\right) \quad (13)$$

3.4 Student performance prediction

After the above steps, we get the student's hidden learning state sequence $\{H_1, H_2, \dots\dots H_T\}$ and the exercise sequence $\{x_1, x_2, \dots\dots x_T\}$, both of which will affect the student's final answer. We utilize two layers of bidirectional neural networks to obtain the predicted student performance, as shown in the formula:

$$y_{T+1} = Tanh(W_1 \cdot [H_T \oplus \widetilde{x_{T+1}}] + b_1) \quad (14)$$

$$\widetilde{r_{T+1}} = \sigma(W_2 \cdot y_{T+1} + b_2) \quad (15)$$

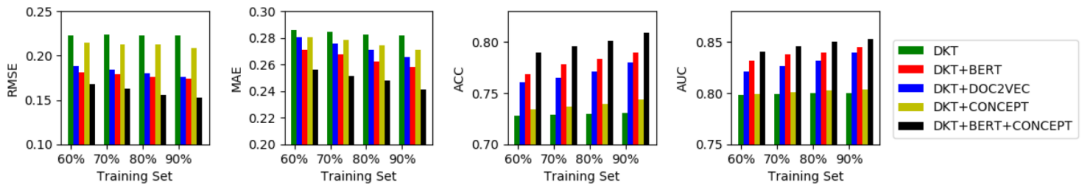

Figure 4. Four indicators performance after adding multi-dimensional feature.

The first layer uses the Tanh activation function, and the second layer uses the sigmoid activation function. After two layers, the final prediction result $\widetilde{r_T}$ is obtained. It is a scalar, which represents the probability of answering the question e_T correctly.

3.5 Training and optimization

The method is optimized by conducting the binary cross-entropy loss function, which calculates the loss between the true response r_T and the probability of correct answer $\widetilde{r_T}$, and adjusts the model parameters such as exercise embedding parameters and student response embedding by inverse transfer until the value converges. The loss function is defined as:

$$\mathcal{L} = -\sum (r_T \log \widetilde{r_T} + (1 - r_T) \log(1 - \widetilde{r_T})) \qquad (16)$$

4. EXPERIMENTS

In order to ensure the reliability of the experimental results, we carry out several baseline comparison experiments on a real dataset. This section will focus on the selection of data set and the comparison of benchmark models, as well as a discussion of the final experiments on a real dataset. This section will focus on the selection of data set and the comparison of benchmark models, as well as a discussion of the final experimental results.

4.1 Dataset

The method we proposed was validated on a dataset called Eanalyst-math. The data comes from a widely used evaluation system in China [16], from offline to online, that selects elementary school math exercises as experimental subjects. The data collected by EAnalyst-math mainly includes homework, unit tests, and term tests. Each assignment or evaluation is regarded as a collection of exercises, which is more in line with the actual education situation in China. EAnalyst-math recorded a total of 525,638 interactions from 1,763 students, with an average of 298.1 responses per student.

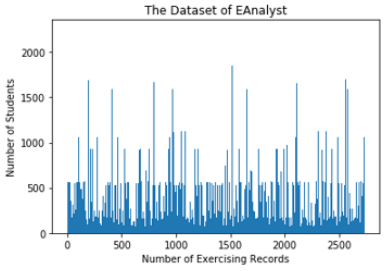

Figure 3. Student-interaction distribution diagram of the Eanalyst-math dataset.

4.2 Settings

In order to predict students' future response, we can evaluate it by classification and regression respectively [17]. From the perspective of classification, the area under the Receiver Operating Characteristic (ROC) curve AUC and the prediction accuracy ACC are used to measure the prediction performance. From a regression point of view, we choose Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) to quantify the distance between the predicted result and the actual response.

Each data set is divided into 7:3 based on students, 70% is utilized for training verification, and 30% for testing. In order to avoid the contingency of the evaluation results, we implement the standard five-fold cross-validation division for all models and all training validation subsets, that is, 80% training set and 20% validation set, and exploit the average value as the final comparison result.

There are many hyperparameters in the model, among which the number of hidden units (h), batch_size (b) and learning rate (l) will have a greater impact on the results. We conducted many experiments to explore the influence of the changes of these hyperparameters on the performance of the model, and finally found that the performance results were optimal when l=0.09, h=16, and b=16.

4.3 Results

4.3.1 Accuracy comparison

We compare our ERAKT with three other baselines on the dataset. The experimental results are shown in Table 2. In general, ERAKT has significantly improved AUC and ACC results, MAE and RMSE results are significantly lower, which proves that the performance of ERAKT is better than the others. Especially, our ERAKT performs better the EERNN, a state-of-the-art model which including the exercise content information. Next, the exercise-aware methods (i.e. EERNN and ERAKT) outperform other models that ignore the exercise content (i.e. DKT and DKVMN). This experimental result validates the conclusion of EKT [11].

Table 2. Accuracy comparison

Method	AUC	ACC	MAE	RMSE
DKT	0.79	0.7301	0.2827	0.2233
DKVMN	0.8783	0.8072	0.2678	0.1346
EERNN	0.8836	0.8213	0.2495	0.131
ERAKT	0.9025	0.8407	0.2203	0.1278

4.3.2 The influence of multi-dimensional features of exercises on the prediction results

In view of the fact that multi-dimensional features will affect the performance of knowledge tracing, we explore the impact of different features on the performance of the model by adding them into the model. The results are shown in Table 3. It can be seen that the effect of ERAKT, which integrates multi- dimensional features, is significantly better than other models which only add semantic features or concepts features. It is worth mentioning that all the models we mentioned above perform better than the original DKT model.

Table 3. The influence of multi-dimensional features of exercises on the prediction results

None	DKT	0.79
Semantics	DKT+Doc2Vec	0.8266
	DKT+Bert	0.8325
Concept	DKT+Concept	0.83
Multi-dimensional features	DKT+Bert+Concept	0.8463

From a semantic point of view, no matter which method (Doc2Vec or Bert) is adopted to obtain the exercise representation, the results after embedding the method have been greatly improved, which shows that the text content of the exercises does have a non-negligible impact on the prediction result. From the perspective of concepts, the addition of conceptual features, while not much improved, was still about 1% higher than the original knowledge tracking method.

In order to better eliminate the influence of the data set division ratio on the results, 60%, 70%, 80% and 90% of the data set are applied as the training set, and the rest as the test set. As shown in Figure 4, the result is consistent with the performance of 70% division, with both AUC and ACC increasing and RMSE and MAE decreasing as the data set increases, which proves that the increase in the training set can Enhance forecasting effect.

4.3.3 The impact of association on the prediction results

After the experiment proved that integrating exercises representation can improve the accuracy of prediction, we then designed a comparative experiment to explore the impact of exercises association in predicting.

Table 4. The influence of exercise association on prediction results

RNN	LSTM	GRU	BI-LSTM
0.8463	0.8543	0.8637	0.9065

After we integrate exercises representation, we chose different time series modeling methods to model and predict student's responses. A comparison of the more commonly applied RNN [18], LSTM [19] and GRU [20] with the Bi-LSTM used in our method is shown in table 4. It can be seen that RNN is the worst performer, with LSTM and GRU in the middle, and Bi-LSTM the best. It proves that exercises association has a great influence on the prediction performance.

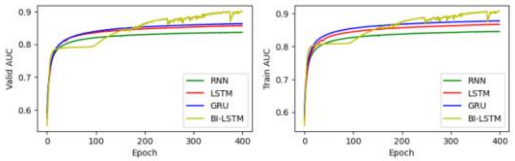

Figure 5. Auc and Loss convergence fluctuation diagram after adding exercise association

We have drawn the model convergence of the four time series modeling methods. It can be seen that the Bi-LSTM fluctuates slightly, and the model convergence curves of the other three methods are relatively smooth.

5. CONCLUSION AND DISCUSSION

In our proposed method, we propose a new context-aware KT method that integrates mathematical exercise representation and association of exercises, through which we can predict the performance of a student on the exercises, thus helping teachers to adjust their teaching plans dynamically.

Experiments have verified the effectiveness and reliability of our method. It can be seen from the experimental results that the prediction results are significantly improved after integrating multi-dimensional features and exercise association.

As for the exercise semantic representation, Bert can obtain more exercise information, which is better than Doc2Vec after integrating. This is because Bert realizes the processing of data of time series through the attention mechanism and it supports parallel computing, which is validated in Bert [8]. In the case of sufficient resources, the computing speed of Bert will be much faster than LSTM, and the residual network which inside of Bert can prevent the network structure from being too complicated. It makes the model perform better.

In the aspect of exercise association, in section 4.3.3, we use four different time series modeling methods, in which the Bi-LSTM exploited in ERAKT method has the best effect, then GRU's performance is relatively well among the remaining three. This is because of the internal structure of them. LSTM and GRU can solve the problem of long-term memory and can avoid the problem of gradient disappearance in RNN. Compared with LSTM, GRU can reduce the risk of over-fitting. Therefore, GRU has the best prediction performance and RNN is the worst, this conclusion can also be obtained in LSTM [19] and GRU [20]. But all of them three can not get the association between exercises.

The bidirectional structure of Bi-LSTM not only preserves the past information, but also the future one. Therefore, all the content can be effectively used to obtain the association between the exercises, which greatly improves the accuracy of prediction.

6. FUTURE WORK

At present, our research has achieved phased results, which can be applied in the actual teaching environment to assist teachers in teaching activities. Our future work will focus on two aspects:

(1) Explore knowledge tracking model that integrates multiple knowledge concepts, and at the same time integrate the sequence association between them.

(2) Show the students' mastery of each knowledge concept systematically. So as to to improve the accuracy of prediction, systematically promote it to facilitate the teaching work of teachers.

ABSTRACT

Gaining insight into course choices holds significant value for universities, especially those who aim for flexibility in their programs and wish to adapt quickly to changing demands of the job market. However, little emphasis has been put on utilizing the large amount of educational data to understand these course choices. Here, we use network analysis of the course selection of all students who enrolled in an undergraduate program in engineering, business or computer science at a Nordic university over a five year period. With these methods, we have explored student choices to identify their distinct fields of interest. This was done by applying community detection (CD) to a network of courses, where two courses were connected if a student had taken both. We compared our CD results to actual major specializations within the computer science department and found strong similarities. Analysis with our proposed methodology can be used to offer more tailored education, which in turn allows students to follow their interests and adapt to the ever-changing career market.

Keywords

Community detection, higher education, Louvain method, bipartite networks, student network, course selection

1. INTRODUCTION

University students enter higher education with a plethora of courses to choose from on their path to graduation. Gaining insight into student choices holds significant value for universities, especially those who aim for flexibility in their programs and those who wish to adapt quickly to changing demands of the job market. For example, the fast rise in popularity of machine learning over the past years could impel universities to make machine learning and related courses readily available to their students. In contrast, more subtler trends could be directly identified by the students' choices rather than an obvious shift in the job market.

Numerous studies based on questionnaires and surveys have found that there are various components that contribute to a student's course selection [2, 19, 20]. These are factors such as learning value, workload, age and academic performance [2]. Of these, the learning value of the course (which refers to factors such as intellectual level and interest in the topic) has been found to be the most influential factor in course selection. Course selection has also been a target in studies aiming to understand the gap between student mindsets and career demands [20]. Maringe [19] found that although intrinsic interest was important, course choices depend mainly on future career goals. According to the author, universities may need to adapt their strategies to the idea that students' course choices now seem to reflect their expectations of future employment rather than simply interests. Thus, universities would benefit greatly from a deeper understanding of the path their students choose towards their degree.

Educational data mining (EDM) has risen as a new field to answer these and other questions about students and their learning environment. It utilizes a variety of analytical methods and applies them to the vast amounts of data that has become available with increased digitization of administrative educational information. For example, EDM methods have already been applied to try to accurately predict college success using common classification algorithms with different feature sets [31]. They have also been used to analyze student clicking behavior in online courses to determine students' learning strategies and how those strategies can have an impact on their learning outcomes [1], as well as to predict student dropout [10]. One area of educational stud-

ies that has not received much attention is student course selection, despite its importance in understanding student interests and preparing them for a future career [28].

In this paper, we aim to reveal patterns in course selection through EDM, providing a new data-driven technique based on institutional analytics to gain insight into students' interests that would otherwise be difficult to discern. This knowledge can then be used for monitoring student interests and ensuring that courses reflecting those interests are available. We examine whether network analysis applied to students' course data, with a focus on community detection (CD), can effectively be used to identify university students' fields of interest. To accomplish this, we use a weighted projection network in combination with CD to explore student course selection. We focus on communities of elective courses for different majors and compare them to some of the official specializations the university already has to offer. Deeper understanding of students' choices is a stepping stone into allowing students to take more control over their studies, improve flexibility in the curricula, and facilitate students' pursuit of their interests.

2. RELATED WORK

A promising method for EDM is to represent educational data as networks. In general, networks consist of nodes and edges, where the nodes can for example represent people, countries or cells, and edges represent connections between nodes based on factors such as spatial and temporal proximity or social connections such as friendships [12, 8]. Network analysis is used to look at internal characteristics and the connections and patterns of nodes and edges, providing the ability to better understand the fundamental structure of networks and the real-life phenomena they model [29]. Different methods can be used to analyze networks, for example by looking at structural characteristics such as centrality, which indicates the importance of any given node in the network by assuming nodes that are more central have higher control over information passed through the network [8]. Community detection is another common way of analyzing networks which allows for the aggregation of different nodes into communities based on shared characteristics by identifying groups of nodes that have a high number of edges within themselves but fewer edges to other groups [12].

A common application of network analysis in educational settings is to understand social connections between students. This has helped reveal the negative effects of student interdependence in music education programs and its relationship to the program's friendship networks [26], as well as identifying how positive and negative friendship ties emerge [27]. Network analysis has also helped clarify the relationship between students' social networks and the development of their academic success [6, 14]. Furthermore, looking at students' social networks over time, close coequal communities are typically formed early on [30], although in some cases, students enhance their performance due to social relations outside their assigned group [24].

Although students' social networks have been studied, the exploration of students' course choices through network analysis has few precedents. Within the EDM field, Kardan et al. [16] used neural networks to predict course enrollment based on various factors such as course and instructor characteristics, and course difficulty. Further, Turnbull and O'Neale [28] used network analysis with CD and entropy measures to explore enrollment in STEM courses at the high school level. Among other results, they revealed that indigenous populations showed higher levels of entropy in their enrollment patterns, which was moderated by adolescent socioeconomic status. Neither of these studies focused on detecting student interests from course selection patterns.

3. METHODS

3.1 Data Source

Here, we use student and course data from Reykjavík University (RU). The university offers many different areas of study, including preliminary studies, undergraduate and graduate degrees. Most RU students are undergraduate students, and the RU undergraduate programs also offer the most variety of courses. Generally, the majority of RU undergraduate programs' courses are mandatory. These are the core courses each department decides is essential to their study program. The rest of the courses are either free choice electives, which can be any course in the university that the student qualifies for, or restricted elective courses from a selection tailored to the specific major.

We sample data from all graduated RU students that enrolled in the year 2014 or later and completed undergraduate programs in engineering, business, or computer science (CS) before 2021 (the total number of students was 1481). The university offers other programs as well, but we left them out since they have fewer students. The variables we look at include the student's registration ID and registration semester, the name and semester of each course a student has completed, and whether they passed or failed the course. We also include each student's department, major, and type of study (undergraduate, graduate, etc.).

To anonymize the data, we remove anything that could identify students, specifically their social security number and a numerical registration ID and give them a unique random sequence of numbers to replace both original numbers. For each student, we also remove any courses that they had de-registered from early in the semester. Further, for each major, courses taken by fewer than 5% of students are considered outliers and removed.

3.2 Network Analysis

3.2.1 Bipartite networks

We apply network analysis to the data to explore the fields of interests of RU students from a data driven perspective. Many real-world networks have a bipartite structure, where nodes belong to one of two groups or divisions and edges connect nodes of opposite groups without within-group edges [3]. In our bipartite network, the students make up one division of the nodes, and courses the other. If a student has taken a course, an edge is created between the respective nodes. Since edges represent that a student has taken a course, there is no edge between two students nor between two courses (see Figure 1, left).

Although bipartite networks give a more realistic and detailed representation of the system, analyzing them can be

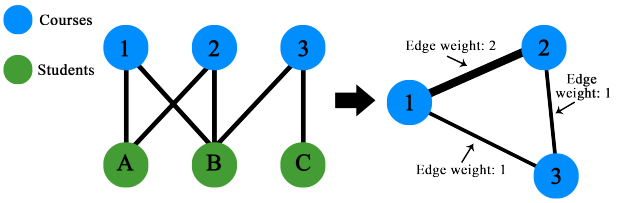

Figure 1: From bipartite network to weighted projected network. Left: a bipartite network, where the blue nodes represent courses and the green nodes, students. Right: a unipartite network has been obtained from the bipartite network, where the nodes are courses and the edges have weights that determine how many students have taken both courses.

complex. Therefore we project the bipartite network onto its unipartite counterpart (see Figure 1, right) [3]. This leaves a network with one type of nodes that can be analyzed with typical network methods. The resulting projected network consists of nodes representing the courses and edges between two nodes indicating that a student has taken both courses. We assign weights to the edges to represent the number of students who have taken both courses (see Figure 1).

A base problem with projection of bipartite networks is that a lot of important information in the original bipartite network is lost. Thus, we may end up connecting all courses in the network to each other –and form a clique– as long as they have at some point been taken by the same student, without taking into account how many students connected the two courses in the original bipartite network. Here, we address this by assigning weights to the edges in the projected network [3], where the weights represent the number of students who have taken both courses (see Figure 1).

3.2.2 *Community detection*

Building on the weighted projected networks, we use CD with the objective of inferring fields of interests in students' course selection. To identify fields of interest, we want to emphasise electives. However, in our data set, the information on which courses are mandatory and which are electives is incomplete. Mandatory courses along with very popular electives appear in the network as hubs, which usually occur in real-world networks as nodes with much higher degrees and edge weights than the other nodes [4]. We therefore define hubs in a data driven way, where a node is a hub if its total edge weight is at least one standard deviation above the mean edge weight of all nodes. We remove hubs from the network based on this definition.

Next, we apply the Louvain algorithm for CD [7]. This is an established, computationally efficient, fast converging method that produces accurate communities with high network modularity, especially in smaller networks [7, 17, 12, 23]. It has been successfully applied to identify communities of intrinsic brain systems [9], and to help create friend lists for Facebook users [18]. Modularity, is a measure of edge density within a partition (or proposed community) as opposed to edge density between partitions, whereby a higher modularity suggests a more cohesive community, separate from the others in the network. Importantly for our analysis using weighted projected networks, the Louvain algorithm can be used both with weighted and unweighted edges. The method starts by assigning each node to its own community [7], as seen in Figure 2. It then iterates over all nodes of the network and assesses the modularity gain obtained by assigning the node to the same community as each of its neighboring nodes. Next, the node is assigned to the community that yields the largest positive modularity gain, or maintains its current community if no positive modularity gain can be achieved by switching communities. This way, each new community assignment brings us closer to optimal modularity. The nodes are usually considered multiple times and the final iteration is determined when no switch leads to a gain of modularity, resulting in optimal partitioning of the network. This optimal partitioning is a local maxima, as the result is influenced by which node is considered first and the order in which nodes are visited. For some communities, we re-apply the Louvain algorithm for more detailed results, while using the inter/intra weight density ratio described below to ensure our communities maintain high quality.

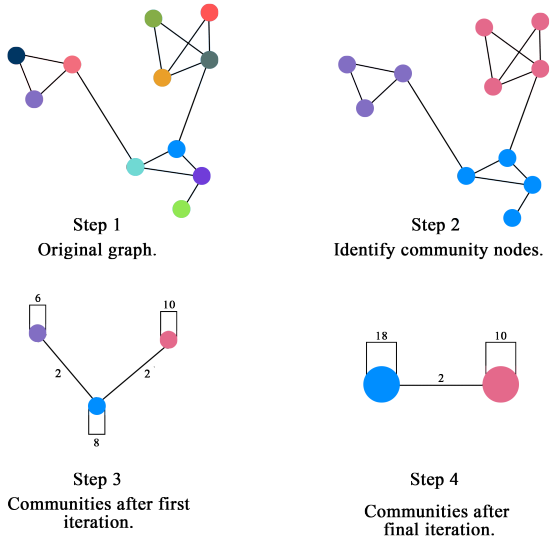

Figure 2: The Louvain algorithm. The first step of the algorithm is to assign each node to its own community. In step 2, a random node is selected to start the community aggregation process. All nodes are visited and allocated to the community of one of their neighbors or maintain their current community, depending on which choice gives the highest gain in modularity for the network. When no more modularity gain is possible in the network, step 3 is to aggregate the nodes of each community into new super-nodes. Here, the numbers given show the sum of node edges within and between supernodes. Steps 2 and 3 are then repeated until modularity has been optimized, as seen in step 4.

3.2.3 *Community validation*

Although the objective of CD is to split nodes into groups based on their connections within versus outside the group, there are many more aspects to consider [12]. One important factor is intra-cluster density, which refers to how many edges there are within the community as a ratio of how many possible edges there could be if all nodes of the community were connected to each other. This is contrasted by inter-

cluster density, which shows how many edges go from the community to the rest of the network as a proportion of the maximum possible connections. High intra-cluster density may suggest a strong and cohesive community, however if it coincides with equally high inter-cluster density, it may simply suggest a strong and cohesive overall network.

To assess the quality of our communities, we use intra and inter weight density [13]. This is the same as intra and inter edge density previously described, but now accounting for weighted edges. The two are defined as follows:

$$WD_{\text{inter}} = \frac{w_C^{\text{ext}}}{\bar{w} n_C (n - n_C)} \text{ and } WD_{\text{intra}} = \frac{w_C^{\text{int}}}{\bar{w} n_C (n_C - 1)/2},$$

where w_C^{ext} is the sum of edge weights connecting the community to the rest of the network, or external community edges. We divide this by the estimated total edge weight of the network, which shows the edge weight going from the community to the rest of the network as a proportion of the maximum possible edge weight (assuming that the average edge weight of the fully connected network were unchanged). Here, $\bar{w}$ is the average edge weight of the network, n is the total number of nodes in the network and n_C is the total number of nodes within the community. Similarly, w_C^{int} refers to the sum of edge weights inside the community, which is divided by the expected total edge weight within the community. We then use a ratio of these two measures (WD_{inter} / WD_{intra}) to obtain the community strength on a scale where 0 is the strongest value, indicating a community that is disconnected from the rest of the network, and a value of 1 indicates a community equally connected within itself as to the rest of the network. We call this measure *density ratio* and use it not only to determine the community strength, but also to ensure that as we create smaller and more focused communities, community strength is not compromised.

3.2.4 Comparing communities and specializations

To further assess the real-world application of the communities we detect, we compare them to specializations within RU's Computer Science (CS) department, described in Table 4 in the Appendix. Any student who pursues an undergraduate degree in CS at RU has the option to graduate with a specialization in a certain field. The specializations do not need to be declared at enrollment but any student who fulfills the requirements can choose to add this to their graduation certificate. The specializations offered are Artificial Intelligence, Law, Web- and User Experience (UX) Design, Sports Science, Game Development and FinTech. Each specialization has 2-4 core courses that students need to complete, along with 1-3 courses from a pool of specialization-specific electives. Our approach to defining fields of interest is purely through data driven CD. Comparing the detected communities with these specializations helps validate the results and perhaps provide a reference for the creation of new specializations. We compare both the courses in each community and specialization, and the number of students belonging to a specialization versus those belonging to the corresponding community. We define a student as belonging to a community if they have taken at least 50% of the community's courses, with a special case of two course communities where both courses have to be completed.

3.3 Tools

Aside from the initial retrieval and anonymization of data, which we do using C# and SQL, all code for the data analysis was written in Python 3.9. We use multiple Python libraries to help with the data analysis. For our network analysis, we mainly utilize the NetworkX library [21]. For more general data manipulation, we use the pandas library [22]. We used Gephi for the majority of our network visualization [5], along with the Matplotlib library [15].

4. RESULTS

4.1 Communities that Reflect Interest Fields

We conducted CD with the Louvain algorithm on three undergraduate majors: engineering, business, and computer science. These majors have quite different program structures and emphases on electives, with the business major having the lowest number of elective courses allowed in their study plan (four electives). This is followed by the CS major with 11 electives and finally engineering, which offers only four free electives but nine "guided electives" (that is, nine electives must be specific to engineering), depending on the chosen engineering specialization.

We first look at the communities for the engineering department, see Figure 4 and Table 2 in the Appendix, which after hub removal consisted of 81 courses taken by 496 undergraduate students. Reykjavík University offers various undergraduate engineering programs such as biomedical engineering, financial engineering, and mechatronics engineering. These engineering majors all fulfill the same core courses in addition to some additional major-specific requirements. These majors are quite structured and offer few free elective courses. Due to the similarity in the core courses of these programs, we group them together into a more general engineering major. This means that the hub removal method removed general core engineering courses but leave most specialty-specific courses in the network. The resulting engineering network has 81 course nodes and 2614 edges. The weighted average inter/intra weight density ratio is 0.24. This suggests that hub removal was effective and the average community is relatively strong. The communities we have detected were eight in total as seen in Table 2. Note that communities are named after common characteristics between the majority of the courses, even though rarely all courses of a community fall within that definition. As expected, these communities mainly correspond to the official engineering majors such as financial, biomedical, and electrical engineering, with electrical engineering being our strongest community (WD_{inter} / $WD_{\text{intra}} = 0.05$). However, we also observe unrelated communities that supersede the official majors, such as a community of applied design and another for business related courses not mandatory in the financial engineering major. Courses in these communities are commonly taken together by engineering undergraduates, suggesting a common interest not credited to the specialized majors.

There are 334 undergraduate students in our data set who majored in business. For this major, the network consists of 36 course nodes and 504 edges, with a weighted average WD_{inter} / WD_{intra} of 0.25, again suggesting strong communities, see Figure 5 in the Appendix. This is not unexpected, as the business major only allows electives in the final year,

giving business students less room to pursue distinct interests outside their core subjects. Table 3 in the Appendix shows the five communities identified within the business major. The strongest community is that of popular courses,

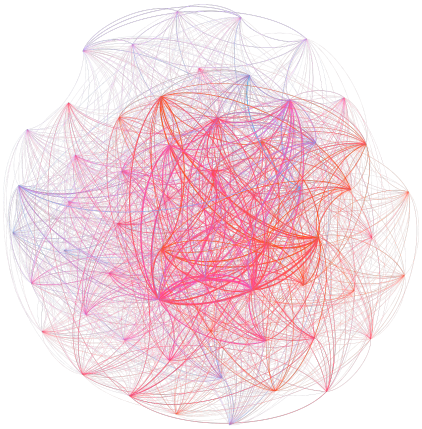

Figure 3: The network with communities for the BSc program in CS.

Table 1: Community detection results for BSc in CS.

	Community	No. courses	Density ratio
●	UX and Business	15	0.25
●	Engineering	13	0.17
●	Web and Software	10	0.20
●	Artificial Intelligence	7	0.39
●	Deprecated Courses I	6	0.08
●	Game Development	4	0.10
●	Deprecated Courses II	4	0.23
	Weighted average		**0.21**

which includes the most common electives in the business majors along with a handful of newer core courses (WD_{inter} / $WD_{\text{intra}} = 0.07$). These core courses were recently added to the study plan, meaning that they were only mandatory for a minority of the students in our data set. This is why these core courses were not identified as hubs and removed during hub removal. The business major also contains the weakest community of all the majors, management (WD_{inter} / $WD_{\text{intra}} = 0.71$). As the name suggests, this community includes various courses on management, such as service management and project management. The low inter and intra weight density ratio is interesting, as intuitively these courses would seem very connected. This is why measuring community strength is vital in determining the importance of the detected communities. The other business communities are both strong and reflect more specific interests, suggesting that there are students of the business major who actively seek distinct interests despite the program having no official specializations. The last major we explore is CS, with 377 students. Computer science has the least structured study plan of the three majors, as it puts a higher emphasis on unstructured flexibility and free electives. The CS course network consists of 59 nodes and 1492 edges. The communities (see Figure 3 are the strongest we found, with a weighted average WD_{inter} / WD_{intra} of 0.21. Most, but not all, detected communities seem to reflect an interest in a CS sub-field. However, the strongest community we have discovered was Deprecated Courses I (see Table 1), which represents older courses that may have been core courses at some point but are no longer being offered (WD_{inter} / $WD_{\text{intra}} = 0.08$). We conjecture that this community exists as some older students re-register to complete their undergraduate degree, for example after previously completing a CS diploma or taking a longer study break. It is therefore very intuitive that this specific sub-field is combined into our strongest community. Aside from communities based on deprecated courses, the other communities suggest that there is in fact an underlying pattern of interest fields present in the CS major, as observed for the other majors explored here.

4.2 RU Communities and Specializations

As a final validation of the communities we have detected for the CS undergraduate major, we now cross-reference our results with the actual specializations available for CS students. Unlike the other majors, CS offers a number of specializations meant to aid students in pursuing a specific subfield (see Table 4 in the Appendix for a short description of each specialization). However, only a subsection of students choose to do this. Of the students who graduated between 2014 and 2020, inclusive, only 9.5% fulfilled the requirements for a specialization. A further 13% partially fulfilled a specialization's requirements, by completing at least 60% of the specialization's core courses and 60% of the restricted electives needed.

Comparing the specializations and the communities we detected (shown in Table 1), we find interesting similarities. Our CD reveals that some communities are consistent with the specializations, but there is no absolute match. For the AI specialization (taken by 11 students, or 29% of those who graduated with a specialization), there is a partially corresponding community that includes both of the AI core courses (Artificial Intelligence and Machine Learning). There are 28 students who belong to this community, making it more popular than the official AI specialization. Although this community does not include any of the other courses from the specialization, it does include more theoretical and academically demanding courses than most other communities, suggesting a reflection of interest in theoretical computer science in general rather than specifically AI.

To fulfill the official AI specialization requirement, students must complete two core courses and three or more courses from a list of specialization-specific electives. However, in our data set most of these other electives were removed during either data cleaning (where we removed courses taken by fewer than 5% of students) or during hub removal and are therefore not part of any community. Interestingly, two of the remaining electives overlap between the AI specialization and that of Game Development. Both these courses have been sorted by our algorithm into a community that reflects Game Development much more strongly than AI, with 67 students. This is intriguing, as we know that students are much more likely to specialize in Artificial Intelligence than Game Development (only one student in our data set fulfills the requirements for Game Development), but this indicates that the gaming sub-field of Artificial Intelligence may be the

biggest area of interest for these students.

The final specialization for which we discovered a similar community is Web and UX design, which was by far the most popular specialization taken by students (with 23 students, or 64% of all students who had a specialization). While this specialization encompasses both web programming and user experience, the corresponding community of Web and Software Development (with 84 students) is much more web than UX specific. Most of the UX related courses belong to a separate community of 21 students that unites UX and business rather than UX and web design. This suggests that dividing the Web and UX design specialization into two distinct specializations (Web design and UX design) might be more appealing to students. Interestingly, the remaining four official specializations have no corresponding community in our results. This was to be expected, as these remaining specializations are very rarely pursued by students. That is, the communities we have detected are able to represent the specializations that students are actually choosing, but did not reflect other specializations. This is exactly what we expect of CD, with the added bonus of identifying fields of interests that may not have been previously considered.

5. DISCUSSION AND CONCLUSION

With this project, we aimed to find whether CD could be used to effectively identify students' fields of interest at RU. To maintain the scope of the results, we have presented only the findings for undergraduate majors in engineering, business, and CS. Our resulting communities vary slightly in strength and size, yet almost all of them contain courses of a general theme that seem to indicate that they do in fact reflect fields of interest. This builds on the results found by Turnbull and O'Neale [28], who performed CD on a similar school course network, but without hub removal. This resulted in much more general course communities that demonstrated important but slight differences in the overall majors. In focusing on fields of interests, removing the hubs has allowed us to increase the granularity of the resulting communities while still maintaining community strength and cohesion. However, one of the commonalities between these majors is that the largest community detected usually included the major's most popular courses, be that electives or new mandatory courses our hub removal does not consider. As Fortunato [13] suggested, using the inter/intra weight density, we were able to evaluate the quality of the communities that were detected with the Louvain algorithm.

The communities we have discovered encapsulate various distinct areas of interests for the different undergraduate majors RU has to offer. Additionally, for the CS department, we have verified that the detected communities also reflect the main areas students choose to specialize in, which further validates our findings. To our knowledge, applying CD in this way and for this purpose has not been done before. This provides an exciting new tool for universities to better understand their students' aspirations.

In improving knowledge of student course selection, we provide academic institutions with more tools to increase study flexibility for their students. This knowledge can then be used to decide which courses the university wants to offer. This knowledge is also useful for academic counselors when helping students to discover their own field of interest. Based on previous studies, we assume that interest is the main motivation behind course choices [2, 19]. However, these communities may be based on other factors. Examining the characteristics of courses that make up different communities might reveal other factors that contribute to course selection, such as course difficulty, grading, teacher characteristics, and more [25, 2, 19].

Although we were able to successfully apply network analysis to our student and course data, there were a few setbacks. One drawback in our analysis is the fact that although RU's administrative data has largely been digitized, this has not always been done in the most structured and data-mining friendly way. For example, all information on specializations was retrieved directly from RU's website and formatted manually, as this information is not stored in the university's data warehouse. Reliable information on the mandatory courses of each major was also not available, which was why we decided to use data driven hub removal. Improving data availability, centrality and consistency is currently a priority at RU, but should also be considered by other universities wanting to take full advantage of EDM methods.

Our findings show that network analysis with CD is a useful tool in understanding students' course selection. The course choice patterns found here can still be explored further. For example, the current results are based on data from students who enrolled in the same program at different times. Thus any small changes in the program structure between years can introduce noise in the data. Looking at individual registration years, perhaps including a larger university with more students, could give clearer results. Further, it would be interesting to repeat the same analysis over separate periods to discover changes in interest fields over time. Finally, it was out of the scope of the current paper to analyze trends based on more detailed characteristics such as gender, age or grades. Augmenting the communities with these factors could for instance provide a tool to identify differences in choices made by students who graduate successfully and those who struggle more with their studies, perhaps yielding an opportunity for early intervention.

Educational data mining is an exciting new field with the potential to greatly influence educational institutions and their students going forward [11]. This project aimed to reveal how network analysis could be used to enhance student course selection by improved understanding of students' academic interests. Our analysis has successfully led to meaningful results that could easily be replicated by most interested universities with digitized information. Coupling this increased understanding of student interests with added academic support gives universities the tools to raise flexibility within majors while maintaining educational quality. Hopefully, this and other research in the field can be used to offer more tailored and student-led education, which in turns allows students to follow their interests and easily adapt to the ever-changing demands of the job market.

6. ACKNOWLEDGMENTS

We appreciate the contributions made by Kolbrún Eir Óskarsdóttir who had a big impact on the conceptualization and development of this research.

	Asset Management	4	0.36
	Weighted average		**0.25**

Table 4: Official specializations in the CS program.

Name	Description
Artificial intelligence	Core courses reflecting an interest in AI and machine learning, with electives focused on game development and analytical skills.
Game design	Core courses encompass game development in general, computer graphics and game engine architecture. Electives reflect more general programming skills and AI.
FinTech	Both core courses and electives focus on the financial part of the Financial Technology discipline, as all students taking these courses gain software development skills from the core courses of the CS major.
Web and UX design	As the name suggests, most courses for this specialization directly relate to either web programming (such as the courses Web Programming II and Web Services) or user experience (User-Focused Software Development, Human-Computer Interaction).
Psychology	Core courses in psychology that emphasize cognitive processing and research methodology. Any other psychology courses can then be chosen as electives.
Law	General law courses with some emphasis on intellectual property rights and negotiations.
Sports science	General sports science courses.

Automated Claim Identification Using NLP Features in Student Argumentative Essays

ABSTRACT

The current study explores the ability to predict argumentative claims in structurally-annotated student essays to gain insights into the role of argumentation *structure* in the quality of persuasive writing. Our annotation scheme specified six types of argumentative components based on the well-established Toulmin's model of argumentation. We developed feature sets consisting of word count, frequency data of key n-grams, positionality data, and other lexical, syntactic, semantic features based on both sentential and suprasentential levels. The suprasentential Random Forest model based on frequency and positionality features yielded the best results, reporting an accuracy of 0.87 and kappa of 0.73. This model will be included in an online writing assessment tool to generate feedback for student writers.

Keywords

Argumentation, Claim identification, Argumentative writing

1. INTRODUCTION

Written argumentation has been an important area of study for many years [43, 45]. Recent developments in natural language processing (NLP) have introduced new approaches to automatically detect the discourse structure of argumentative essays [7, 8, 9, 10, 26, 33, 34, 38, 44, 45]. These studies have shown that content (i.e., lexical, syntactic, and semantic) and structural features (i.e., the positionality of tokens, sentences, and paragraphs) are effective in detecting discourse elements.

Researchers have used fixed discourse markers at the word and phrase levels [5, 12, 18, 42] as indicators of different argumentative structures. This approach has been applied in discourse [17, 19, 22] and NLP analyses [7, 8, 9, 47]. These studies generally identify relations between discourse markers and their functions according to the conceptual framework of conjunctive relations [36]. For instance, phrases such as *in summary* and *in conclusion* are associated with the discourse function of 'summarizing' an argument. Such discourse markers have been used to identify the attributes of the structural elements in argumentative essays [8, 9, 36, 37]. For example, Burstein et al. [7] annotated structural information of argumentative essays collected from TOEFL, GRE, and GMAT. Discourse markers indicating each of the argumentative functions were extracted automatically from the essays. A word list that contained the discourse markers and their corresponding argumentative functions was formed and used to automatically predict instances of argumentation. Similarly, Palau and Moens [37] implemented a context-free ruled-based approach for argumentation mining in legal texts. They focused on and developed rules based on common expressions encountered in the legal documents such as *for these reasons*, *in light of all the material*, and discourse markers, such as *however* or *furthermore*. Using this approach, they obtained accuracy of approximately 0.6 in detecting the argumentation structures, while maintaining F1-measure of around 0.7 for recognizing premises and conclusions in legal texts.

In more recent work, Stab and Gurevych [44, 45] provided publicly available corpora comprising students' argumentative essays and annotation guidelines for parsing argumentations. In these corpora, the essays were annotated based on three major argumentative categories: major claim, claim, and premise. They then used lexical, structural, syntactic, discourse markers, and other features to identify argument components. The lexical features consisted of binary lemmatized unigrams and the 2,000 most frequent bigrams extracted from a training corpus. The structural features captured the position of components in the text and the number of tokens in those components. Discourse markers included logical connectives such as *therefore*, *thus*, or *consequently* and the use of first-person pronouns (which indicated major claims). The syntactic features included part of speech (POS) distributions, number of sub-clauses, and the tense of the main verb. Using support vector machine models, Stab and Gurevych [45] found that a combination of all these features yielded an F1 score of 0.77. Khatib et al. in [3] employed a classifier for argumentativeness based on the research in [37, 44, 45], and evaluated its performance on student essays from [44]. Khatib et al. used n-grams, syntax, discourse makers and part of speech (POS) features in an argument. Their results indicated that a combination of n-grams, POS tags, and syntax features yielded accuracy of 0.64, 0.62, and 0.59 on classifying arguments in students' essays, while the full feature set model yielded an accuracy of 0.67. Though only unigram through tri-grams were included in the POS feature.

Though the use of discourse markers, n-grams and POS as indicators has been common in the detection of argumentative elements, few studies have examined whether using longer

Qian Wan, Scott Crossley, Michelle Banawan, Renu Balyan, Yu Tian, Danielle McNamara and Laura Allen "Automated Claim Identification Using NLP Features in Student Argumentative Essays". 2021. sequences of n-grams (beyond tri-grams) and their POS tags would contribute to identifying argumentative features. We also note that other types of linguistic features related to lexical, structural, cohesion, and affective features were not tested in previous studies [e.g., 37, 45]. Therefore, this study explores a wider range of NLP features, and examines their contribution to model accuracy. We do so specifically on a corpus of student essays annotated on theoretically-aligned classifications of argumentative elements expected in academic settings. This is in contrast to most of the existing corpora in English that are annotated for argumentative structures and are from the domains of law [e.g., 4, 37], biology and medicine [e.g., 20], and user-generated content, e.g., Wikipedia articles or debate data, see [1, 2, 27, 41]. Few corpora [44, 45] have been developed for argumentation mining in the educational settings. In this study, we build on Stab and Gurevych's work [44, 45] by developing a structurally annotated corpus based on the Toulmin model [46] of argumentation that better reflects the structure of student essays. Our objective is for the corpus – and the models of argumentation developed from the corpus – to contribute to the development of writing assessment tools that can deliver useful feedback to student writers.

Thus, in this study, we introduce a new corpus of essays annotated for argumentative features. We then develop NLP approaches to automatically identify claims in structurally annotated argumentative essays using length, frequency data of significant n-grams and POS tags, positionality data, and a wide range of lexical, syntactic, cohesion, and cognitive features extracted from a number of NLP tools [14, 15, 25, 24]. We compared the identification accuracy of multiple machine learning classifiers using different types of derived features at different levels (based on sentences or argumentative elements that are suprasentential). Our goal is to better understand whether and how the selection of the linguistic features, the level of units for identification (both sentential and suprasentential), and the choice of classifiers influence the accuracy of claim identification. Finally, we conduct an error analysis of the best model and discuss the distribution of the misclassification instances and related features. This study is guided by the following research question:

To what extent do length, frequency of significant n-grams (and POS tags of n-grams), lexical, syntactic, and semantic features, and positionality predict argumentative claims in essays?

2. METHOD

2.1 Corpus

For the analysis, we annotated 314 persuasive essays. The essays were written by undergraduate students (N = 314) at a public university in the United States who were native speakers of English. Two prompts from retired test banks of the Scholastic Assessment Test (SAT) were used. The prompts were counterbalanced such that half of the students wrote about 'originality and uniqueness' while the other half wrote about 'heroes versus celebrities.' All essays had been scored previously by expert raters for holistic writing quality. For each essay, we extracted the average number of letters per word, the number of words, number of types, type-token ratio, average number of words per sentence, the number of sentences and paragraphs. Descriptive statistics for these items of the 314 essays are reported in Table 1.

Table 1. Descriptive statistics of the persuasive essays

	Mean	SD	Median	Range
Letters per word	4.52	0.24	4.51	1.50
Number of words	354.46	118.20	344.00	680.00
Number of types	178.17	50.01	173.00	279.00
Type-token ratio	0.52	0.07	0.52	0.41
Words per sentence	17.74	4.30	17.06	35.08
Number of sentences	20.65	7.42	20.00	48.00
Number of paragraphs	3.86	1.38	4.00	7.00

2.2 Annotation of argumentative elements

The essays were structurally annotated by normed raters for argumentative elements. We used the modified Toulmin models [46] presented in [35] and [30] as the basis for the annotation rubric. The rubric adopted six elements (i.e., micro-categories) as the building blocks of the argumentation framework: Final Claim, Primary Claim, Counterclaim, Rebuttal, Data, and Concluding Summary. The definitions of each of these elements are presented in Appendix A.

The essays were coded by two annotators on the web-based text annotation platform 'Tagtog'[1]. The two annotators were both native speakers of English and were undergraduate students majoring in applied linguistics at a public university in the United States. Before independent annotation, a norming process was conducted to help ensure consistency in annotations. Once normed, the two annotators worked independently and coded the 314 essays in the opposite order to avoid recency effects.

The two annotators made decisions on both the boundary of an argumentative element and the category of the element. An argumentative element was inherently suprasentential (i.e., according to the annotation scheme derived from the norming session, it could contain one or more sentences, and the content could be over the span of paragraphs). Inter-rater reliability calculated using Fleiss's Kappa for all the annotations was 0.584 (p < 0.001), indicating fair to good agreement [16]. Disagreements of either boundary or category of the argumentative elements between the two annotators were adjudicated by an expert adjudicator who had years of experience teaching and conducting writing research. In the case of disagreement, the expert adjudicator compared the annotations from both annotators and made the final decision for both the boundary and the category of the argumentative element.

The current study focuses on the identification of claims versus non-claims, mainly because of the small sample size of the corpus and the distribution of micro-categories. Thus, we combined the categories of Final Claim, Primary Claim, Counterclaim, and Rebuttal into a single category of claims. The remaining categories of Data and Concluding summary were classified as non-claims as was any non-annotated text.

[1] https://www.tagtog.net

2.3 Training and test sets

Annotation of the data led to the classification of 2264 argumentative elements. As mentioned in Section 2.2, the argumentative elements were inherently suprasentential. We further split the elements into sentences to determine whether this influenced accuracy. All sentences from the same argumentative element were given the same annotation as the original category (i.e., claims or non-claims). We thus had two data sets: 1) a sentence-tokenized data set (N = 6326) and 2) a suprasentential data set (N = 2264). We randomly selected 70% of the argumentative elements as the training set, and the remaining 30% of the elements as the test set for both datasets. We report the number of argumentative elements, and number of claims and non-claims for the datasets in Table 2.

Table 2. Numbers of elements, claims and non-claims for the training and test sets

Data set	Number of elements	Number of claims	Number of non-claims
Suprasentential training set	1594	639	955
Suprasentential test set	670	267	403
Sentential training set	4401	935	3466
Sentential test set	1925	409	1516

2.4 Features

2.4.1 Word count

We extracted the number of words for each claim and non-claim at the sentential and suprasentential level.

2.4.2 N-gram frequency

We extracted n-grams and the POS combinations of these n-grams for both claims and non-claims. We assume that some n-grams (or POS n-grams) are more likely to identify claims versus non-claims (and vice versa), and the frequency of these key n-grams (or POS n-grams) could serve as good indicator of the type of an argumentative element or sentence. We used keyness values [21] as the measurement of importance of the n-grams or POS n-grams in claims and non-claims. Keyness values can provide evidence of whether n-grams and POS n-grams are more common in one corpus as compared with the other corpus. In the current study, we treated the claims and non-claims as two separate corpora.

Raw and normalized frequency (i.e., normalized by the total number of words in all claims and non-claims, respectively) for each n-gram (or POS n-gram) that occurred both in claims and non-claims were calculated. The keyness value of each n-gram was also calculated based on the frequency data following Rayson and Garside's guidelines [40]. Specifically, if an n-gram or POS n-gram had a keyness value greater than 3.84 (equivalent to $p < 0.05$), and if it had a higher normalized frequency in claims, it was considered more likely to occur in claims over non-claims, and vice versa. The range of the n-grams and POS n-grams was from unigram to seven-grams. NLTK [6] was used to tokenize the texts into n-grams and label the POS for the n-grams. For example, the following phrases *should be*, *would be*, *can be*, and *will be* were converted to the same POS n-gram combination: MD (modal) + VB (verb base). We did not remove stopwords before n-gram tokenization. For each suprasentential and sentential argumentative element in the training and test sets, we calculated the frequency of each type of the significant n-grams or POS n-grams (e.g., bigrams that were significant in claims), and normalized the frequency by the length (word counts).

2.4.3 Positionality of the elements

Beyond n-gram frequency, studies have shown that, the position of argumentative elements is an indicator of their structural function [e.g., 7, 8, 10]. In this study, two types of normalized positional variables for each argumentative element or sentence were calculated as positionality features.

Normalized element or sentence position in an essay was computed as the ratio of the element/sentence position in an essay to the number of elements/sentences in the essay (e.g., if an argumentative element or a sentence was the 5th element or sentence in an essay of 10 elements/sentences in total, the value of this variable would be 5 divided by 10, or 50%). The normalized position of the element or sentence in a paragraph was computed as the ratio of the element/sentence position in a paragraph to the total number of elements/sentences in that paragraph. That means, if an argumentative element or a sentence was the 2nd element (sentence) in a paragraph, in which there were 5 elements (sentences) in total, the value would be 2 divided by 5, or 40%).

2.4.4 Other lexical, syntactic, and semantic features

To explore whether additional lexical, syntactic, cohesion, and cognitive text features increased the accuracy in identifying claims and non-claims, we extracted 925 features for each of the argumentative elements. These features were extracted using the Suite of Automatic Linguistic Analysis Tools (SALAT) [14, 15, 25, 24]. SALAT includes multiple NLP tools including TAACO (Tool for the Automatic Analysis of Cohesion), TAALES (Tool for the Automatic Analysis of lexical Sophistication), TAASSC (Tool for the Automatic Analysis of Syntactic Sophistication and Complexity), and SEANCE (Sentiment Analysis and Cognition Engine). Two-sample t-tests or Wilcoxon's tests were conducted using the variables after removing SALAT variables that were not normally distributed. We then removed those variables where the results of t-test or Wilcoxon's test were not significant between the group of claims and non-claims. Finally, by visual inspection, 20 out of 131 variables that were relevant to argumentative elements were selected. Hand selection of variables was done to avoid problems of overfitting. The selected NLP features and their descriptions are presented in Appendix B.

2.4.5 Feature reduction

To avoid multicollinearity, we conducted correlation analyses among all the derived features (one versus all) for the two training sets, respectively. If two or more variables correlated with $r >$ 0.699, the variable(s) with the lower correlation with the category of the argumentative element/sentence were removed, and the variable with the higher correlation was retained. The feature reduction process was done on the two training sets first and then applied to the test sets. After feature reduction, the frequency features that were retained included word count (of the argumentative element or sentence), the frequency of the significant unigram in claims and in non-claims, bigrams and quad-grams in claims, and the frequency of significant POS unigrams, trigrams, four-grams, five-grams in claims and in non-claims, and frequency of significant six-grams in claims. The two positionality features and the selected 20 SALAT features were also retained.

Table 3. Model accuracy results

Classifier	Model	Accuracy	Kappa	Label	Precision	Recall	F1
Logistic Regression	Suprasentential - Frequency and positionality	0.852	0.691	Non-Claim	0.874	0.881	0.878
				Claim	0.818	0.809	0.814
	Suprasentential - Full features	0.845	0.675	Non-Claim	0.867	0.876	0.872
				Claim	0.810	0.798	0.804
	Sentential - Frequency and positionality	0.802	0.216	Non-Claim	0.817	0.965	0.885

				Claim	0.506	0.318	0.390
K-Nearest Neighbors	Suprasentential - Frequency and positionality	0.836	0.650	Non-Claim	0.835	0.906	0.869
				Claim	0.837	0.730	0.780
	Suprasentential - Full features	0.787	0.526	Non-Claim	0.760	0.943	0.842
				Claim	0.865	0.551	0.673
	Sentential - Frequency and positionality	0.818	0.286	Non-Claim	0.827	0.973	0.894
				Claim	0.709	0.245	0.364
	Sentential - Full features	0.804	0.196	Non-Claim	0.813	0.976	0.887
				Claim	0.654	0.166	0.265
Support Vector Machines	Suprasentential - Frequency and positionality	0.863	0.714	Non-Claim	0.886	0.886	0.886
				Claim	0.828	0.828	0.828
	Suprasentential - Full features	0.833	0.652	Non-Claim	0.865	0.856	0.860
				Claim	0.786	0.798	0.792
	Sentential - Frequency and positionality	0.818	0.336	Non-Claim	0.839	0.951	0.891
				Claim	0.639	0.325	0.431
	Sentential - Full features	0.822	0.320	Non-Claim	0.833	0.968	0.896
				Claim	0.706	0.281	0.402
Random Forest	Suprasentential - Frequency and positionality	0.873	0.734	Non-Claim	0.886	0.906	0.896
				Claim	0.853	0.824	0.838
	Suprasentential - Full features	0.866	0.720	Non-Claim	0.890	0.886	0.888
				Claim	0.829	0.835	0.832
	Sentential - Frequency and positionality	0.832	0.419	Non-Claim	0.858	0.943	0.898
				Claim	0.664	0.421	0.515
	Sentential - Full features	0.829	0.390	Non-Claim	0.850	0.951	0.897
				Claim	0.672	0.377	0.483

To examine whether adding the SALAT features improved the accuracy of claim identification, we created two versions of the feature sets. The first version comprised the n-gram frequency (including word count) features and positionality features, and the second version comprised all the features (including the SALAT NLP features). Combined with the different levels of discourse units (sentential and suprasentential), four pairs of datasets (training and test sets) were prepared for modeling: the frequency and positionality versions along with the full feature versions at both the sentential and suprasentential levels.

2.4.6 Classifiers

We used the 'caret' [23], 'randomForest' [28], 'e1071' [32], and 'tidyverse' packages [48] in R [13] to apply Logistic Regression, Naïve Bayes, K-Nearest Neighbors, Support Vector Machines, and Random Forest models. 10-fold cross validation with five repeats was used. We trained and tested the four versions of data separately. For the SVM classifier, a linear, polynomial, and radial kernel was applied. The model with the best performance was selected to make predictions on the test set.

3. RESULTS

3.1 Model evaluation

The classification performances (precision, recall, F1 scores, accuracy, and Cohen's kappa) of the multiple models on the test sets are reported in Table 3.

Overall, the models developed on frequency and positionality features slightly outperformed the models developed using all the features. This indicates that adding lexical, syntactic, cohesion, and cognitive NLP features does not improve the accuracy of the classification of claims and non-claims. In terms of the selection of the unit of classification, the suprasentential models outperformed the sentential models. Finally, the suprasentential Random Forest

model based on frequency and positionality features yielded the best accuracy (0.873) and Kappa (0.734), followed by the suprasentential model based on the full feature set, which yielded an accuracy of 0.866 and Kappa of 0.720, which represents good performance based on the scale of Cohen's Kappa values [11].

3.2 Important variables

Variable importance for the best model (the suprasentential Random Forest model based on word count, n-gram frequency and positionality features) was reported by the 'caret' package. Table 4 shows the top 10 important variables and their importance values for this model.

The variable importance values showed that the length (word count) of an argumentative element, the normalized position of the argumentative element in the essay, and the frequency of significant bigrams in claims in the argumentative element are the three most important variables.

Table 4. Variable importance values

Variable	Importance Value
Word Count	289.988
Normalized element position in the essay	162.083
Frequency of significant bigrams in claims	47.992
Frequency of significant unigrams in claims	31.147
Normalized element position in the paragraph	29.791
Frequency of significant POS five grams in claims	28.465
Frequency of significant POS four grams in claims	27.389
Frequency of significant unigrams in non-claims	25.399
Frequency of significant POS unigrams in claims	25.272
Frequency of significant POS unigrams in non-claims	23.812
Frequency of significant POS trigrams in claims	20.364
Frequency of significant POS trigrams in non-claims	18.375
Frequency of significant POS four grams in non-claims	13.745
Frequency of significant four grams in claims	8.676
Frequency of significant POS six grams in claims	8.490
Frequency of significant POS five grams in non-claims	4.210

4. ERROR ANALYSES AND DISCUSSION

We conducted error analyses for the two Random Forest suprasentential models (i.e., the models based on the frequency and positionality feature set and the full feature set). Our goal was to examine the misclassifications of the models to better understand elements that may contribute to model accuracy.

We first examined classification rates. Among all incorrectly classified instances, we found more cases in which a claim was misclassified as a non-claim, whereas non-claims were less frequently misclassified as claims. For both models, around 17% of claims were misclassified and non-claims, and around 10% of non-claims were misclassified as claims. These results indicate that, the models are better at identifying non-claims than claims, potentially due to the imbalanced data between the claims and non-claims. Nevertheless, future studies should examine if there are more representative features in claims that can be integrated into our current feature set.

We next examined if essay quality and length influenced the model accuracy. Specifically, for each argumentative element in the two suprasentential test sets, we extracted the following information: holistic score, number of words, number of sentences, and number of paragraphs in the essay where the argumentative element occurred. We examined differences between the argumentative elements that were correctly and incorrectly predicted for these features using t-tests. No differences were reported for essay quality and length in either model. Thus, the classification of argumentative elements was not related to the quality or the length of essays.

We also examined if differences in model accuracy were related to more specific argumentation categories (i.e., micro-categories). As mentioned in Section 2.2, we merged the argumentation categories of Primary Claim, Final Claim, Counterclaim, and Rebuttal from the original annotated corpus into a larger classification of claims (i.e., a macro-classification). We also classified the remaining categories of Data and Concluding Summary along with Non-annotated texts into non-claims. To assess whether the micro-categories influenced classification of the macro-classification, we compared the prediction accuracies among the seven micro-categories.

The results showed that Counterclaims were not misclassified in either model (likely because of their rarity), Concluding Summaries were not misclassified in the frequency- and positionality-based models, but misclassified 3.9% of the time in the full feature model. Data was misclassified around 9% in both models. Meanwhile, the sub-categories that were more frequently misclassified included: Primary Claims (around 14 misclassified), Final Claims (around 21% misclassified), Non-annotated texts (around 22% misclassified), and Rebuttal (2 out of 3, 66.7% misclassified instances in both models). These results were also in line with findings that claims were more frequently misclassified as non-claims.

To further explore what factors affect the misclassifications among the micro-categories of argumentative types, Welch's t-tests were conducted among all NLP features (see Appendix B) used in the full analysis between correct and incorrect classification instances. However, the analysis was done for the sub-category of Counterclaim since all instances under this category were correctly predicted by the two models. Also, we did not conduct t-tests for the micro-category of Rebuttal due to a small sample size (N =3).

Table 5 presents the features for which significant differences were found between the correct and incorrect classification instances in at least two categories of argumentative types. In general, the classification of Primary Claim, Data, Concluding Summary, and Non-annotated texts seemed to be more strongly influenced by linguistic features. Word count was the strongest indicator of misclassification, in which difference were found for each micro-category. The standard deviation of dependents per object of prepositions was another strong predictor of misclassification, which reflects the development of syntactic complexity [25].

Table 5. Features with significant differences between correct and incorrect classification instances

	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Primary claim		Yes	Yes		Yes	Yes	Yes			Yes		Yes	Yes	
Final claim		Yes									Yes			Yes
Data	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes			Yes	Yes	Yes	
Concluding summary	Yes	Yes						Yes	Yes		Yes		Yes	Yes
Nonannotated	Yes	Yes		Yes					Yes	Yes		Yes	Yes	

Note. Shaded gray cells with 'Yes' indicate significant difference ($p < .05$) were found between the correct and incorrect instances. 1 = Number of named entities, 2 = Word count, 3 = Normalized element position in the paragraph, 4 = Normalized element position in the essay, 5 = Frequency of significant unigrams in claims, 6 = Frequency of significant POS trigrams in claims, 7 = Frequency of significant quad-grams in claims, 8 = Hu Liu proportion score, 9 = Objects component score, 10 = Brown frequency score, 11 = Bigram lemma type-token ratio, 12 = Nouns as modifiers score, 13 = Dependents per object of the preposition (SD), 14 = T-units per sentence.

The number of named entities was a strong indicator for the non-claims, wherein the incorrect instances of non-claims contained fewer named entities versus the correct instances. The nouns as modifier scores were also predictive of misclassification, which measured the use of nouns as nominal modifiers in general and the variation in the number of modifiers per nominal [25]. Other linguistics features that influenced the classification accuracy included: the normalized position of the element in paragraph and in essay, the bigram type-token ratio, the frequency of key unigram, quad-gram, and POS trigram in claims, the number of T-units per sentence, the number terms that reference objects, the proportion of the number of words with positive sentiments to the words with negative sentiments, and the mean frequency score based on London-Lund Corpus of Conversation.

5. CONCLUSION

In this study, we proposed an approach that combined the frequency, positionality, and other lexical, syntactic, cohesion, and cognitive NLP features to predict claims and non-claims in argumentative essays. Our model performed well in the classification of these argumentative elements. Our exploration of the features, the comparison between sentential versus suprasentential models, and investigation of the factors that influenced classification accuracy in the error analyses should contribute to the field of automated identification and evaluation of discourse elements in argumentative writing.

It is important to note that the corpus used for this study was relatively small, comprising 314 student essays. Thus, to gain higher accuracies and reliabilities in classifying argumentative elements, we plan on annotating more essays and expanding the current corpus. That also means we will use essays written to more prompts allowing us to extract key n-grams and POS n-grams that are more generic and less restricted to the specific prompts used here. In addition, due to the small sample size, our classification of argumentative elements was simplified to focus on claims versus non-claims. We are interested in exploring the classification of the micro-categories (Primary Claim, Final Claim, Counter Claim, Rebuttal, Data, and Concluding Summary) in a larger corpus. We also plan to include the prediction of the quality of these argumentative elements in students' writing.

The models developed in this study will be included in an online Writing Assessment Tool (WAT). Implementing the classification algorithm within WAT, WAT's automatic writing evaluation (AWE) system will have the capacity to predict the number of claims in the essay and whether the claims mention the key n-grams that reflects the argument topic. This will afford providing feedback to students on argumentation quality within student essays. The study also provides insight into the length, position, content (e.g., the key n-grams), and other NLP features in claims versus non-claims in students' writing, which will contribute to finer-grained feedback components in our AWE system.

This study also provides important information for others who are developing AWE algorithms to drive feedback on argumentative essays, or more broadly to better understand the use of claims in essays. Specifically, the results of this study inform features related to feedback that can be provided to students about the number of claims, mentioning the argument topic, how to better position argumentative elements within their essays, and how to pay attention to specific linguistic features (such as the use of named entities when giving evidence) in their writing. This is an important achievement in the realm of writing feedback given the crucial need to automate feedback to students on their use of claims and evidence in argumentative essays.

Another important contribution of this study is that we also introduce a new corpus of essays annotated for argumentative elements, which is made publicly available at linguisticanalysistools.org. This corpus includes theoretically aligned argumentative elements that complement existing corpora [44, 45] and adds new components including prompts, holistic scores, additional categories of argumentation, and different educational settings. As such, this study provides the opportunity for other scientists to build upon our work such that we can better understand writing, and the features related to successful composition.

APPENDIX

A. Definitions of argumentative elements

Elements	Definitions	Examples
Final Claim	An opinion or conclusion on the main question	In my opinion, every individual has an obligation to think seriously about important matters, although this might be difficult.
Primary Claim	A claim that supports the final claim.	The next reason why I agree that every individual has an obligation to think seriously about important matters is that this simple task can help each person get ahead in life and be successful.
Counterclaim	A claim that refutes another claim or gives an opposing reason to the final claim.	Some may argue that obligating every individual to think seriously is not necessary and even annoying as some people may choose to just follow the great thinkers of the nation.
Rebuttal	A claim that refutes a counterclaim.	Even though people can follow others' steps without thinking seriously in some situations, the ability to think critically for themselves is a very important survival skill.
Data	Ideas or examples that support primary claims, counterclaims, or rebuttals.	For instance, the presidential debate is currently going on. In order to choose the right candidate, voters need to research all sides of both candidates and think seriously to make a wise decision for the good of the whole nation.
Concluding Summary	A concluding statement that restates the claims.	To sum up, thinking seriously is important in making decisions because each decision has an outcome that affects lives. It is also important because if you think seriously it can help you succeed.
Non-annotated	Any text that doesn't fall into any of the above categories	People always strive to be unique or different. This idea clashes with creativeness all through our lives.

B. Descriptions of the SALAT NLP features

NLP features from SALAT	Descriptions
Bigram lemma type-token ratio	Number of unique bigram lemmas (types) divided by the number of total bigram lemmas (tokens)
Brown frequency score	Mean word frequency score based on London-Lund Corpus of Conversation
Brysabaert concreteness score	Sum of concreteness scores based on all words divided by number of words with concreteness scores
COCA academic bigram association strength	Sum of approximate collexeme strength score divided by the number of bigrams in text with collexeme scores
Dependents per clause (SD)	The standard deviation of the total number of dependents per clause
Dependents per object of the preposition (SD)	This score captures the variation (standard deviation) in the prepositional objects
Direct objects per clause	The number of direct objects per clause
Free association tokens response score	Number of response tokens elicited by word as stimuli in discrete word association experiment (based on function words)
Hu Liu proportion score	Proportion of the number of words with positive sentiments to the words with negative sentiments
LDA age of exposure score	Based on Incremental Age of Exposure for words across 13 grade levels; calculated based on 1/slope of linear regression
Lexical decision time	Standardized lexical decision reaction time across all participants for this word (z-score, based on function words)
Nouns as modifiers score	This score captures the use of nouns as modifiers and modifier variation
Number of named entities	The number of named entities
Number of prepositions per clause	This score captures capture noun phrase elaboration and clause complexity
Objects component score	This component score represents the number of terms that reference objects
Possessives component score	This component score captures the use of possessives in general, and specifically captures the use of possessives in nominal subjects, direct objects, and prepositional objects
Sentiment score of dominance	This score captures the sentiment of dominance, measured by the number of words of dominance
Sentiment score of overstating	This score captures the sentiment of overstating, calculated based on words indicating emphasis in realms of frequency, causality, accuracy, validity...
T-units per sentence	Number of T-units in text divided by number of sentences in text
Verb argument constructions association strength	Average approximate collostructional strength score based on the COCA academic corpus

Using Keystroke Analytics to Understand Cognitive Processes during Writing

Mo Zhang, Hongwen Guo, and Xiang Liu
Educational Testing Service (Princeton, NJ, 08541)
MZhang, HGuo, XLiu003@ETS.org

ABSTRACT

We present an empirical study on the use of keystroke analytics to capture and understand how writers manage their time and make inferences on how they allocate their cognitive resources during essay writing. The results suggest three distinct longitudinal patterns of writing process that describe how writers approach an essay task in a writing assessment. Discussion of the potential applications of keystroke analytics for improving teaching, learning, and assessing writing are also provided.

Keywords

keystroke logging, writing, cognitive process, time management, writing pattern

1. INTRODUCTION

The study of writing process has long been of interest to the writing research community (e.g., [4], [18], [12], [19], [22]). With the advances in technology, keystroke logging has become a practical and popular tool to capture and study the process of composition in a wide range of contexts [10]. In this study, we demonstrate some research findings on the use of keystroke analytics to understand writers' time management during their writing process. The results have practical implications for the teaching and learning of writing in classrooms.

Previous research on writing cognition suggested several subprocesses of writing [9], including task analysis, text planning, idea generation, translating ideas into natural language, transcribing langauge onto paper (handwriting) or a screen (keyboard-based writing), text revision, copy editing and reviewing. Figure 1 illustrates a simplified version of Hayes coginitive writing model, which specified four main subprocesses of writing. Specifically, idea generation and task preparation (i.e., *proposer*) often manifest as pauses at the start of writing and at sentence boundaries; fluency of putting ideas into language (i.e., *translator*) primarily relates to the size of long sequences of text production without major interruption (also known as "burst"); orthographic proficiency and motor skill (i.e., *transcriber*) typically relates to pauses inside a word and to edits designed to make immediate corrections to spelling errors or typos; and editing and reviewing (i.e., *evaluator*) usually show up as jumps to different locations in the text to make changes or replace large chunks of existing text with new content.

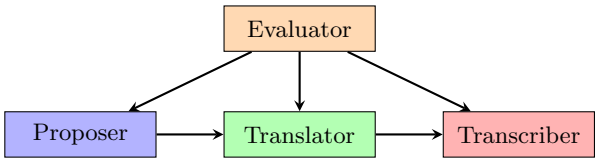

Figure 1: A Cognitive Model of Writing Process

One important implication from the cognitive model is that writing is not a linear process and successful writing calls for effecitive management and coordiation of the subprocesses. Drawing from the cognitive theories of writing, an overview of the types of activities occuring during text composition can be found in [5]. The cognitive resources, as stated in [3], required to carry out each activity do not distribute randomly over the text-production process. Writers often need to decide on which goals to prioritize at which time point because they simply do not have unlimited working memory to accomplish everything at once [11]. With the availability of keystroke logs, how writers distribute their time and cognitive resource to various subprocesses of writing can be quantified and analyzed, which is described in the next section. In this study, we aim to tackle a specific *research question* of whether there are distinct writing-process patterns that may be detected with regard to how writers allocate their cognitive resource to various subprocesses of writing. An identification of meaningful writing profiles will have practical implications for instructors to design curriculum suitable to their classes, and personalize their instruction for learners with different needs and characteristics.

1.1 Keystroke Logging

We consider keystroke logging as a recording of every keypress that the writer makes on the keyboard. The gap time between two consecutive keypresses is often called an interkey interval (IKI), which is also recorded in keystroke logging. A single keystroke record in JSON format may look like this: {"p": "1", "o": "", "n": "I", "t": "0.57"}, where

Table 1: An Example Keystroke Log Segment

Index	PosInText	Content	ContentLen	TimeStamp	ActionType	Context	WordIntended	CursorJump	TextToDate
0	1	I	1	0.57	Insert	WordStart	It	N	I
1	2	t	1	0.62	Insert	InWord	It	N	It
2	3	(*space*)	1	0.99	Insert	BetweenWords		N	It
3	4	i	1	1.30	Insert	WordStart	is	N	It i
4	5	s	1	1.42	Insert	InWord	is	N	It is
5	6	(*space*)	1	1.61	Insert	BetweenWords		N	It is
6	7	a	1	2.12	Insert	WordStart	a	N	It is a
7	8	(*space*)	1	2.22	Insert	BetweenWords		N	It is a
8	9	g	1	2.35	Insert	WordStart	fun	N	It is a g
9	10	o	1	2.43	Insert	InWord	fun	N	It is a go
10	11	o	1	2.55	Insert	InWord	fun	N	It is a goo
11	12	d	1	2.68	Insert	InWord	fun	N	It is a good
12	12	d	1	3.01	Delete	InWord	fun	N	It is a goo
13	11	o	1	3.16	Delete	InWord	fun	N	It is a go
14	10	o	1	3.30	Delete	InWord	fun	N	It is a g
15	9	g	1	3.53	Delete	InWord	fun	N	It is a
16	10	f	1	3.71	Insert	InWord	fun	N	It is a f
17	11	u	1	3.93	Insert	InWord	fun	N	It is a fu
18	12	n	1	4.11	Insert	InWord	fun	N	It is a fun
19	13	(*space*)	1	4.30	Insert	BetweenWords		N	It is a fun
20	14	d	1	4.49	Insert	WordStart	day	N	It is a fun d
21	15	a	1	4.62	Insert	InWord	day	N	It is a fun da
22	16	y	1	4.90	Insert	InWord	day	N	It is a fun day
23	17	.	1	5.13	Insert	PuncMark		N	It is a fun day.

Note: ContentLen=Content Length. ContentLen usually takes the value of 1 unless the writer cuts or pastes in a chunk of text with more than one character. PuncMark=Punctuation Mark. CusurJump can take a binary value of "Y" or "N".

"p" is the position in the text box, "o" is the current text at that position, "n" is the change made to that position, and "t" is the time elapsed since the start of writing. In this example, the writer inserted a chatacter "I" at position 1 in the text box at a timestamp of 0.57 seconds, computed relative to when the writing started (i.e., at 0 elapsed seconds). The overall behaviral process of text production can then presented by a sequence of keystroke records. More importantly, qualitative labels may be attached to characterize a keystroke record in terms of the type (e.g., insertation, deletion) and location (e.g., inside of a word, end of a sentence) of an action, along with the content and associated time stamp. For the hypothetical example given in Table 1 (for illutration purpose only), the writer spends 5.13 seconds to write a full sentence: "It is a fun day." During the process, the writer changed the choice of a word from "good" to "fun" evidenced by a sequence of the "delete" actions. Cursor location is tracked so that if the cursor moves suddenly to a different location away from the current location, the jump behavior can be detected.

As Table 1 indicates, keystroke logs allow the visible aspects of the text-production process to be precisely reconstructed and retrospectively replayed. Figures 2 and 3 demonstrate one approach to visualizing the dynamics of the text-production process by plotting the time elapsed (horizontal axis) against text length and cursor position (verticle axis). When the writer is appending or deleting text at the end of the text, the dashed purple line (text length) and the solid green line (cursor position) would converge; when the writer is making changes elsewhere in the text, the green cursor-line would diverge from the purple length-line. The gaps between the two lines can indicate the degree of the "jump" action. The length-line can go up or down indicating adding or removing of content. The small-scale zig-zag pattern in both figures suggests that both writers conducted a fair amount of quick fixes or local edits mostly on the word level (e.g., typo correction, word-choice revision, removing/adding punctuation marks) at the end of the text as they write. The writer in Figure 3 showed evidence of global-level editing behavior towards the end of the writing session, when the writer moved the cursor to different parts of the text to make changes, as can be seen from the relatively large gaps between the purple and green lines. This type of jump-edit behavior is rather absent in Figure 2 for which the writer showed a much more linear writing process.

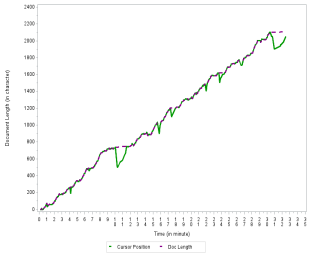

Figure 2: Writing Progression Example a

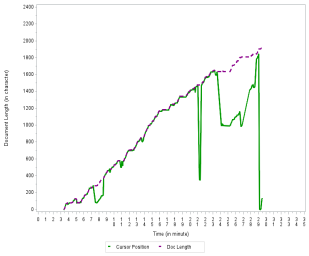

Figure 3: Writing Progression Example b

1.2 Inferences & Relations to Writing Quality

The nature and location of the changes that writers make to their text directly can directly support inferences about where the writer is cognitively in the composition process. For example, a long pause followed by insertion of a written outline is suggestive of task analysis and idea generation; a long pause at the phrasal or sentence boundaries followed by a burst of text production is a sign of sentence planning; alternating between insert and delete actions on a character-level inside of a word is likely an indication of spelling correction or word finding; if a writer types long sequences of words thereby adding new content, it is reasonably safe to assume that the writer is primarily engaged in content generation; and, if a writer jumps to various locations (tracked by cursor position) in the text to make changes, the writer is more likely in the state of text reviewing and revision (e.g., [6], [16]). Previous research has reported that the

process of writing, such as the total time spent on writing, between-word pause tempo, initial pause length before typing a word, length of long burst (i.e., stretches of long sequence of text production), and extent of text editing and revision, relate to the quality of the final written product (e.g., [3], [17], [2], [27]). In this study, we largely followed the practice described in [8] by classifying each interkey interval (i.e., gap time betweeb two keystrokes) into one of the following four cognitive states in writing. These states intend to operationalize the theoretical subprocesses proposed in Hayes model, although there will unavoidably be gaps between theory and practice. *Long Pause* state, representing text planning, idea generation and deliberation, or hesitation and struggle with text production; *Text Production* state, representing relatively fluent content generation without major interruption where interruption is signaled by an extended pause; *Local Editing* state, representing localized (mostly on the word-level) minor text editing; and *Global Editing* state, representing reviewing, revision and copy editing on the whole passage/text level.

2. METHOD

2.1 Data Set

The data set was collected from a high-school equivalency testing program, which contains five subject tests: English language arts – reading, English language arts – writing, math, science, and social science. The focus of this study was the essay writing task in the writing subtest. In responding to the essay task, the examinees are expected to read two sources with different perspectives on a common issue (e.g., whether success is more the result of talent or of hard work), and then express and explain their opinions in writing while appropriately incorporating evidence from the sources. Each submitted essay was scored holistically on a 0-6 scale by two trained human raters according to a standardized grading rubric. Essays receiving a human score of 0 were excluded from analysis as those essays tend to have aberrant characteristics such as being empty, not in English, or consisting of random keystrokes. In this study, we selected two writing forms administered between September 2017 and August 2018 for investigation. Each form contained one essay writing task, or prompt. The sample size used for analysis was approximately 500 in each prompt. The analyses were conducted on the first (base) prompt, and then replicated on the second prompt to validate the consistency of the findings.

2.2 Propensity Score Matching

To ensure comparability, propensity score matching (PSM) [1] was used to minimize irrelevant factors such as performance level and the paraticipants' demographics and to balance covariates between the participants who responded to either of the two prompts. Also, the two different prompts were not administered at random, thus necessitating this step. A logistic regression model was developed to generate the propensity scores, and a one-to-one greedy matching without replacement algorithm with a caliper value of 0.05 was applied to find the matches in the prompt 2 sample to make it most comparable to the prompt 1 sample [15]. The caliper value refers to the maximum distance in propensity scores; hence the smaller the caliper value, the closer the match. In performing the PSM, the covariates were chosen based on our understanding of the examination and the examinee population, and on findings from previous reports on subgroup differences in writing process (e.g., [7], [25]). The covariates included for propensity score matching were gender (Male or Female), ethnicity (White, Black, Hispanic, or others/unreported), employment status (Full-time, Part-time, Unemployed, or others/unreported), highest education level (Below Grade 9, Some high school, others/unreported), English as best communicative language (Yes or No), as well as scores on the subject tests other than writing. All the demographic background variables were self-reported by the participants on a voluntary basis.

2.3 Feature Extraction

Keystroke logs were recorded automatically as writers composed their essays. A two-stage procedure was applied for feature extraction. In Stage 1, we classified each interkey interval (IKI) into one of four heuristically-defined and mutually-exclusive writing states by following the practice in [8] with some modifications. In Stage 2, we split each log into ten time periods by evenly dividing the total writing duration into ten segments, as one way to align and compare the logs of different length in duration. The choice of ten time-periods was made to balance the duration of each segment, which should be long enough to detect any patterns related to time distribution, *and* the number of segments, which should be sufficient for detecting longitudinal patterns.

Stage 1: Classification of writing states. The general programming logic is as follows.

- Step 1. Define Long Pause (LP) state. If an IKI is longer than n times in-word typing speed, it is then labelled as P. The keystroke sequence in between two adjacent Ps is considered a burst.
- Step2: Define Text Production (TP) state. Inside of a burst, if there is an absence of Delete action, or the max number of a Delete sequence is smaller than k, label all IKIs in this burst as TP. If there is a consecutive delete action sequence with k or more number of Deletes, temporarily change all IKIs in this burst to R, which will be refined in the next step.
- Step 3. Define Local Editing (LE) state. Use an m-IKI moving window to scan through the keystroke sequence within an R-burst. That is, the first moving window contains the 1^{st} to the m^{th} IKIs in a burst; the second moving window contains the 2^{nd} to the $(m+1)^{\text{th}}$ IKIs in the burst; and so on.
  - If all IKIs in a moving window are Inserts or contain less than s Deletes, change the first record in the moving window from R to TP. Continue with the same logic to the next moving window.
  - If a moving window contains equal to or more than s Delete actions, label all the m records in the moving window as LE.
- Step 4. Define Global Editing (GE) state. GE is indicated by text deletion while crossing sentence boundaries or making jump-edits elsewhere in the text away from the current location.

- If d or more consecutive Delete actions contain the following punctuation marks – comma, period, semicolon, exclamation mark, and question mark – label the entire Delete sequence as GE.
- If the position of an IKI in the text is different from the one before it by more than q, then the IKI is labeled as Jump Back (JB to an earlier place in the text) or Jump Forward (JF to a later place). Find the longest JB-JF pair in distance, and label all the IKIs in between to GE.

The parameters n, m, k, s, d, and q used in state definitions are customizable. In this study, we chose n=10, m=3, k=3, s=3, d=2, and q=4 as a starting point, mainly following [8]. Once all the IKIs are labelled, consecutive IKIs of the same state can be further aggregated. Each keystroke log can be described by the total number of states, the duration of each state, proportion of time spent on each state, the frequency of various transitions, etc. Among the four states, there are 12 state-transition possibilities (e.g., TP $\rightarrow$ GE) in total.

Stage 2: In this stage, we used the state classification generated above to calculate a writer's time distribution at various points during the writing process. To accomplish this goal, we divided each keystroke log into ten even time-periods. We then calculated the proportion of time spent in each writing state within a time period. As a result, each keystroke log was represented by a vector of 40 elements (i.e., four states times ten segments). The elements' values (i.e., percentages) could range from 0 to 100. When it is a 0, it simply means that the writer did not spend time on an activity (e.g., Local Editing) during that time period (which is one tenth of the total time). Similarly, when the value is 100, it means that a writer spent all his/her time on an activity (e.g., Global Editing) during that time period. With this information, the longitudinal pattern of time allocation can be revealed and investigated. We can analyze, for example, how writers spend their time at the beginning, middle, or end of their writing process, whether writers distribute their effort evenly or differently at various time-points during the writing process, and whether there are distinct profiles with regard to time management of an individual writing process.

2.4 Cluster Analysis and Interpretation

Using the writing samples in each of the two prompts, we conducted hierarchical cluster analysis (agglomerative approach) with Ward linkage using the Euclidean distance metric [23, 20]. The proportion of time spent in each state at the ten time-points was used to create 40 input variables. Each input variable was standardized to a mean of zero and standard deviation of one across individuals in a prompt [13]. The cluster analysis was done separately for each prompt, with the second prompt serving as a replication sample to verify results from the base prompt. Because there is no established convention for choosing the number of clusters, we used the Pseudo-F statistic, model R-squared, and semipartial R-square statistics to help us determine the appropriate number. The pseudo-F statistic is calculated as the ratio of the between-cluster variance to the within-cluster variance [14]. Larger values indicate better separation between the clusters. The model R-squared indicates the proportion of variance accounted for by the clusters. The semipartial R-square indicates the decrease in the proportion of variance accounted for due to joining two clusters. We plotted these statistics against the number of clusters to examine the impacts of joining or splitting clusters. Dendrograms visualizing the distances between the keystroke logs were also examined to help select the final number of clusters.

To interpret identified clusters, we compared how writers falling into different clusters allocated their efforts during the writing process. Since the proportions of time spent on Text Production, Local Editing, Global Editing, and Long Pause were used as input variables in the cluster analysis, this comparison would be the most direct way to examine any distinct patterns exhibited by each cluster. It would also be informative to know whether clusters are associated with distinct patterns of writing proficiency or in cluster members' demographic background. Therefore, to further substantiate the meaning of identified clusters, we compared the essay scores, essay length (in words), time on task (in minutes), the proportion of cluster members belonging to specific demographic categories, as well as a rough measure of writing efficiency calculated as essay length divided by time on task, between the clusters.

3. RESULTS

3.1 Outcome of Propensity Scoring Matching

The samples resulting from the propensity score matching are closely comparable between the two prompts (Table 2). In the first (base) prompt, males and females were evenly distributed; 53% of the examinees self-identified as White, 12% as Black, 14% as Hispanic; 4% reported that their highest grade level was below Grade 9, 62% reported having some high school education; 16% were working part-time, 17% were working full time, 23% were unemployed at the time of the examination. The majority of the examinees, 94%, indicated English as their best communicative language. The demographic background distribution of the second prompt, after matching, was very similar to that for the base prompt. The matched samples for prompt 2 also showed comparable means of the subtest scores to those for the base prompt.

3.2 Cluster Analysis Results

To decide the optimal number of clusters, we first examined the dendrograms, which indicated a solution of 3 or 4 clusters for both prompts. Figures 4 and 5 show the results of the Pseudo-F statistic and Sempartial R-square statistic that were considered for model selection in prompt 2. The results for prompt 1 are similar. The X-axis in both plots is the number of clusters ranging from 1 to 50. The Y axis is the Pseudo-F statistic on the left plot, R-squared on the middle plot, and semipartial R-square on the right plot. The results suggested a peak on the Pseudo-F statistic with a 3-cluster solution. The semipartial R-square plot shows an elbow point at cluster 3. The model R-squared (not shown) appears to go up continuously without a clear turning point. Considering all the evidence, we decided on three clusters as the most parsimonious and sensible solution for the this study sample.

3.3 Comparing the Clusters

Given the multivariate nature of the clustering variables, we drew radar charts to visualize the time distribution at the

Table 2: Comparability between Prompts after Propensity Score Matching

	Proportion										Mean Score (Scale: 0 - 20)			
Prompt	Female	White	Black	Hisp.	Below9	HS	PT	FT	Unemp.	Eng(Y)	Reading	Math	Science	SS

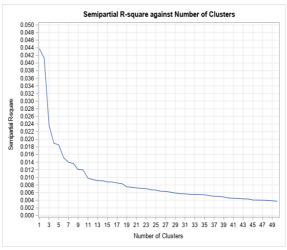

Figure 5: Semipartial R^2 x N of Cluster

ten consecutive time-points during the writing process of the logs belonging to each of the three clusters (Figures 6 and 7). The axes represent the average proportions of time spent on a state at a certain time. For example, "TP_1" refers to the proportion of time spent on Text Production at the beginning of writing – the 1st of the ten duration segments. It is clear from Figures 6 and 7 that the three clusters demonstrated rather different polygonal shapes over all axes, which are consistent between the two prompts.

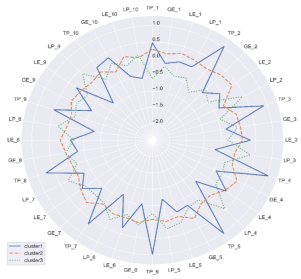

Figure 6: Radar Chart (Prompt 1)

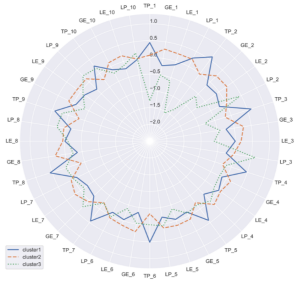

Figure 7: Radar Chart (Prompt 2)

Cluster 1 (blue colored, solid line in both prompts) writers have a distinct pattern with notable spikes on the TP state over the course the writing process. Because the total writing time is constrained and writers can only do one thing at a time, if the writers spend more time on text production, they would necessarily spend less time on the other activities such as editing or revision. This constraint is evident from the plots where, for Cluster 1, the proportion of time spent on long pauses and editing is relatively smaller. Cluster 2 (orange colored, dashed line) writers, on average, have a much smoother circle compared to Cluster-1. Cluster 2 writers appeared to have distributed their efforts more evenly throughout the writing process. The allocation of time across the four writing states is relatively balanced over the course of the writing session. In general, Cluster 1 seems to represent a group of writers that compose linearly without showing much editing behaviors, while Cluster 2 seems to represent writers that also consistently produce text but still spend time on text planning and conduct text editing and revision as they write. Cluster 3 (green colored, dotted line) writers further showed a distinct time-management pattern from the other two clusters. The writers in Cluster-3 appeared to have difficulties in generating text at the start of the writing session, as evidenced by the lack of text production (TP_1) and a higher proportion of the local editing behaviors (GE_1 and LE_1) in the first time period, which suggested possible false starts during the writing process. This "struggling" pattern appeared to have persisted into later stages of the writing process, as evidenced by a higher proprotion of time spent on long pauses compared to text production or editing.

We also examined the actual length of time writers stayed in a state before transitioning to a different state. The results suggest that the three clusters not only differ in their relative time distributions during writing, but also in the total time writers stayed in different states. Each cluster displayed distinct patterns consistent across prompts: Cluster 1 writers spent considerably less time on long pauses than Clusters 2 and 3 writers; Cluster 2 writers spent notably larger amounts of time making word-level local edits than Clusters 1 and 3 writers by approximately 1 minute in Prompt 1 and 2 minutes in Prompt 2; and Clusters 3 writers generally spent less time on text production than Clusters 1 and 2 writers by about 1-2 minutes in Prompt 1 and about 3.5 minutes in Prompt 2. An additional interesting difference between Clusters 1 and 2 is that Cluster 2 writers not only spent longer time on local editing, but also on global editing by about 3 minutes in both prompts. A close comparison between Clusters 2 and 3 further revealed that Cluster 2 writers also appeared to spend more time on long pauses than Cluster 3 writers by a small margin in Prompt 1 and by a rather large margin in Prompt 2.

Taking into account both absolute time spent in each state, and relative time in each state, Cluster 2 writers appear to have shown a stable-tempo, iteractive process pattern in which they switch repeatedly between the activities of text planning, text production, and text editing over the course of their writing sessions. Although more data are needed to verify this interpretation, the long pauses demonstrated by Cluster 3 writers throughout the writing session appeared to be signals of hesitation and difficulties in content generation. Finally, Cluster 1 writers seem to be relatively quick and fluent at generating ideas (as evidenced by fewer long pauses) and at translation and transcription (that is, at expressing their ideas in written form).

To better understand and interpret the identified clusters, Table 3 further compares the characteristics of student essays across the three clusters. Cluster 1 writers spent the shortest time on the writing task on average (22.94 minutes

Table 3: Proficiency and Demographic Distributions of Clusters

		Prompt 1			Prompt 2		
	Variable	Cluster 1	Cluster 2	Cluster 3	Cluster 1	Cluster 2	Cluster 3
	n	65	264	168	169	259	71
	Essay Score (scale: 2 - 12)	5.51 (1.70)	5.64 (1.54)	5.43 (1.53)	5.38 (1.59)	5.42 (1.74)	4.51 (1.80)
	Essay Length (in words)	305 (136)	324 (145)	289 (128)	287 (129)	290 (127)	236 (118)
	Time on Task (in minutes)	22.94 (11.56)	36.60 (15.65)	32.36 (14.16)	25.45 (12.39)	36.04 (14.86)	26.88 (14.37)
	Efficiency (words/min)	15.02 (6.19)	9.94 (4.43)	9.96 (4.09)	12.85 (5.71)	8.97 (3.98)	10.82 (6.41)
	Female	0.52	0.56	0.43	0.49	0.54	0.39
	White	0.62	0.51	0.50	0.58	0.51	0.46
	Black	0.12	0.14	0.13	0.12	0.12	0.13
	Hispanic	0.06	0.13	0.18	0.09	0.17	0.13
Proportion	Below Grade 9	0.03	0.02	0.02	0.05	0.03	0.03
	Some high school	0.54	0.63	0.64	0.60	0.62	0.68
	Part-time	0.15	0.13	0.20	0.17	0.16	0.14
	Full-time	0.12	0.19	0.22	0.17	0.17	0.20
	Unemployed	0.20	0.21	0.18	0.21	0.24	0.28
	English as Best (Y)	0.96	0.94	0.96	0.96	0.92	0.94

Note: Values in parenthesis are standard deviations. Values on the lower-half of the table are the percent of various subgroups within a cluster.

in Prompt 1; 25.45 minutes in Prompt 2). The difference in the total time on task between Clusters 1 and 2 is drastic – about 14 minutes difference in Prompt 1 and about 10 minutes difference in Prompt 2. Cluster 1 writers wrote notably more words/minute than Cluster 2 writers (15.02 vs 9.94 in Prompt 1; 12.85 vs. 8.97 in Prompt 2). The overall evidence seems to suggest Cluster 1 writers were more efficient than Cluster 2 writers, in that they spent significantly less time writing, yet achieved comparable text quality (essay scores).

In relation to demographic background, several results are noteworthy. On both prompts, Cluster 1 contained a notably greater proportion of White writers, a lower proportion of Hispanic writers, and a lower proportion of examinees with high-school experience, compared to the overall demographic distribution in Table 2. Cluster 2 included a slightly greater proportion of female writers than the average on both prompts, while all other demographic variables fell close to the mean for each prompt. Finally, Cluster 3 had a considerably lower proportion of White or female writers. But the results in general are less consistent between the two prompts for Cluster 3. The evidence seems to suggest that writers from different demographic background and having different educational experience may display distrinctive patterns in their writing processes. However, without further evidence, we cannot infer any causal connection between demographic group membership, writing process patterns, and overall writing performance.

4. DISCUSSION

In this paper, we presented a study on the use of keystroke analytics to understand writers' cognitive processes during writing. One possible outcome of this study, and of the larger research program of which it is a part, would be to providing actionable writing feedback to instructors and learners. However, before we can reach this goal, we need to develop a clear understanding of how writing processes change as a result of learning and instruction. This study provides a first attempt to address this issue, by identifying characteristic longitudinal patterns of time management that writers display when they respond to an essay writing task. The current results suggest that there are at least three distinct writing profiles that describe how writers approach an on-demand essay writing task. Though, it will be critical that the analysis to be replicated with more data. In the future, for writers placed into different profiles, we can imagine giving customized suggestions on writing strategies to improve learning and practice. Obviously, more research is needed to further validate the meaning and interpretation of the profiles we have detected. Possible approaches include cognitive interviews to elicit writers' understanding of what they were doing, combining eye-tracking technique with keystroke logging to get a better sense of where the writer's attention was focused and how changes in the focus of attention interacts with pause patterns, and convening an expert panel to determine whether the clusters derived by atatistical analysis align with expert judgments about what the writers were doing at each point in the writing process. The availability of keystroke logs makes it possible to replay a writer's composition process like a movie. Such replays can then be presented as stimuli to assist and guide cognitive interviews or the expert review process. Statistical tests will be necessary to detect if the profiles are significantly different beyond the practical importance. It will also be essential to replicate our analyses on a wide range of writing prompts, a broader variety of writing tasks, and across many different writer populations, as well as to study how well findings resulting from timed-writing tasks can be generalized to writing tasks with no time restriction.

The association between cluster assignment and demographic background is worth further investigation. The study of writing process ought to integrate with the social and linguistic context [21]. Previous studies have reported subgroup differences in writing processes (e.g., between native and non-native speakers in [24], between male and female writers in [26], between black and white students in [7]). It is concievably helpful and valuable to give information about writing profiles to provide customized feedback to writers from different linguistic, social, and educational backgrounds.

Finally, although this is beyond the scope of the current study, it is worth mentioning that keystroke-enabled process visualization such as those illustrated in Figures 2 and 3, in and of itself, may have instructional value, by making it easier for students to understand and self-reflect their writing processes. For instance, teachers may select replays and graphs to demonstrate a specific writing subprocess or a writing strategy, to help the class understand how to implement a more effective writing process. Teachers might also be able to use such graphs during their one-on-one con-

ference with their students to help them better understand their writing strengths and weaknesses (such as lack of editing, low-level engagement, or lack of sufficient attention to idea generation) that are revealed by the keystroke log. Future research is encouraged to gather teacher and students feedback on the assistive value of keystroke logs in their teaching and learning experience.

ABSTRACT

Predicting academic performance using trace data from learning management systems is a primary research topic in educational data mining. An important application is the identification of students at risk of failing the course or dropping out. However, most approaches utilise past grades, which are not always available and capture little of the student's learning strategy. The end-to-end models we implement predict whether a student will pass a course using only navigational patterns in a multimedia system, with the advantage of not requiring past grades. We experiment on a dataset containing coarse-grained action logs of more than 100,000 students participating in hundreds of short course. We propose two approaches to improve the performance: a novel encoding scheme for trace data, which reflects the course structure while remaining flexible enough to accommodate previously unseen courses, and unsupervised embeddings obtained with an autoencoder. To provide insight into model behaviour, we incorporate an attention mechanism. Clustering the vector representations of student behaviour produced by the proposed methods shows that distinct learning strategies specific to low- and high- achievers are extracted.

1. INTRODUCTION

A large amount of trace data about learner behaviour has recently become available from online learning environments [30]. Hence, it is now possible to improve the delivery, assessment and intervention quality using data mining techniques, giving rise to technology-enhanced learning. Educators are especially interested in receiving early alerts when students are at risk of failing the course or dropping out. With these alerts, timely intervention can be organised. To estimate this risk, machine learning classification models are built to predict student performance based on their interaction with the course content. There are several ways to define student performance: it can be a binary or a multi-level grade on either the next exercise or the entire course. This study focuses on a binary grade for the given course (fail or pass), a common scenario on student performance prediction [15, 28, 27].

Traditionally, the primary source of information for this task is past academic performance records [31]. They might include the grades for the previously taken courses or intermediate test scores. However, apart from those, online learning platforms also provide information about other types of interaction between students and the content. Depending on the technical implementation and medium, it can be fine-grained click-stream video data, the text of discussion forum messages, or more coarse-grained information such as whether a person liked a video or performed a search query. Our models operate on such coarse-grained sequential records of interacting with different content types on the online learning platform and does not rely on previous grades. The motivation for it is three-fold. First, the past scores might not be available, or it can be time- and effort-consuming to provide them. For example, grading an essay usually requires a specialist, which is not scalable for MOOCs. Second, by focusing on interaction with the content, such as video views, we obtain the representation of student behaviour that is more likely to capture their learning strategies. In other words, we can discover whether they prefer a specific medium or actively interact with other students in online discussions. Third, if we work with navigation patterns, the resulting model has the potential to inform a recommendation system that would nudge a struggling student in the right direction. For instance, when students explore the platform, we can automatically recommend the next learning item to interact with (e.g., a video or a reading material they might find useful or interesting).

This study applies recurrent neural networks for academic performance prediction in short online courses. The approach we describe works without manual feature engineering or information about previous scores. In contrast to most works in the area of course grade prediction, our models operate instead on raw sequences of multiple-type interactions with the content (video view/like, discussion message, search request, exercise attempt). We propose several encoding schemes for action logs and demonstrate that they can increase classification performance. Among them, we intro-

duce a flexible scheme that reflects relative progress within the course while being independent of its length. We also use autoencoders to extract student representation in an unsupervised way. Vector representations of student behaviour produced by different methods are clustered to compare how well they indicate (un)successful learning strategies. In order to illuminate the inner workings of the model, we provide cluster visualisations and experiment with an attention mechanism.

Thus, our research questions are the following. **RQ1**: Can we capture the information about course structure in the action sequences in a flexible way (that can be extended dynamically when new exercises or longer courses are added)? **RQ2**: Can we improve predictive performance by pretraining unsupervised embeddings (using autoencoder models)? **RQ3**: Can we improve predictive performance further by adding attention to an autoencoder?

2. RELATED WORK

While working with educational trace data, there are various ways to extract features from the raw sequences. The easiest and perhaps the most popular approach is to count the number of actions – despite its simplicity, it is a solid baseline, used even in the most recent studies [27], [28], [21].

Unfortunately, by aggregating the data in such a way, we ignore the time delay between actions and the information about their order. A common way to engineer additional, more time-sensitive features from trace data is to represent student behaviour in chunks, called studying sessions. For instance, we can define the sequence of actions as a session if less than 15 minutes passed between actions. The threshold is usually determined heuristically [20]. However, the need to choose this threshold manually is a clear drawback. Moreover, additional manual feature engineering is often required to aggregate features over sessions (e.g., experts have to define what qualifies as session intensity).

Furthermore, even though the described measures are sound and easy to use, their high volume does not necessarily contribute to the high quality of learning. Neither does it allow actionable insight beyond relatively trivial advice to spend more time in the system. As justly noted by the learning analytics community, it is the specific learning strategies adopted by individual students that are important [12].

Therefore, various approaches based on deep learning were proposed to overcome these limitations. The sequential nature of the data lends itself well to the use of recurrent neural networks (RNNs) [37]. The pioneering Deep Knowledge Tracing (DKT) model applied RNNs and its variations to the history of students' answers to predict whether they will answer the next exercise correctly [26]. One of the benefits of such neural architectures is that they can complement the educational theories proposed by human experts with insights obtained in the bottom-up, data-driven way [23]. Another benefit is that end-to-end models adapt to new domains easier and are more cost-efficient.

The success of DKT led to a new strand of research. Aiming to get rid of its simplifying assumptions, such as disregard to skill interaction or exercise text, researchers developed more advanced neural models for knowledge tracing [8].

In contrast to many grade prediction approaches such as [18], our approach does not require knowing previous academic performance or past grades. Instead, we investigate whether a binary course grade can be predicted from the trace data alone, with no intermediate exercise scores. Thus, an advantage of our approach is that we can detect low- and high-achievers without assessing the correctness of students' answers. The benefit is especially important for courses that include open-answer questions since those usually require costly human experts to be graded reliably (for example, essays in humanities subjects).

Our models work on raw sequences actions without aggregation of count or session variables. Recent studies on using RNNs on click-stream data [22], [17], [7], [16] and [18] are conceptually close to our approach in terms of using RNNs to work with sequences of actions. However, all of them but [18] operate only on video interaction and exercise answer features, whereas we also include search queries and discussion messages. [18] does not explore the autoencoders or attention and does not investigate the extracted student representation. Moreover, in most of them, aggregation still happens: [17] uses cumulative counts, [16] – weekly snapshots and in [22] interaction features are binary per item, while we feed the raw sequences as an input to predictive models. Besides, their task is to predict the next exercise response while we predict the overall course success.

Concerning the use of deep learning for unsupervised feature extraction, only a few recent publications have explored it [7]. For example, autoencoders, a popular approach in natural language processing [35], have only recently entered the educational data mining field [36]. Motivated by this, we extend recent end-to-end approaches to feature engineering on trace data by using autoencoders (including an attentional one) to embed student behaviour.

Regarding the character of the trace data used, we operate on short courses which contain multimedia content (such as videos and discussion messages; details are provided in section 3). The dataset also addresses the variability across a range of subjects [24]. Moreover, it allows us to showcase the methods in a real-life scenario, as the data is collected from a commercial educational platform. It should be noted that only coarse-grained trace data is available, i.e. there are no details of interaction with videos, such as replays. To enrich the data representation without changes to the original platform, we introduce several encoding schemes that capture the relative progress within the course.

Despite their promising results, the state-of-the-art deep learning methods are black-box models, which renders the interpretation of the prediction making process and incorporation of domain knowledge far from straightforward [10]. Such lack of interpretability can seriously hinder the adoption of otherwise efficient models in decision-critical domains such as education, as stakeholders cannot control or assess the fairness of the process. In order to illuminate how the model makes a decision, we can cluster the produced student behaviour representations or investigate attention heatmaps. In spite of the apparent success of attention mechanisms in

natural language processing [2], few researchers have utilised them for academic performance prediction so far [25].

While our primary focus is on predicting academic performance, it is also necessary to provide an insight into the learning strategies of students [12]. While this concept is reminiscent of learning styles [9], it avoids their heavily criticised assumptions [29] by performing analysis bottom-up based on raw data, instead of fitting the students in a rigid framework. One way to investigate different learning strategies is to cluster students based on their trace data. The resulting clusters implicitly classify students according to how they receive and process information or whether they are high- versus low-achievers. The obtained cluster assignment allows us to improve personalisation mechanisms since we can now use the student's preferred mode of interaction (for example, adjust the proportion of videos versus readings based on how much of a visual learner the student is). Previous research in this field relied on Hidden Markov Models, pattern mining, or Levenshtein distance between sequences [6, 13]; on numerical features, Partitioning Around Medoids [11] or k-Means are used. This study clusters the embeddings produced by predictive models and autoencoders. We expect students with similar learning strategies to appear in the same clusters. By aligning these clusters with academic performance scores, we could distinguish strategies typical for low- and high- achievers.

3. DATA & FEATURES

3.1 Data

The dataset for this study consists of student trace data extracted from an online educational platform for secondary school students (12-18 years old), with a focus on mathematics and Dutch language courses. The dataset contains interaction logs for 44 333 students and 467 short courses (177 873 students-course tuples) from 20 September 2012 to 8 August 2020. Each course includes several lessons with associated videos, discussion threads and exercises (mostly multiple choice).

The target variable is the score that the student obtains for the course. We converted the original score (from 0 to 100) into a binary variable ($I(score > 50)$), as we are interested in patterns corresponding to general success or failure in the course. Thus, for a given student-course tuple, we need to predict 0 if the student is likely to fail the course and 1 otherwise.

For this binary classification case, there is a noticeable class imbalance: there are 124 248 (70%) instances in class 1 and 53 625 (30%) in class 0. It is also important to note that the courses on the platform are rather short compared to most datasets in the field: the median number of actions per student-course tuple is 8, and the median duration of a course is approximately 14 minutes. In comparison, [7] use information about 44 920 students participating in a 4-month course focused on a single subject, with 20 interaction features.

3.2 Features

We distinguish three ways to engineer features (see Table 1 for the example data entry). Count and session features are traditional predictors. Sequences of actions are also often aggregated per timestep (e.g. a chapter in the course) instead of being used as-is. In contrast, we use the sequences in their raw, original format as input for neural models. Such a general data format can be applied in any online course with minimal technical requirements for tracking student behaviour, which benefits smaller learning platforms. More precisely, the features we use are as follows:

1. counts of actions X_c. For example, the student with id 77 watched four videos in a course with id 60. These features include the number of: video views, video likes, messages posted in forums, search queries, questions attempted (without making a distinction between correct or incorrect answer).

2. manually engineered session features X_s. We experimented with multiple threshold timeout values (as we did not have access to login and logout timestamps for students), settling on 15 minutes. We then aggregated statistics about individual studying sessions, resulting in 4 features: average session duration in seconds, number of sessions, session frequency (the ratio of number of sessions to the course duration in hours) and session intensity (average number of actions per session). This is a typical set of features engineered in similar studies [32], which we use as a benchmark.

3. raw action sequences X_a. There are five possible actions: a video view, a video like, a discussion forum message post, a search request for a term, and an attempt to answer an exercise (without the indicator of whether the answer was correct).

Due to the short duration of courses, encoding with just five types of actions without any additional information leads to low variability in data: out of 177 873 sequences, only 10 058 are unique. As a consequence, the same behaviour pattern could correspond to both passing and failing the course. To overcome this issue, we consider several ways to encode additional information in elements of the sequence. We list them by their generalisability, from least to most.

Concatenating global content item id and the corresponding actions. For instance, for a video with id 12, we would encode the action as "video_view_12" (we give examples for videos, but the idea transfers directly to other content items as well). We can also encode items associated with the video:

answering the exercise about this video would be encoded as "exercise_answer_12". The downside is that both these approaches do not generalise to new courses: we have to assume that the number of either courses or content items is fixed. Otherwise, a model needs to be retrained. It is a common problem also found in such popular approaches as DKT [33]. Besides, this approach quickly leads to an inflated vocabulary, making it computationally inefficient if one would use the bag-of-words approach (hence it is not featured in Table 2 for machine learning models, only for recurrent networks).

Encoding actions using local content item ids, preserving their relative order in the course. In other words, if the video with id 12 is the first video in a given course, then we encode the action as "video_view_1". This scheme has the potential for interesting insights into student behaviour. For example, we can see whether consequently watching the videos contributes a lot to better performance. Besides, we can gauge the engagement and background knowledge by checking whether the student immediately watched later videos. Regarding the disadvantages, the applicability to new courses is still limited: the number of videos should be the same or less than in the courses we have seen before. Using the out-of-vocabulary token or setting the maximum possible number of videos high is the simple workaround. However, a more flexible solution might be required – for which we suggest the progress percentage encoding.

Encoding the rounded percentage of the total number of videos in the course. For instance, if there are five videos in total, then the view of the second one will be represented as "video_view_40" (40%). Even though we can no longer focus on the exact content item as if the case with the other encoding schemes, we can still potentially recommend the section of the course to revise. This is the most flexible way, as it scales to new courses (of arbitrary length, with previously unseen exercises) as well.

We provide experimental results using the four proposed encoding schemes (raw X_a, global content id X_{a-gid}, local content id X_{a-lid} and progress percentage id X_{a-pid}, respectively) in section 5. To each of the above schemes, we can also add the difference in seconds with the previous action if the timestamps are available.

4. MODELS

We trained three types of classification models on numerical count features X_c and session features X_s: Logistic Regression, Decision Tree and Random Forest. For sequence data X_a, we used two popular variations of RNN – Long-Short Term Memory (LSTM) [14] and Gated Recurrent Unit (GRU) [4]. We have experimented with convolutional neural networks, but their performance was lower than that of recurrent ones. As such, for the sake of brevity, we do not focus on them in this study.

On a general level, neural classification models embed action sequences and pass them through recurrent layers to the final feed-forward layer(s) with sigmoid activation. It produces a probability of success which is then converted into a classification prediction score. A recurrent neural network takes a sequence of vectors $\{x_t\}_{t=1}^{T}$ (T is the number of timesteps) as an input and maps them to an output sequence $\{y_t\}_{t=1}^{T}$ by calculating hidden states $\{h_t\}_{t=1}^{T}$ which encode past information that is relevant for future predictions. LSTM uses a more elaborate structure in each of the repeating cells, allowing it to learn long-term dependencies. It includes so-called forget, input and output gates, which control what information to retain and pass to the next step. GRU simplifies the cell by combining the forget and input gates into a single update gate and merges the cell state and hidden state.

An encoder-decoder framework uses an RNN to read a sequence of vectors $\{x_t\}_{t=1}^{T}$ into another, context vector c in an auto-regressive fashion. If we set the desired output sequence equal to the input one – so that the goal becomes the reconstruction of the original data – we obtain an autoencoder. Then, the context vector, if its dimensionality is chosen to be lower than that of the input, will contain a denoised representation of the data that can be used in other models. This way, an autoencoder allows us to learn efficient data representation in an unsupervised manner.

Bahdanau attention mechanism allows the network to focus on certain parts of the input [2]. It is achieved by computing the context vector as a weighted sum of vectors produced by the encoder. The weights are learnt by a feed-forward neural network jointly with the rest of the model. Transformer model is a recent competitive alternative to the encoder-decoder framework [34] which foregoes the recurrent cells in favour of stacked self-attention and feed-forward layers.

5. EXPERIMENTS

We apply machine learning models on count and session features and compare them with deep learning ones on sequences of actions (with different encoding schemes used, as outlined above). Besides, we embed action sequences using an LSTM autoencoder and use its output X_{auto} as input for the classification models.

Neural network models were implemented using Keras [5] with Tensorflow backend [1] and machine learning ones with sklearn [3]. The parameters were optimised using the grid-search with stratified 10-fold cross-validation (5-fold for neural models). For recurrent neural networks, we checked the following parameter values: 32/64/128 recurrent units, 32/64/128 hidden units in feed-forward layers, 32/64/128 embedding dimensions. The maximum sequence length was set to 50. The models were trained with binary cross-entropy loss, using the Adam optimiser [19], early stopping and learning rate reduction on a plateau.

5.1 Classification

For the binary classification task, the cross-validation ROC AUC scores are presented in Table 2. Inspecting the table, we can conclude that end-to-end models perform at least as well as the ones using manually engineered features, even when the length and variability of actions sequences are limited.

Concerning **RQ1**, the contribution of different encoding schemes, we can see that global content id encoding performs the best. However, as mentioned above, it does not scale to new content items. However, using the percentage encoding scheme

Table 2: Cross-validation ROC AUC scores for classification models. Input features: count features X_c, session features X_s, action sequences X_a with encoding scheme variations (no id X_a, global content id X_{a-gid}, local content id X_{a-lid}, progress percentage id X_{a-pid}), actions embeddings by LSTM autoencoder X_{auto}, actions embeddings by an attentive (Bahdanau) LSTM autoencoder X_{auto_B}.

	X_c	X_s	X_{a-lid}	X_{a-pid}	X_{auto}	X_{auto_B}
Logistic Regression	0.62	0.62	0.69	0.67	0.77	0.76

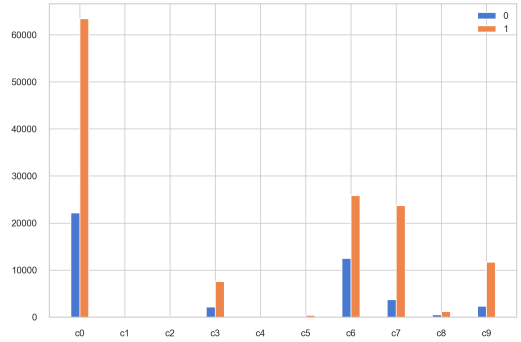
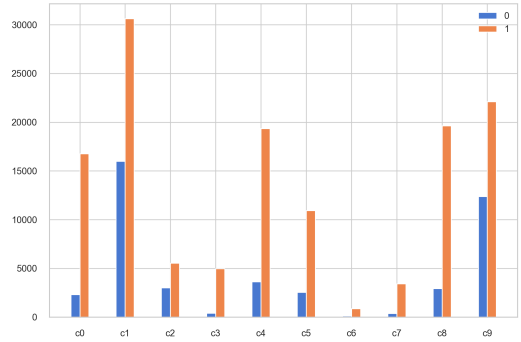
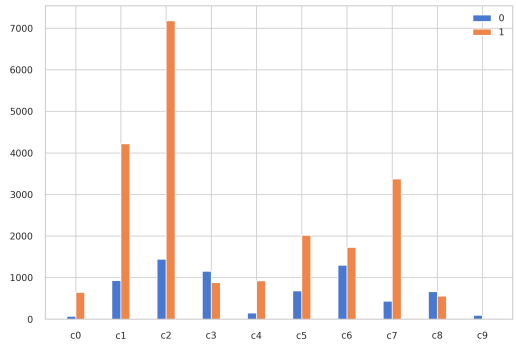
Decision Tree	0.73	0.80	0.79	0.80	0.80	0.80
	X_a	X_{a-gid}	X_{a-lid}	X_{a-pid}	X_{auto}	X_{auto_B}
LSTM	0.73	0.88	0.82	0.81	0.82	0.83
GRU	0.73	0.87	0.81	0.81	0.83	0.82



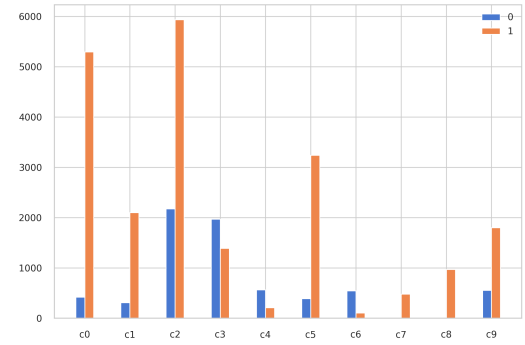
(a) X_c (count features)



(b) X_s (session features)



(c) X_a (LSTM embeddings on action data)



(d) X_{a-pid} (LSTM embeddings on action data with progress percentage id)

Figure 1: Distribution of target variable (pass/fail score) over the K-Means clusters based on different data representations (with Euclidean distance; K of 3, 5, 10 and 20 were tried). LSTM embeddings distinguish better between high- and low-achievers, producing clusters that clearly correspond to one class more than the other, while for traditional count (a) and session (b) data, most of the clusters contain a mix of both classes. For LSTM embeddings on action data (c), clusters appear that contain more failing students than passing – and are thus more useful for early warning systems. The effect is even more pronounced if we use progress percentage encoding (d).

also gives a steady increase in ROC AUC score: from 0.73 to 0.81 for Random Forest, where we use count features, and similarly for recurrent networks, where we use sequences. Using unsupervised embeddings obtained with an autoencoder (the focus of **RQ2**), we gain an improvement as well: from 0.73 to 0.82 for both machine and deep learning models.

Contrary to our expectations for **RQ3**, adding attention did not significantly improve the results. We experimented with including an attention mechanism directly into the classification models, both Bahdanau and Transformer. It can be done, for example, by training a simple Transformer, then using the average of its encoder's hidden states as an input to a classification model on top. Unfortunately, those modifications did not influence performance in our experiments, in contrast to [25]. We hypothesise that the features might be too coarse-grained and the sequences too short to take full advantage of the technique; there are also no skill labels that would provide the hierarchical structure that attention mechanisms can reflect. However, using attention allows us to produce visualisations that a first step to understanding the decision-making process of the neural network. Thus, we provide the attention scores from a Bahdanau-attention classification model below for illustration purposes.

To gain more actionable insight from our models, we also investigated the predictive performance on partial action sequences. Being able to predict early that a student will fail the course would allow sending a timely alert to the educator, signalling the need for intervention. Hence, we explored how the performance of the models changes when only the first N actions are available. For these experiments, to ensure that the model does not have full information, we only used courses with more than five questions and more than eight actions. As depicted in Figure 2, sequential data lead to higher scores than count features and proposed encoding schemes outperform raw action sequences.

5.2 Clustering & Visualisation

We clustered the student-course tuples based on different data representations using k-Means and plotted the distribution of the target class over these clusters (see Figure 1d) to investigate how the models distinguish between learning strategies of low- and high-achievers. For traditional count and session data, most of the clusters are not easily interpretable, as they contain a mix of both classes, roughly following the target label distribution. For instance, when using count features, almost all student-course pairs are in just three clusters, so there is little distinction between learning strategies. It should be noted that even though some clusters appear empty, in fact they still contain a very small number of students.

When we increase the representation's complexity, the extracted groups are more distinct. The distribution of high- and low-achievers in them shifts so that clusters with the prevalence of a single class emerge. The improvement is even more noticeable with progress percentage encoding: more clusters are extracted where one class is prevalent. For LSTM embeddings on action data, clusters appear that contain more failing students than passing, signalling that this is an unsuccessful strategy (clusters 4 and 6 on 1). This information is vital for early warning systems. The effect is even more pronounced if we use the progress percentage encoding, which encourages the application of these schemes for distinguishing between successful and unsuccessful learning strategies.

Another way to shed light on the prediction process of a neural network is to visualise attention heatmaps, where higher scores correspond to actions in the sequence that are more important for the classification decision (Figure 3).

Limitations & Future work. A wide range of topics covered in these courses might influence the performance, as different subjects are likely to demand different behaviour patterns to successfully pass the course (e.g., humanities versus technical subjects). We plan to investigate them separately and include information about exercise content. Finally, we plan to train a recommendation system informed by the extracted learning strategies to aid navigation.

6. CONCLUSION

We show that it is possible to predict whether students will pass the course using only their navigation pattern sequence in the online learning platform, without information about past grades. The findings of our study suggest that features extracted with deep learning are efficient even if the courses are extremely short, cover multiple different subjects, and only a limited number of interaction types is available.

We propose a flexible way to increase the classification performance with minimal preprocessing of the raw sequences of actions extracted from the learning platform required. A novel and relatively simple percentage progress encoding scheme is introduced which captures the course structure while scaling well to the new data. It results in an improvement of almost 10% in ROC AUC score. We also demonstrate a positive effect of using pre-trained unsupervised embeddings obtained with autoencoders (up to 15% improvement when using in machine learning models, compared to traditional features). We cluster resulting embeddings to show that using action sequences has more potential for distinguishing between strategies specific to high and low achievers than simple count or session features. It is possible to visualise attention heatmaps and see the contribution of individual actions to the classification decision to interpret retrieved strategies.

Our research supports decision-makers, as it allows detecting (un)successful students from their navigation patterns alone, without having to grade intermediate exercises. The action sequences corresponding to high achievers can be used to inform learning design patterns and recommendation systems in a more meaningful way than the standard count features. As the proposed models are shown to outperform several baselines on extremely short, incomplete action sequences, they allow us to intervene early if a student begins to follow a trajectory associated with a lower chance of success.

APPENDIX

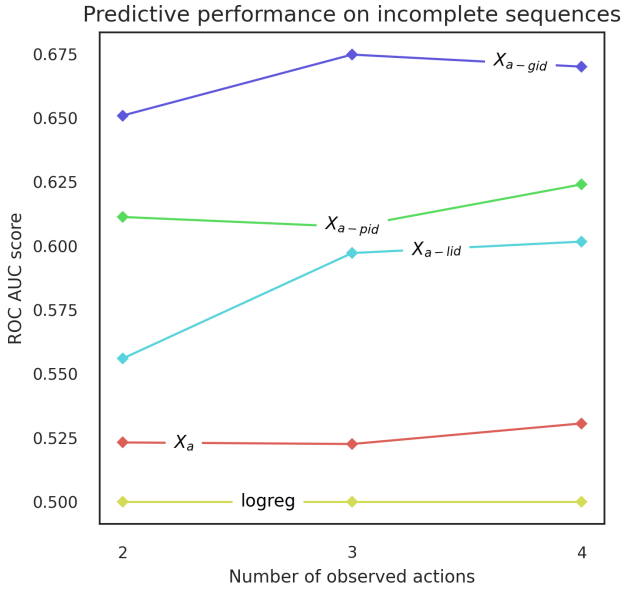

Figure 2: Comparison of validation ROC AUC scores of an LSTM on encoding schemes in the incomplete sequence scenario. We can see that percentage and local content id encoding schemes perform better than raw actions. As such, we would be able to detect whether a student is likely to fail from the first two actions already.

Figure 3: An attention heatmap of the RNN model with Bahdanau attention mechanism on action data (multiple sequences view). Higher scores (brighter colours) correspond to actions in the sequence that are more important for classifying the student as passing or not. If we use an encoding scheme which includes content id (such as the global content id here), we see which content items contribute more to the classification decision: for example, in the bottom row, the viewing of the video with id 264231 is more important for the network than the others.

Assessing Attendance by Peer Information

ABSTRACT

Attendance rate is an important indicator of students' study motivation, behavior and Psychological status; However, the heterogeneous nature of student attendance rates due to the course registration difference or the online/offline difference in a blended learning environment makes it challenging to compare attendance rates. In this paper, we propose a novel method called Relative Attendance Index (RAI) to measure attendance rates, which reflects students' efforts on attending courses. While traditional attendance focuses on the record of a single person or course, relative attendance emphasizes peer attendance information of relevant individuals or courses, making the comparisons of attendance more justified. Experimental results on real-life data show that RAI can indeed better reflect student engagement.

Keywords

attendance, peer information, engagement, academic performance, comparison, clustering

1. INTRODUCTION

While studying offline is the norm for most schools, during epidemic periods all or a portion of students are forced to study online due to university closure. In such a blended learning environment, tracking the study status and the wellbeing of students is an important issue for the university. Students' attendance in classes is a measure that reflects students' enthusiasm for the course and their status in the university [29]. Many studies suggest a correlation between attendance and attainment at university [5, 26, 14]. Several studies detect attendance rates using mobile devices and include attendance as a feature to predict academic performance [27, 19, 28]. Attendance is also correlated with behavior and Psychological problems such as video game addiction [24] and depression [26]. Detecting unusual attendance rate changes can help to identify abnormal behaviors and Psychological problems in an early stage and provide in time intervention to students in need.

The successful applications of attendance data call for fair comparisons among peer attendance, especially in universities. Traditionally, the attendance rate of a course or a student is isolated and might not be compared fairly, because in many universities students are allowed to select some courses on their own so that the course registration records of two students can be different. In addition, each course can have its own attendance policy, making it harder to compare attendance rates. Courses that have mandatory attendance requirements usually have higher attendance rates than those do not, so that it is not fair to compare course attendance rates without considering attendance requirements. Similarly, students who registered for courses with mandatory attendance requirements usually have higher attendance rates than students who registered for courses with voluntary attendance requirements, so that the attendance rate does not always reflect the attainment of a student. Attendance of online and offline courses may not be compared directly as well, because the efforts to attend those courses can be significantly different. Attending online courses could be as simple as a mouse click away, while attending offline courses usually requires travelling from place to place physically.

Traditionally it is not easy to fairly compare attendance in a university, due to not just the diversity of course registration and attendance requirements but also the difficulty of collecting campus-wide attendance data. Without attendance information of peer students or courses, the attendance data of a student or a course is isolated and difficult to adjust. However, in the era of Big Data, many new technologies [12, 18, 31] have been proposed to collect attendance data for many courses simultaneously, making it possible to analyze the attendance structure of the student population, and develop new attendance calculation methods.

Careful comparisons of attendance can also provide insight into students' academic interest. If a student attends a course that has a generally low attendance rate, it indicates that the student is more willing to attend the course than their classmates are; On the other hand, if a student attends a course that has a generally high attendance rate, it indicates that the student is just doing what others are doing.
