In this paper, we propose a novel method called Relative Attendance Index (RAI) to measure attendance, which reflects the efforts on attending courses and makes comparisons of attendance more justified. To our knowledge, this is the first study on fair comparisons of attendance. While traditional attendance focuses on the record of a single person or course, we define a notion for attendance contribution to course attendance and add the attendance information of relevant individuals or courses to make the comparisons of attendance fairer. We perform a campus-wise study on attendance and analyze its effects on course grades and GPA. Our experiment results show that RAI has a higher correlation with academic performance than the traditional attendance rate.

The rest of this paper is organized as follows. Section 2 describes the related studies. Section 3 introduces the RAI definition. Section 4 presents the experiment results on real-life data from a university. Section 5 discusses an application of RAI on clustering student populations. Section 6 describes the limitations and future work. Section 7 lists the acknowledgments.

2. RELATED STUDIES

With the advancement of technology, many new methods have been proposed to collect campus-wide attendance data. Several studies [13, 11, 18] measured attendance via QR code systems in which QR codes are generated and then scanned by students to authenticate themselves. Wang et al. [26] deployed an APP to students' cell phones to detect attendance by GPS signals and WiFi tracing. A method independently developed in [19] and [28] used WiFi log to calculate attendance. Studies in [2, 25] proposed Bluetooth/Beacon based attendance prediction systems. Shoewu and Idowu [22] used fingerprints and Kar et al. [12] used face recognition to detect individual attendance rates.

Some studies measured offline and online attendance at the same time. Brennan et al. [4] detected physical attendance by thermal sensors and online behaviors by clickstream data. The change of online and physical attendance through time was observed. However, due to a technology limit, the method did not link physical attendance to individuals and did not study the issue of attendance comparison. Nordmann et al. [17] mixed the data of physical attendance and online recording clickstream together to form the total attendance rate instead of studying them separately. However, attendance of live lectures is still a stronger predictor than recording use on students' academic performance.

Many studies confirmed the correlation between attendance and academic performance [1, 3, 7, 16]. See [15] for a survey. [15] also reviewed factors that affect attendance. To work around the issue of fair comparisons of attendance, many studies focused on samples from the same course or samples with similar registration records (e.g., first year students) [1, 3, 10]. [3] also controlled factors such as age, gender, nationality etc. in their regression analysis. Studies in [7] and [16] divided the students into bands according to grades and used the average attendance of each band for correlation studies.

Student subtyping and clustering are widely used in analyzing learning process and predicting academic performance. Yang et al. [30] applied EM-IRL to students learning behavior data and observed significant differences between groups. Romero et al. [20] used clustering on online forum data to predict students' final performance. Resulting model turned out to be suitable and highly interpretable. Cerezo et al. [5] studied both learning process and clusters' relation with performance using LMS logs data. Resulting clusters are well-interpreted and showed satisfying correlation with final marks.

Many studies explored the reasoning for student class attendance. Friedman et al. [9] and Moore et al. [14] reported positive relationship between class attendance and students' motivation. Sloan et al. [23] further found that the level of interest has significant impact on attendance. These studies indicated that attendance, along with other features, can better show students' academic interest than traditional models.

None of the above studies has applied peer information to revise attendance measurements.

3. METHOD

The traditional attendance rate of a class or a student is defined in a straightforward way. Only the information of the class or the student is involved. We give the definition of Attendance Rate (AR) formally as in Definition 1.

Definition 1 (Attendance Rate r_c and r_s): Given class c and student s, let n_c^{reg} and n_c^{att} be the number of students registered c and the number of students attended c respectively; let n_s^{reg} and n_s^{att} be the number of classes registered by s and the number of classes attended by s. Then the Attendance Rate (AR) of class c (r_c) and of student s (r_s) are defined as below respectively.

$$r_c = \frac{n_c^{att}}{n_c^{reg}}, \tag{1}$$

$$r_s = \frac{n_s^{att}}{n_s^{reg}} \tag{2}$$

Students can have different sets of registered classes, and classes can have very different attendance requirements. When comparing the attendance rates of two students, it is necessary to analyze the set of classes attended by these two students and the attendance rates of these classes. If a student attends a class attended by almost everyone, the student makes little contribution to the attendance rate of the class; on the other hand, if a student attends a class that has a low attendance rate, the student makes a significant contribution to the attendance rate. To capture the concept, we propose the notion of attendance contribution as in Definition 2.

Definition 2 (Attendance Contribution D_{sc}): Let r_c be the attendance rate of class c, and a_{sc} be a function indicting whether student s attended class c or not, then the Attendance Contribution of student s on the attendance rate of class c is defined as

$$D_{sc} = a_{sc} - r_c, \text{ with} \tag{3}$$

$$a_{sc} = \begin{cases} 1, & \text{if } s \text{ attended } c \\ 0, & \text{if } s \text{ did not attend } c \end{cases} \tag{4}$$

Since $r_c \in [0, 1]$, Attendance Contribution is a number between -1 and 1. If s has registered c and s attended c, then the attendance rate of c cannot be zero and D_{sc} can approach 1 but never reach 1.

With Attendance Contribution, we can compare the attendance rates of two students by computing the average Attendance Contribution on registered classes. We defined the notion as Relative Attendance Index (RAI) in Definition 3.

Definition 3 (Relative Attendance Index RAI_s**):** Given student s, Let K_s be the set of classes registered by s, the Relative Attendance Index (RAI) of s is defined as

$$RAI_s = \frac{\sum_{c \in K_s} D_{sc}}{|K_s|} \tag{5}$$

RAI considers both the student's individual attendance status of a semester and the attendance status of the student's classmates. The peer information is injected into the new measure through the course attendance rate in Attendance Contribution.

LEMMA 1: $-1 < RAI_s < 1$.

Proof: The RAI_s definition only considers classes registered by s. When $a_{sc} = 0$, $r_c \in [0,1)$; When $a_{sc} = 1$, s attended c, therefore $r_c \in (0,1]$. Thus $a_{sc} - r_c \in (-1, 1)$, Therefore $RAI_s = \frac{\sum_{c \in K_s}(a_{sc} - r_c)}{|K_s|} \in (\frac{|K_s| \times -1}{|K_s|}, \frac{|K_s| \times 1}{|K_s|})$ = (-1, 1). □

RAI is a number between -1 and 1. When RAI approaches -1, a_{sc} is mostly 0 and r_c approaches 1 for most classes, indicating that

the student has skipped many well attended classes. On the other hand, when RAI approaches 1, a_{sc} is mostly 1 and r_c approaches 0 for most classes, indicating that the student has attended many poorly attended classes. Therefore, RAI shows the difference of attitudes toward classes between students and their classmates.

4. Results

4.1 Data and Setup

The anonymous attendance and grade data used in this paper were collected in 2018 and 2019 from a university[1] in China. We applied the method proposed in [19] and [28] to calculate the attendance. Note that our Relative Attendance Index can be applied to attendance data collected using other methods such as QR code [18]. The student IDs were converted into hash codes, then the attendance and grade data were connected through the hash codes. The university did not have a mandatory attendance policy; however, while most instructors followed the university policy, some instructors had their own attendance requirements. Some instructors used in-class discussions and quizzes to encourage attendance. The data came from 4838 students from Cohort 14 to 19 in 44 majors, spanning over 3 semesters, with 1489 courses grouped into 37 categories by the university. For most courses, students received letter grades from A to F. Courses with other grades such as P/F were excluded. The traditional attendance rate (AR) for a student was calculated using Formula (2) in Definition 1, and the corresponding RAI was calculated using Formula (5) in Definition 3.

4.2 Correlation with Academic Performance

Many previous studies show that attendance is correlated with academic performance. Given that the purpose of student attendance comparison is usually to assess the attainment of the students, we calculated the correlation between attendance rates and GPA to assess the fairness of attendance comparisons. A more correctly calculated attendance assessment will have a higher correlation with the GPA. The Pearson correlation between RAI and GPA is 0.48, which is significantly higher than that of AR (0.37). The p-values of the two correlation values are 3.7×10^{-225} and 2.6×10^{-129} respectively. Since they are well below the 0.05 threshold, the correlation values are generally considered significant.

We also calculated the correlation between attendance and academic performance within each course category. The result is shown in Table 1 (sorted by the RAI correlation). Some course categories were filtered out because they had small enrollments and did not generate correlation values with low enough p-values (<0.05) to be statistically significant. For 19 out of the 26 course categories, RAI has a higher correlation than AR. Only for two categories, GED and FRN, AR has a higher correlation than RAI (The descriptions of the categories are listed in Table 1). AR and RAI are tie for the five categories of FMA, GNB, ERG, CHM and CSC. We remark that language related courses such as ENG (English) have low correlations because those courses usually have in-class discussions resulting in an unofficial mandatory attendance requirement. Categories that rely on prior knowledge in high school, such as Chemistry and Physics, also have low correlations. Since most students attending this university did not study Calculus in high school and Calculus accounts for a large faction in Mathematics courses, it is reasonable to see the MAT category having a much higher correlation.

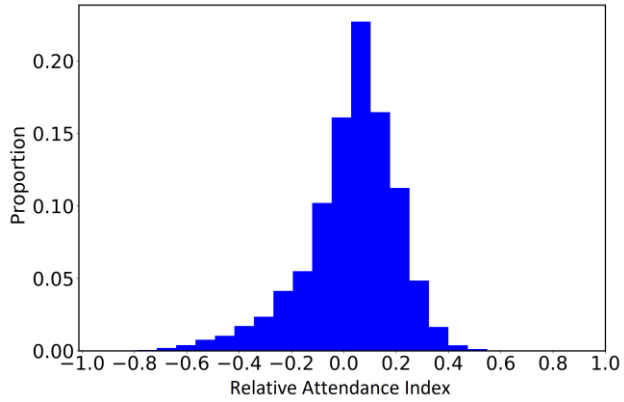
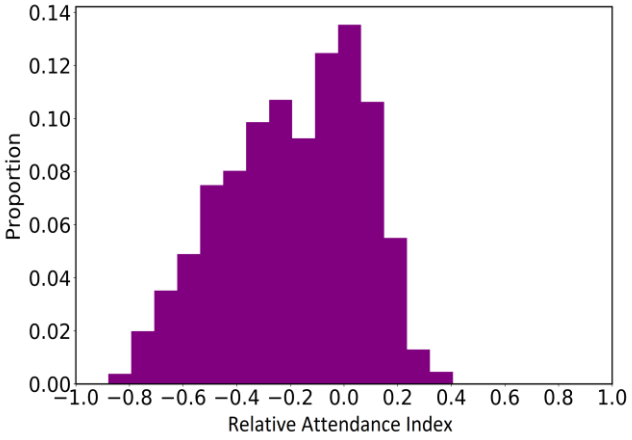
4.3 RAI Distribution

To illustrate the different distributions on RAI for high and low course grade students, we collected two sets of samples, with one set having a course grade no less than B+ and the other set no greater than C. Each sample is a triplet with a hashed student ID, a course ID, and the corresponding grade received by the student in the course. We then calculated the RAI of the student in the corresponding course. Figure 1 (a) shows the distribution of the first set. It shows that more than 50% of samples have RAI > 0 (better than normal). Figure 1 (b) shows the distribution of the low course grade set. It shows that the majority of samples have RAI < 0 (worse than normal), with some down to -0.8. For easier comparisons of both sets, the values in both subfigures have been

[1] The use of the data by our project has been approved by the university management and the committee in charge of personal information in this university.



(a) Samples with grades ≥ B+



(b) Samples with grades ≤ C

Figure 1. RAI of high and low course grade samples.

normalized as the proportion values. We can see that the first set has a more concentrated distribution than the second set. This indicates that students receiving grade C or lower have a much higher probability of having extreme attendance behaviors (skipping many courses).

5. DISCUSSION

In this section, we showcase an application of RAI on clustering the student population.

We formatted the attendance values in the 37 course categories as a vector for each student, then applied a clustering algorithm on the vectors. Since the dimensionality of 37 is too high for most clustering algorithms, we applied PCA to reduce the dimensionality. The clustering algorithm we applied was the DBSCAN clustering algorithm [8] using the Euclidean distance. DBSCAN performs density-based clustering and does not require the input of the cluster number. The parameters we tuned in this experiment are specified in Table 2. We applied silhouette score [21] to select the best set of parameters with the highest silhouette score.

Table 2. Parameters to tune for the clustering.

Parameters	Range
Number of PCA components	[5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15]
Eps of DBSCAN	[0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0]
MinPoints of DBSCAN	[5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20]

We applied the same clustering procedure to AR and RAI attendance values respectively. For AR, the procedure failed to generate meaningful clustering (the result contained one big cluster only). For RAI the procedure produced 8 clusters with 616, 472, 665, 520, 130, 1799, 61, and 549 students respectively. 26 student samples were labeled as noise by DBSCAN and excluded in the follow-up study. For each cluster, we identified the top five most popular majors among the samples in the cluster to analyze students' academic interest and performance.

Figure 2 shows the profiles of the 8 clusters from the RAI clustering, labeled as cluster 1 to 8. We combined the dimensions of student numbers, distribution of majors, RAI attendance rates, top 10% academic performance ratio, and last 10% academic performance ratio to show how RAI attendance is related with academic performance and how the analysis can provide guidance on major selection. While some of the findings are interesting, we admit that not all phenomena can be fully explained due to the complexity behind attendance and attainment [15]. For all subfigures in Figure 2, the X is the major of the students. Figure 2(a) shows the number of students in each major for the 8 clusters in a row. Some of the clusters are very specific. Cluster 5 contains two majors only, TRAN (Translation) and PSY (Psychology); Cluster 7 contains the major of FE (Financial Engineering) only. Figure 2(b) shows the distribution of majors among the clusters (whether a cluster accounts for a significant portion of the students in a major), with each bar representing a fraction of the corresponding major in the university. For example, as shown in Figure 2(b), close to 70% of the students majoring in PSY are in cluster 5; close to 50% of the students majoring in CSE (Computer Science and Engineering) are in Cluster 6, with other large portions of CSE students in Cluster 2, 3 and 4. Figure 2(c) shows the RAI attendance of the clusters. Students in Cluster 6 have significantly lower RAI values than the other clusters. Figure 2(d) shows the ratio of students with a GPA in the top 10% of the major. If a bar of major *m* is higher than the 0.1 line, it means that the students from the cluster in major *m* outperform the average level of students in major *m*. Similarly, Figure 2(e) shows the portion of students with a GPA in the last 10% of the major. The higher the value, the worse the performance of the students, which is the opposite of Figure 2(d).

Figure 2 illustrates how RAI correlates with academic performance. Figure 2(c) shows that Cluster 6 has the overall lowest RAI values, with all the five majors having negative RAI values. Cluster 6 also has the worst top 10% ratio in Figure 2(d) (only one major is barely over the average cutline), and the worst last 10% ratio in Figure 2(e) (all five majors worse than the average). The TRAN major has about the same number of students in Cluster 5 and Cluster 8. The TRAN in Cluster 8 has a higher RAI value as well as a higher top 10% ratio and a much lower last 10% ratio than TRAN in Cluster 5. There are exceptions though. CSE in Cluster 3 has a negative RAI, but its

top 10% ratio is the highest in Cluster 3. However, this is consistent with our result in Table 1, which shows that CSE courses have a relatively low RAI correlation with academic performance (CSE major students usually take many CSE courses).

Another interesting finding is that in all the 7 clusters with more than one major, the major that has the highest RAI value also has the lowest last 10% ratio except for Cluster 2. In Cluster 2 it is the second highest RAI major EIE that has the lowest last 10% ratio. The highest RAI major in Cluster 2 is BIFC (Bioinformatics), a new major with a relatively small enrollment. Students facing the risk of poor academic performance may consider selecting or switching to the major with the highest RAI in the same cluster. While we admit that this is by-no-mean a correlation between RAI and students' academic interest, we remark that the interest in a subject is generally believed to be a weapon to fight against poor performance. Together with the fact that DBSCAN worked better on RAI than AR, we believe this phenomenon may suggest that RAI has a better potential than AR for exploring students' academic interest.

6. LIMITATIONS AND FUTURE WORK

In this study, we defined the Relative Attendance Index to adjust the attendance measurement, with the objective of better reflecting students' attainment and interest. While attendance is affected by many factors [15], the new information we introduced is only the attendance of the peer. Further improvements should address more factors of attendance.

When clustering on student data, the clustering algorithm DBSCAN worked better on RAI than AR data, and the clustering analysis confirmed the correlation between RAI and academic performance. We admit that we have not been able to confirm the correlation between RAI and students' academic interest, which is an interesting topic to be further explored.

The raw attendance data was collected using a WiFi based method [19, 28]. It is possible that some students closed the WiFi connection on their cell phones or even closed their cell phones all together before class, leading to a false label of absence. If a student had less than 50 WiFi connection records in a week, their data in that week were excluded from the statistics. While we admit that this could generate some noise in the attendance, we

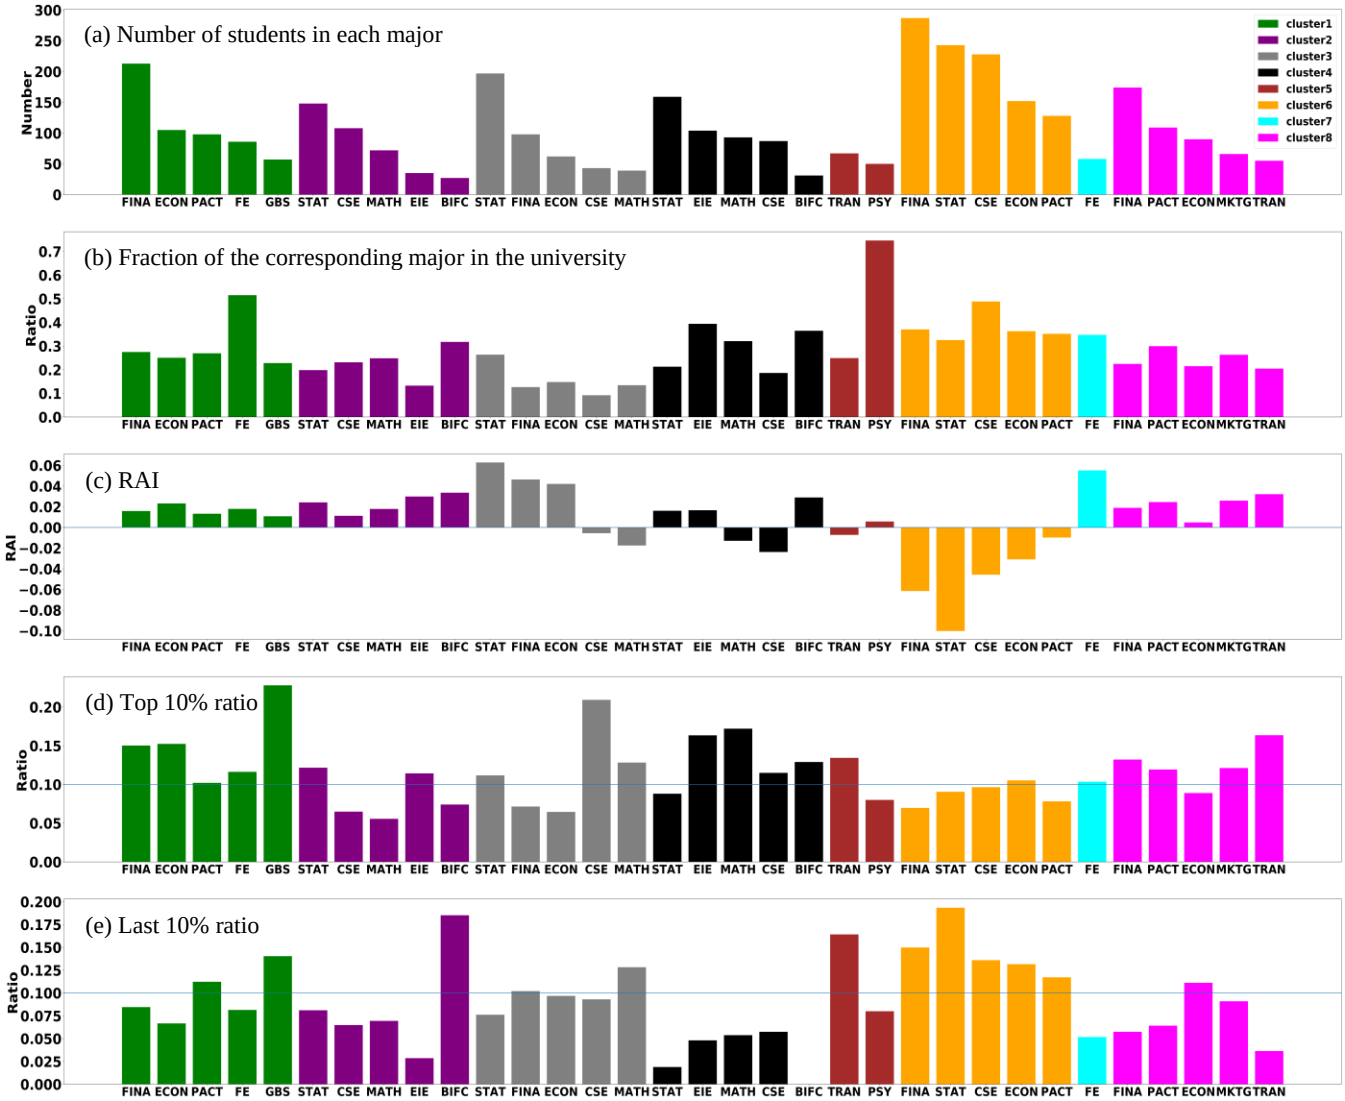


Figure 2. Student Clustering.

observed that this situation only occurred rarely. For example, in Fall term 2019 we found that only 2 out of 4838 students turned off WiFi completely, and only 3.34% of the students had some weeks of data filtered out. We conjecture two reasons for this phenomenon. First, usage of laptops and tablets is popular among the students in this university. Many students carry them to the classroom to view course materials. Laptops and tablets usually can connect WiFi only. Secondly, students use time confetti before and after class to chat with friends or read the news. It will be interesting to see how RAI performs on other attendance data such as QR code scanning and online attendance data.

ABSTRACT

Traditionally, clustering algorithms focus on partitioning the data into groups of similar instances. The similarity objective, however, is not sufficient in applications where a *fair-representation* of the groups in terms of protected attributes like gender or race, is required for each cluster. Moreover, in many applications, to make the clusters useful for the end-user, a *balanced cardinality* among the clusters is required. Our motivation comes from the education domain where studies indicate that students might learn better in diverse student groups and of course groups of similar cardinality are more practical e.g., for group assignments. To this end, we introduce the *fair-capacitated clustering problem* that partitions the data into clusters of similar instances while ensuring cluster fairness and balancing cluster cardinalities. We propose a two-step solution to the problem: i) we rely on fairlets to generate minimal sets that satisfy the fair constraint and ii) we propose two approaches, namely hierarchical clustering and partitioning-based clustering, to obtain the fair-capacitated clustering. Our experiments on three educational datasets show that our approaches deliver well-balanced clusters in terms of both fairness and cardinality while maintaining a good clustering quality.

1. INTRODUCTION

Machine learning (ML) plays a crucial role in decision-making in almost all areas of our lives, including areas of high societal impact, like healthcare and education. Our work's motivation comes from the education domain where ML-based decision-making has been used in a wide variety of tasks from student dropout prediction [9], forecasting on-time graduation of students [15] to education admission decisions [21]. Recently, the issue of bias and discrimination in ML-based decision-making systems is receiving a lot of attention [28] as there are many recorded incidents of discrimination (e.g., recidivism prediction [20], grades prediction [4, 14]) caused by such systems against individuals or groups or people on the basis of *protected attributes* like gender, race etc. Bias in education is not a new problem. There is already a long literature on different sources of bias in education [24] or students' data analysis [3] as well as studies on racial bias [31] and gender bias [22]. However, ML-based decision-making systems have the potential to amplify prevalent biases or create new ones and therefore, fairness-aware ML approaches are required also for the educational domain.

In this work, we focus on *fairness in clustering*, as in educational activities, group assignments [8] and student team achievement divisions [30] are important tools that help students working together towards shared learning goals. Clustering is an effective solution for partitioning students into groups of *similar instances* [3, 26]. Traditional algorithms, however, focus solely on the similarity objective and do not consider the fairness of the resulting clusters w.r.t. protected attributes like gender. However, studies indicate that students might learn better in diverse groups, e.g., mixed-gender groups [11, 32]. Lately, fair-clustering solutions have been proposed [1, 2, 5, 6], which aim to discover clusters with a fair representation regarding some protected attributes. In this work, we adopt the cluster fairness of [6], called cluster balance, according to which protected groups must have approximately equal representation in every cluster.

In a teaching situation, it is obvious that the size of the groups should be comparable to allow a fair allocation of work among the students. As traditional clustering algorithms do not consider this requirement, clusters of varying sizes might be extracted, reducing the usefulness and applicability of the partitioning for end-users/teachers. This leads to the demand for clustering solutions that also take into account the size of the clusters. The problem is known as *capacitated clustering problem (CCP)* [25] which aims to extract clusters with a limited capacity while minimizing the total dissimilarity in the clusters. Capacitated clustering is useful in quite a few applications such as transferring goods/services from the service providers (post office, stores, etc.), garbage collection and sales force territorial de-

Tai Le Quy, Arjun Roy, Gunnar Friege and Eirini Ntoutsi "Fair-Capacitated Clustering". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 407-414. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

sign [27]. To the best of our knowledge, no solution exists that considers both fairness and capacity of clusters on the top of the similarity objective.

To this end, we propose a new problem, the so-called *fair-capacitated clustering* that ensures fairness and balanced cardinalities of the resulting clusters. We decompose the problem into two subproblems: i) the fairness-requirement compliance step that preserves fairness at a minimum threshold of balance score and ii) the capacity-requirement compliance step that ensures clusters of comparable sizes. For the first step, we generate fairlets [6], which are minimal sets that satisfy fair representation w.r.t. a protected attribute. For the second step, we propose two solutions for two different clustering types, namely hierarchical and partitioning-based clustering, that consider the capacity constraint during the merge step (hierarchical approach)/assignment step (partitioning approach). Experimental results, on three real datasets from the education domain, show that our methods result in fair and capacitated clusters while preserving the clustering quality.

2. RELATED WORK

Chierichetti et al. [6] introduced the fair clustering problem with the aim to ensure equal representation for each protected attribute, such as gender, in every cluster. In their formulation, each instance is assigned with one of two colors (red, blue). They proposed a two-phase approach: clustering all instances into fairlets - small clusters preserving the fairness measure, and then applying vanilla clustering methods on those fairlets. Subsequent studies focus on generalization and scalability. Backurs et al. [1] presented an approximate fairlet decomposition algorithm which can formulate the fairlets in nearly linear time thus tackling the efficiency bottleneck of [6]. Rösner and Schmidt [29] generalized the fair clustering problem to more than two protected attributes. A more generalized and tunable notion of fairness for clustering was introduced in Bera et al. [2]. Anshuman and Prasant [5] introduced a fair hierarchical agglomerative clustering method for multiple protected attributes.

The capacitated clustering problem (CCP), a combinatorial optimization problem, was first introduced by Mulvey and Beck [25] who proposed solutions using heuristic and subgradient algorithms. Several approaches exist to improve the efficiency of solutions or CCP approaches for different cluster types. Khuller and Sussmann [17], for example, introduced an approximation algorithm for the capacitated k-Center problem. Geetha et al. [10] improved k-Means algorithm for CCP by using a priority measure to assign points to their centroid. Lam and Mittenthal [19] proposed a heuristic hierarchical clustering method for CCP to solve the multi-depot location-routing problem.

In this work, we introduce the problem of fair-capacitated clustering which builds upon the notions from fair clustering and capacitated clustering. In particular, we build upon the notion of fairlets [6] to extract the minimal sets that preserve fairness. Regarding the CCP we follow the formulation of [25] to ensure balanced cluster cardinalities. To the best of our knowledge, the combined problem has not been studied before and as already discussed, comprises a useful tool in quite a few domains like education.

3. PROBLEM DEFINITION

Let $X \in \mathbb{R}^n$ be a set of instances to be clustered and let $d() : X \times X \to \mathbb{R}$ be the distance function. For an integer k we use $[k]$ to denote the set $\{1, 2, ..., k\}$. A *k-clustering* $\mathcal{C}$ is a partition of X into k disjoint subsets, $\mathcal{C} = \{C_1, C_2, ..., C_k\}$, called *clusters* with $S = \{s_1, s_2, ..., s_k\}$ be the corresponding cluster centers. The goal of clustering is to find an *assignment* $\phi : X \to [k]$ that minimizes the objective function:

$$\mathcal{L}(X, \mathcal{C}) = \sum_{s_i \in S} \sum_{x \in C_i} d(x, s_i) \tag{1}$$

As shown in Eq. 1, the goal is to find an assignment that minimizes the sum of distances between each point $x \in X$and its corresponding cluster center $s_i \in S$. It is clear that such an assignment optimizes the similarity but does not consider fairness or capacity of the resulting clusters.

Capacitated clustering: The goal of capacitated clustering [25] is to discover clusters of given capacities while still minimizing the distance objective $\mathcal{L}(X, \mathcal{C})$. The capacity constraint is defined as an upper bound Q_i on the cardinality of each cluster C_i:

$$|C_i| \leq Q_i \tag{2}$$

Clustering fairness: We assume the existence of a binary protected attribute $P = \{0, 1\}$, e.g., gender={male, female}. Let $\psi : X \to P$ denotes the demographic group to which the point belongs, i.e., male or female.

Fairness of a cluster is evaluated in terms of the balance score [6] as the minimum ratio between two groups.

$$balance(C_i) = \min \left(\frac{|\{x \in C_i | \psi(x) = 0\}|}{|\{x \in C_i | \psi(x) = 1\}|}, \frac{|\{x \in C_i | \psi(x) = 1\}|}{|\{x \in C_i | \psi(x) = 0\}|} \right) \tag{3}$$

Fairness of a clustering $\mathcal{C}$ equals to the balance of the least balanced cluster $C_i \in \mathcal{C}$.

$$balance(\mathcal{C}) = \min_{C_i \in C} balance(C_i) \tag{4}$$

We now introduce the problem of fair-capacitated clustering that combines all aforementioned objectives regarding distance, fairness and capacity.

Definition 1. (Fair-capacitated clustering problem)
We define the problem of (t, k, q)-fair-capacitated clustering as finding a clustering $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ that partitions the data X into $|\mathcal{C}| = k$ clusters such that the cardinality of each cluster $C_i \in \mathcal{C}$ does not exceed a threshold q, i.e., $|C_i| \leq q$ (*the capacity constraint*), the balance of each cluster is at least t, i.e., $balance(\mathcal{C}) \geq t$ (*the fairness constraint*), and minimizes *the objective function* $\mathcal{L}(X, \mathcal{C})$. Parameters k, t, q are user defined referring to the number of clusters, minimum balance threshold and maximum cluster capacity, respectively.

4. FAIR-CAPACITATED CLUSTERING

4.1 Fairlet decomposition

Traditionally, the vanilla versions of clustering algorithms are not capable of ensuring fairness because they assign the data points to the closest center without the fairness consideration. Hence, if we could divide the original data set into subsets such that each of them satisfies the balance threshold t then grouping these subsets to generate the final

clustering would still preserve the fairness constraint. Each fair subset is defined as a fairlet. We follow the definition of fairlet decomposition by [6].

Definition 2. (Fairlet decomposition)
Suppose that $balance(X) \geq t$ with $t = f/m$ for some integers $1 \leq f \leq m$, such that the greatest common divisor $gcd(f, m) = 1$. A decomposition $\mathcal{F} = \{F_1, F_2, ..., F_l\}$ of X is a fairlet decomposition if: i) each point $x \in X$ belongs to exactly one fairlet $F_j \in \mathcal{F}$; ii) $|F_j| \leq f + m$ for each $F_j \in \mathcal{F}$, i.e., the size of each fairlet is small; and iii) for each $F_j \in \mathcal{F}$, $balance(F_j) \geq t$, i.e., the balance of each fairlet satisfies the threshold t. Each F_j is called a fairlet.

By applying fairlet decomposition on the original dataset X, we obtain a set of fairlets $\mathcal{F} = \{F_1, F_2, \ldots, F_l\}$. For each fairlet F_j we select randomly a point $r \in F_j$ as the *center*. For a point $x \in X$, we denote $\gamma : X \to [1, l]$ as the index of the mapped fairlet. The second step, is to cluster the set of fairlets $\mathcal{F}$ into k final clusters, subject to the cardinality constraint. The clustering process is described below for the hierarchical clustering type (Section 4.2) and for the partitioning-based clustering type (Section 4.3). Clustering results in an assignment from fairless to final clusters: $\delta : \mathcal{F} \to [k]$. The final fair-capacitated clustering $\mathcal{C}$ can be determined by the overall assignment function $\phi(x) = \delta(F_{\gamma(x)})$, where $\gamma(x)$ returns the index of the fairlet to which x is mapped.

4.2 Fair-capacitated hierarchical clustering

Given the set of fairlets: $\mathcal{F} = \{F_1, F_2, \ldots, F_l\}$, let $W = \{w_1, w_2, \ldots, w_l\}$ be their corresponding weights, where the weight w_j of a fairlet F_j is defined as its cardinality, i.e., number of points in F_j.

Traditional agglomerative clustering approaches merge the two closest clusters, so rely solely on similarity. We extend the merge step by also ensuring that merging does not violate the cardinality constraint w.r.t. the cardinality threshold q.

THEOREM 1. *The balance score of a cluster formed by the union of two or more fairlets, is at least t.*

$$balance(\mathcal{Y}) \geq t, \text{ where } \mathcal{Y} = \cup_{j \leq l} F_j \text{ and } balance(F_j) \geq t$$

PROOF. We use the method of induction to derive the proof. Assume we have a set of fairlets $\mathcal{F} = \{F_1, F_2, \ldots, F_l\}$, in which, $balance(F_j) \geq t, \quad j = 1, \ldots, l$. We first consider the case for any two fairlets $\{F_1, F_2\} \in \mathcal{F}$. We have $balance(F_1) = \frac{f_1}{m_1} \geq t$ and $balance(F_2) = \frac{f_2}{m_2} \geq t$. We denote by $\mathcal{Y}$ is the union of two fairlets F_1 and F_2, then

$$balance(\mathcal{Y}) = balance(F_1 \cup F_2) = \frac{f_1 + f_2}{m_1 + m_2} \tag{5}$$

It holds:

$$\begin{aligned} &\frac{f_1}{m_1} \geq t \quad \text{or, } \frac{f_1}{m_1 + m_2} \geq \frac{tm_1}{m_1 + m_2} \\ &\text{Similarly, } \frac{f_2}{m_1 + m_2} \geq \frac{tm_2}{m_1 + m_2} \\ \implies &\frac{f_1}{m_1 + m_2} + \frac{f_2}{m_1 + m_2} \geq \frac{tm_1}{m_1 + m_2} + \frac{tm_2}{m_1 + m_2} \\ \implies &\frac{f_1 + f_2}{m_1 + m_2} \geq \frac{t(m_1 + m_2)}{m_1 + m_2} = t \end{aligned} \tag{6}$$

Therefore, from Eq. 5 and Eq. 6 we get,

$$balance(\mathcal{Y}) \geq t \tag{7}$$

Thus, the statement given in Theorem 1 is true for any cluster formed by the union of any two fairlets. Now we assume that the statement holds true for a cluster formed from i fairlets, i.e, $\mathcal{Y} = \cup_{j \leq i} F_j$, where $1 < i < l$. Then,

$$balance(\mathcal{Y}) = \frac{\sum_{j \leq i} f_j}{\sum_{j \leq i} m_j} \geq t \tag{8}$$

Consider another fairlet $F_{i+1} \in \mathcal{F}$ which is not in the formed cluster $\mathcal{Y}$, $balance(F_{i+1}) = \frac{f_{i+1}}{m_{i+1}} \geq t$. Then, by joining F_{i+1} with the cluster $\mathcal{Y}$ we get the new cluster $\mathcal{Y}'$ such that,

$$balance(\mathcal{Y}') = \frac{f_{i+1} + \sum_{j \leq i} f_j}{m_{i+1} + \sum_{j \leq i} m_j} \tag{9}$$

Following the steps in Eq. 6, we can similarly show that,

$$\frac{f_{i+1} + \sum_{j \leq i} f_j}{m_{i+1} + \sum_{j \leq i} m_j} \geq t \implies balance(\mathcal{Y}') \geq t \tag{10}$$

Hence, the theorem holds true for cluster formed with $i + 1$ fairlets if it is true for i fairlets. Since i is any arbitrary number of fairlets, thus the theorem holds true for all cases. □

Theorem 1 shows that for any cluster formed by union of fairlets, the fairness constraint is always preserved. Henceforth, we don't need further interventions w.r.t. fairness.

The pseudocode is shown in Algorithm 2 of Appendix B. In each step, the closest pair of clusters is identified and a new cluster is created only if its capacity does not exceed the capacity threshold q. Otherwise, the next closest pair is investigated. The procedure continues until k clusters remain. The remaining clusters are fair and capacitated according to the correponding thresholds t and q. To compute the proximity matrix (line 1 and line 8), we use the distance between centroids of the corresponding clusters. The function *capacity*(*cluster*) in line 5 returns the size of a cluster.

4.3 Fair-capacitated partitioning clustering

Partitioning-based clustering algorithms, such as k-Medoids, can be viewed as a distance minimization problem, in which, we try to minimize the objective function in Eq. 1. The vanilla k-Medoids does not satisfy the cardinality constraint since the allocating points to clusters step is only based on the distance among them. Now, if we change the goal of this assignment step to find the "best" data points with a defined capacity for each medoid instead of searching for the most suitable medoid for each point, we can control the cardinality of clusters. We formulate the problem of *assigning points to clusters* subject to a capacity threshold q as a knapsack problem [23].

Let $S = \{s_1, s_2, ..., s_k\}$ be the cluster centers, i.e., medoids, and $\mathcal{C} = \{C_1, C_2, ..., C_k\}$ be the resulting clusters. We change the assignments of points to clusters, using knapsack, in order to meet the capacity constraint q. In particular, we define a flag variable $y_j = 1$ if x_j is assigned to cluster C_i, otherwise $y_j = 0$. Now, we define a value v_j to data point x_j, which depends on the distance of x_j to C_i, with v_j being

maximum if C_i is the best cluster for x_j, i.e, the distance between x_j and s_i is minimum. We formulate value v_j of instance x_j based on an exponential decay distance function:

$$v_j = e^{-\frac{1}{\lambda} * d(x_j, s_i)} \tag{11}$$

where $d(x_j, s_i)$ is the Euclidean distance between the point x_j and the medoid s_i. The higher λ is the lower the effect of distance in the value of the points. The point which is closer to the medoid will have a higher value.

Then, the objective function for the assignment step is:

$$\text{maximize} \sum_{j=1}^{n} v_j y_j \tag{12}$$

Now, given $\mathcal{F} = \{F_1, F_2, \ldots, F_l\}$ and $W = \{w_1, w_2, \ldots, w_l\}$ are the set of fairlets and their corresponding weights, i.e., the number of instances in the fairlet, respectively; q is the maximum capacity of the final clusters. Our target is to cluster the set of fairlets $\mathcal{F}$ into k clusters centered by k medoids. We apply the formulas in Eq. 11 and Eq.12 on the set of fairlets $\mathcal{F}$, i.e, each fairlet F_j has the same role as x_j. Then, the problem of assigning the fairlets to each *medoid* in the cluster assignment step becomes finding a set of fairlets with total weights less than or equal to q and the total value is maximized. In other words, we can formulate the cluster assignment step in the partitioning-based clustering as a **0-1 knapsack problem**.

$$\begin{aligned} &\text{maximize} \sum_{j=1}^{l} v_j y_j \\ &\text{subject to} \quad \sum_{j=1}^{l} w_j y_j \leq q \quad \text{and} \quad y_j \in \{0, 1\} \end{aligned} \tag{13}$$

In which, y_j is the flag variable for F_j, $y_j = 1$ if F_j is assigned to a cluster, otherwise $y_j = 0$; v_j is the value of F_j which is computed by the Eq. 11; q is the desired maximum capacity.

The pseudocode of our k-Medoids fair-capacitated algorithm is described in Algorithm 2. In which, for each *medoid* we would search for the adequate points (line 3) by using function $knapsack(p, values, w, q)$ (line 10) implemented using dynamic programming, which returns a list of items with a maximum total value and the total weight not exceeding q. In the main function, line 12, we optimize the clustering cost by replacing *medoids* with *non-medoid* instances when the clustering cost is decreased. This optimization procedure will stop when there is no improvement in the clustering cost is found (lines 19 to 32).

Algorithm 1: k-Medoids fair-capacitated algorithm

Input: $\mathcal{F} = \{F_1, F_2, \ldots, F_l\}$: a set of fairlets
$W = \{w_1, w_2, \ldots, w_l\}$: weights of fairlets
q: a given maximum capacity of final clusters
k: number of clusters
Output: A fair-capacitated clustering

```

```

5. EXPERIMENTS

In this section, we describe our experiments and the performance of our proposed methods on three educational datasets.

5.1 Experimental setup

Datasets. The datasets are summarized in Table 1.

UCI student performance. This dataset includes the demographics, grades, social and school-related features of students in secondary education of two Portuguese schools [7] in 2005 - 2006. "Gender" is selected as the protected attribute, i.e., we aim to balance gender in the resulting clusters.

Open University Learning Analytics (OULAD). This is the dataset from the OU Analyse project [18] of Open University, England in 2013 - 2014. Information of students includes their demographics, courses, their interactions with the virtual learning environment, and final outcome. We aim to balance the "Gender" attribute in the results.

MOOC. The data covers students who enrolled in the 16 edX courses offered by the two institutions (Harvard University and the Massachusetts Institute of Technology) during 2012 - 2013 [13]. The dataset contains aggregated records which represent students' activities and their final grades of the courses. "Gender" is the protected attribute.

Baselines. We compare against well-known fairness-aware

Table 1: An overview of the datasets

Dataset	#instances	#attributes	Protected attribute	Balance score
UCI student performance	649	33	Gender (F: 383; M: 266)	0.695
OULAD	4,000	12	Gender (F: 2,000; M: 2,000)	1
MOOC	4,000	21	Gender (F: 2,000; M: 2,000)	1

clustering methods and a vanilla clustering method.

k-Medoids [16]: a traditional partitioning clustering technique that divides the dataset into k clusters so as to minimize clustering cost. Cluster centers are actual instances.

Vanilla fairlet [6]: a fairness-aware clustering approach that i) decomposes the dataset into fairlets and ii) applies a vanilla k-center clustering algorithm [12] to form the final k clusters.

MCF fairlet [6]: Similar to Vanilla fairlet but the fairlet decomposition part is transformed into a *minimum cost flow* (MCF) problem, by which an optimized version of fairlet decomposition in terms of cost value is computed.

Evaluation measures. We report on clustering quality (measured as clustering cost, see Eq. 1), cluster fairness (expressed as cluster balance, see Eq. 4) and cluster capacity (expressed as cluster cardinality).

Parameter selection. Regarding fairness, a minimum threshold of balance t is set to 0.5 for all datasets in our experiments. It means that the proportion of the minority group is at least 50% in each resulting cluster. Regarding the λ factor in Eq. 11, a value $\lambda = 0.3$ is chosen for our experiments from a range of [0.1, 1.0] via grid-search. We evaluate the clustering cost and balance score on a small dataset, i.e., UCI student performance dataset - Mathematics subject w.r.t λ. Theoretically, the **ideal capacity** of clusters is $\left\lceil \frac{|X|}{k} \right\rceil$ where $|X|$ is the population of dataset X, k is the number of desired clusters. However, in many cases, the clustering models cannot satisfy this constraint, especially the hierarchical clustering model. Hence, we set the formula in Eq. 14 to compute the **maximum capacity** q of clusters; ε is a parameter chosen in experiments for each fair-capacitated clustering approach.

$$q = \left\lceil \frac{|X| * \varepsilon}{k} \right\rceil \tag{14}$$

To find the appropriate value of ε, we set a range of [1.0, 1.3] to ensure all the generated clusters have members and evaluate the cardinality of resulting clusters on the UCI student performance (Mathematics subject) dataset. ε is set to 1.01 and 1.2, for k-Medoids fair-capacitated and hierarchical fair-capacitated methods, respectively.

5.2 Experimental results

UCI student performance. When k is less than 4, as shown in Figure 1-a, the clustering quality of our models can be close to that of the vanilla k-Medoids method. However, the clustering cost is fluctuated thereafter due to the effort to maintain the fairness and cardinality of methods. Our *vanilla fairlet hierarchical fair-capacitated* outperforms other competitors in most cases. Vanilla fairlet and MCF fairlet show the worst clustering cost as an effect of the k-Center method. Figure 1-b depicts the clustering fairness. As we can observe, in terms of fairness, *vanilla fairlet hierarchical fair-capacitated* has the best performance when k is less than 10. Contrary to that, by selecting each point for each cluster in the cluster assignment step, the *k-Medoids fair-capacitated* method can maintain well the fairness in many cases. Regarding the cardinality, as illustrated in Figure 1-c, our approaches outperform the competitors when they can keep the number of instances for each cluster under the specified thresholds.

OULAD. Our *MCF fairlet k-Medoids fair-capacitated* approach outperforms other methods in terms of clustering cost, although there is an increase compared to the vanilla k-Medoids algorithm, as we can see in Figure 2-a. Concerning fairness, in Figure 2-b, k-Medoids is the weakest method while others can achieve the highest balance. The balance of *Gender* feature in the dataset is the main reason for this result. All fairlets are fully fair; this is a prerequisite for our methods of being able to maintain the perfect balance. Regarding cardinality, our approaches demonstrate their strength in ensuring the capacity of clusters (Figure 2-c). The difference in the size of the clusters generated by our methods is tiny. This is in stark contrast to the trend of competitors.

MOOC. The results of clustering quality are described in Figure 3-a (Appendix A). Although an increase in the clustering cost is the main trend, our methods outperform the vanilla fairlet and MCF fairlets methods. Regarding clustering fairness, as depicted in Figure 3-b, our approaches can maintain the perfect balance for all experiments. This is the result of an actual balance in the dataset and the fairlets. The emphasis is our methods can divide all the experimented instances into capacitated clusters, as shown in Figure 3-c, which proves their superiority in presenting the results over the competitors regarding clusters' cardinality.

Summary of the results. In general, fairness is well maintained in all of our experiments. When the data is fair, in case of OULAD and MOOC datasets, our methods achieve a perfect fairness. In terms of cardinality, our methods are able to maintain the cardinality of resulting clusters within the maximum capacity threshold, which is significantly superior to competitive methods. The fair-capacitated partitioning based method is better than the hierarchical approach since it can determine the capacity threshold closest to the *ideal capacity*. Regarding the clustering cost, the hierarchical approach has an advantage over other methods by outperforming its competitors in most experiments.

6. CONCLUSION AND OUTLOOK

In this work, we introduced the fair-capacitated clustering problem that extends traditional clustering, solely focusing on similarity, by also aiming at a balanced cardinality among the clusters and a fair-representation of instances in each cluster according to some protected attributes like gender or race. Our solutions work on the fairlets derived from

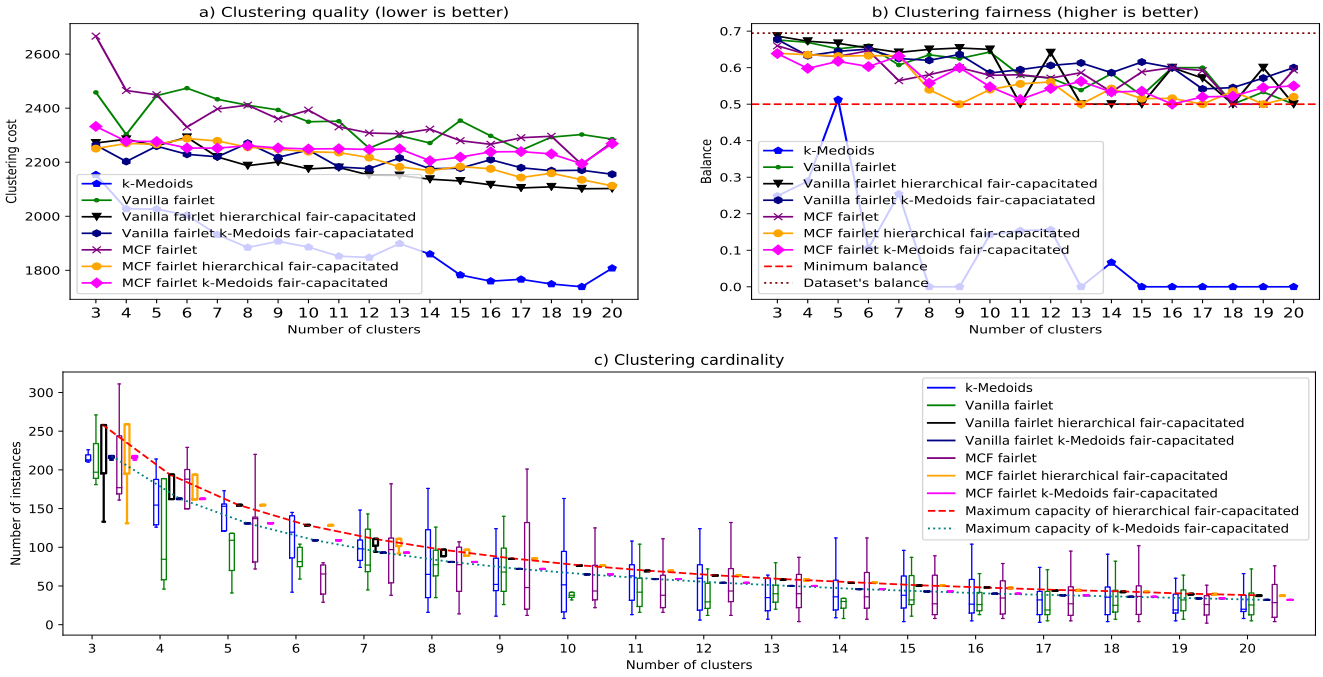

Figure 1: Performance of different methods on UCI student performance dataset

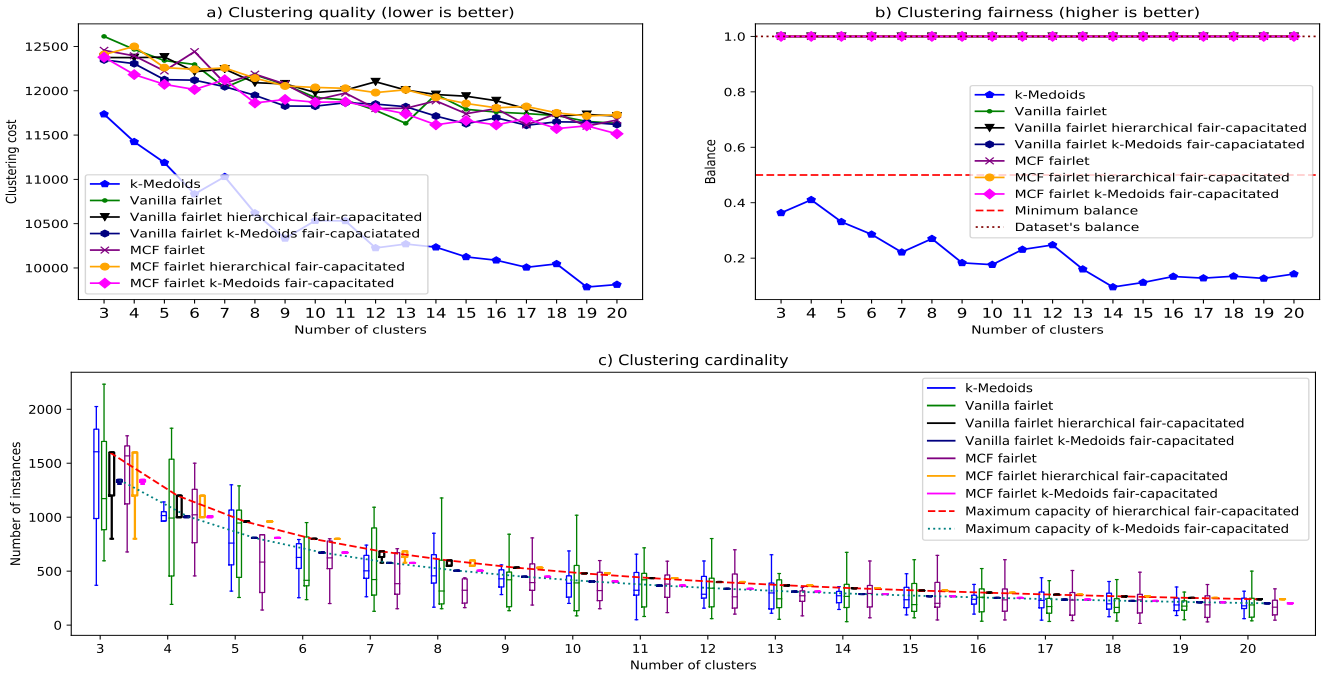

Figure 2: Performance of different methods on OULAD dataset

the original instances: the hierarchical-based approach takes into account the cardinality requirement during the merging step, whereas the partitioning-based approach takes into account the cardinality of the final clusters during the assignment step which is formulated as a knapsack problem. Our experiments show that our methods are effective in terms of fairness and cardinality while maintaining clustering quality. In the future, we plan to extend our approach for more than one protected attributes as well as to further investigate what fair group assignments means in educational settings.

ABSTRACT

Cardiopulmonary resuscitation (CPR) is a foundational life-saving skill for which medical personnel are expected to be proficient. Frequent refresher training is needed to prevent the involved skills from decaying. Regular low-dose, high-frequency training for staff at fixed intervals has proven successful at maintaining CPR competence but does not take into account inherent performance variability across learners. Tailoring refreshers to an individual's past performance would minimize personnel being trained too (in)frequently and would ensure faster knowledge acquisition for new learners. To maximize the benefits of individualized schedules, learning needs gleaned from past training history need to be identified. A recent field study conducted among nursing students showed that a cognitive model-based approach was able to successfully trace the knowledge acquisition and decay of learners and prescriptively devise personalized training regimes that outperformed fixed schedules with regards to both training efficiency and learners' performance. Here, we report a post-hoc analysis of the collected data to investigate whether an alternative modeling approach, blending cognitive modeling and machine learning, could have resulted in even higher quality predictions. Our results reveal modest improvements in predictive accuracy for ensemble models, in which machine learning models predict the prediction errors (i.e., residuals) of the standalone cognitive model. These promising findings reveal strong applied utility for future use in domains where sustained proficiency is a requirement.

1. INTRODUCTION

Cardiopulmonary resuscitation (CPR) is a basic life-saving skill but it has been shown that medical professionals are not able to perform it consistently [1]. To remedy this shortfall, several improvements to skill acquisition and maintenance programs have been proposed [6]. One dimension of the shift in educational focus [5] emphasizes increased re(training) efficiency by moving towards personalized, adaptive scheduling. The current work aims to facilitate this development.

Currently, as in many domains, refresher trainings at fixed intervals (i.e., regular and the same for everyone) are required to maintain CPR compliance. A recent effort [14, 18] has shown that a cognitive model representing regularities of memory can be leveraged to devise personalized training schedules that maintain proficiency at lower cost and risk. This effort will be referred to as *the CPR field study* throughout the current text, and the data collected during this experiment (see sections 2.1 and 2.2 for details) will form the bedrock on which the efforts presented here will build.

Specifically, we conducted a post-hoc simulation study of the CPR field study data to explore whether the cognitive model's predictions could be enhanced by combining it with machine learning (ML) models that can leverage additional information to improve predictive accuracy. The combination of the two modeling approaches is achieved by fitting the models sequentially, forming an ensemble model in which the cognitive model's residuals are learned by the ML models. We show that their combined predictions afford a modest improvement over the cognitive model by itself and are preferable to using the ML models by themselves.

Modern CPR training is an interesting educational data mining domain and modeling task because trainings are conducted on advanced manikins equipped with an array of sensors that quantify various aspects of a student's performance against objective performance guidelines [16]. Consequently, large amounts of high-resolution data are readily collected for a given event. The challenge is that events are usually spaced months apart, which provides a sparse sampling space for knowledge tracing. Consequently, it is difficult to make precise predictions. However, given quality CPR's central

role in the "chain of survival" [6, 5], even small improvements in predictive accuracy can conceivably have large real-life impacts—especially if predictive models can identify those most in need of more frequent refresher trainings and help them to maintain compliance.

Generally speaking, the fields of cognitive science and machine learning have approached the computational modeling of a task like CPR skill acquisition and maintenance with different mindsets [24]. Specifically, cognitive models primarily focus on explaining the mechanisms that drive individual differences; machine learning models primarily focus on out-of-sample prediction. Aiming to combine the best of both approaches, we engineered a pipeline of predictive models: First, a cognitive model that was specifically developed as a prescriptive tool [13] is fit to the training data, which results in residuals that indicate which instances are fit poorly by the cognitive model. Next, a ML model is fit to those residuals, effectively learning to fine-tune the cognitive model's predictions. We show that such an ensemble approach can provide improvements in predictive accuracy without sacrificing interpretability, which is important to retain so that the model's personalized prescriptions are fully explainable. With an eye on advancing predictive tools in the domain of CPR training, our core motivation is to assess whether alternative predictive approaches could have yielded better result in the CPR field study, so that insights gained can be leveraged in future applied settings.

1.1 The current study

Here, we will use the exact version of the cognitive model that was used in the CPR field study as a yardstick to determine: **(I)** How well would alternative instantiations of the cognitive model have performed?, **(II)** Would a number of off-the-shelf ML approaches have yielded superior predictions than the cognitive model?, and **(III)** Could ML models be used to learn the prediction error of the cognitive model?

We believe the last question is the most pertinent. However, the combined approach should be compared to the approaches that only use either of the two modeling approaches in isolation to ascertain whether it has any benefit.

2. METHODS

This section will outline the data we used for our exploration, the input features that are available in the data, the predictive model we employed, and the setup of the simulation study we conducted to address our research questions. Figure 1 provides a schematic overview of the approach and its parts and connections are going to be explained in the following.

2.1 Data

Data were from a multi-phased, longitudinal study conducted at 10 nursing schools across the United States [18]. A total of 475 nursing students started the study. Participants were randomly assigned to 4 initial acquisition conditions where they completed 4 consecutive CPR training sessions that were spaced by 1 day, 1 week, 1 month, or 3 months. Students were additionally randomized to 3 maintenance training conditions where they refreshed their skills for 1 year at intervals of 3 months, 6 months, or at personalized intervals prescribed by the cognitive model. During each session, students completed a series of CPR events using the Resuscitation Quality Improvement (RQI®) system with Laerdal's Resusci Anne® adult QCPR manikin.

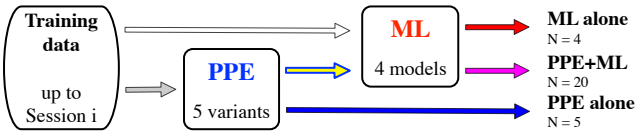

Figure 1: Schematic of the various predictive models.

First, students completed a pre-test consisting of 60 compressions or 12 bag-mask ventilations with no feedback from the manikin, followed by trainings where students received real-time, dynamic feedback to guide, and then post-tests with no feedback. RQI provides composite scores for the quality of compressions and ventilations on scales of 0 to 100, with higher scores corresponding to better performance. The compression score is based on depth, rate, release, and hand placement. The ventilation score is based on volume, rate, and compliance with inspiration time.

Prior to the onset of the study, participants completed a demographic questionnaire. Of the 475 participants that began the study, we included in our study the 393 that completed the initial acquisition phase. Due to the variations in retraining schedules across the maintenance phase, not all students completed the same number of sessions. We focus here on data from the first through the eighth session since the majority of students completed 8 sessions.

2.2 Input features

This section describes all information available in the "training data" box of Figure 1. As sessions progress, the number of available training instances grows but the number of input features is constant. Using the color-coded arrows in Figure 1 to categorize them, these features are detailed in the following and the `labels` correspond to those in Figure 4A.

Gray arrow in Figure 1: `time/lag`: An event's timestamp expressed as the number of seconds since the first/previous recorded event; `score`: The composite performance score recorded for each event.

White arrow in Figure 1: `compvent`: Does the recorded event correspond to performing compressions or ventilations?; `acqint` and `maintint`: What acquisition-maintenance interval combination was this user assigned to? Together, these define the 12 experimental conditions (see previous section for detail) that the condition PPE variant is based on; `session`: Session counter 1 through 8; `pretrnpst`: Was this a pre-test, training, or post-test?; `site`, `age`, `gender`, `height`, and `weight`: Demographic information associated with each user (time-invariant). There were ten sites/locations and other information was coded in years, male/female, inches, and pounds, respectively; `profile`: We reduced the unique user IDs to a low-dimensional set of performance profiles. This approach was inspired by earlier work [2, 23] that showed a small number of descriptive profiles could be obtained by performing k-means clustering [9]. Here, we used $k = 4$, and re-partitioned the training data on each iteration of the

simulation. Specifically, only pre-test scores across both skills were taken into account.

Yellow arrow in Figure 1: `decay rate` and `model time`: The two PPE terms computed when fitting PPE (see section 2.3.1) are passed to the ML models; `residual`: The difference between PPE's fit and `score`.

The three rightmost arrows indicate the predictions that are made, emphasizing that the PPE+ML ensemble models (purple) uses both the cognitive (blue) and machine learning (red) models. Next, we outline which ML models were used and how the five PPE variants were fit to the data.

2.3 Predictive models

As noted in Figure 1, there are a total of 29 models. Here, we describe the PPE and ML models that make up the PPE alone/ML alone predictions. The remaining majority of models are based on combining the PPE+ML models by first fitting the PPE as described below and subsequently computing the PPE's residuals in the training data and training the ML model to predict those. The PPE+ML predictions can thus be thought of PPE predictions that were fine-tuned by a given ML model.

2.3.1 Predictive performance equation (PPE)

The PPE is a set of nested mathematical equations that capture findings in the cognitive science literature associated with the temporal dynamics of human learning and forgetting [26]. These include the power law of learning, the power law of forgetting, the spacing effect, and effects of relearning. Two essential components of PPE are sub-equations that model time and the rate of knowledge/skill decay. The *model time* equation captures the idea that the age of items in memory should be skewed toward the most recent presentations, but the full study history should be represented. Hence, model time for each instance i (across n instances) is $w_i \times t_i$, where $w_i = \frac{t_i^{-0.6}}{\sum_{j=1}^{n} t_j^{-0.6}}$ and t_i is the time, in seconds, relative to the first instance. The *decay rate* equation captures the idea that spacing practice across time produces more stable knowledge that decays at a slower rate, while massing practice produces less stable knowledge that decays at a faster rate. Since model time and the decay rate are essential to how PPE captures learning and decay, we include them separately as features in the machine learning models. For a more extensive description of the mechanics of the PPE, please see [25, 26].

In the CPR field study, PPE was fit separately to each participant's history of compression and ventilation scores. We refer to this variant as the *original* PPE throughout the paper. The rationale for individual fits was from prior research suggesting that each individual would have unique learning and forgetting trajectories across sessions due to psychometric differences, the trajectories would vary for compressions and ventilations, and thus predictive accuracy would be maximized by fitting to each student on each skill.

Here, we conduct post-hoc simulations to explore these assumptions by comparing the methodology used in the field study to less granular PPE variants in which free parameters are fit to: experimental condition (acquisition and maintenance intervals), skill (compressions and ventilations), user, or user's performance profile. By exploring these different groupings for which a set of unique parameters are estimated, we evaluate the trade-space between model flexibility and predictive accuracy, and how this interacts with the amount of data available for fitting the models.

2.3.2 Machine learning models

We used four different machine learning models. Depending on the approach, these were either trained to predict the score (red arrow in Figure 1) or PPE's residuals (purple arrow in Figure 1). For either task, all models had access to all input features outlined in section 2.2 (also see x-axis of Figure 4A). All models were run with the default settings of the cited `R` packages [21].

As the simplest model, we fit a single **decision tree** to the scores/residuals. Each tree was pruned through 10-fold cross validation—as implemented in [22]—to avoid overfitting. In most cases, this resulted in very shallow trees and sometimes even single node "stumps." Hence, the decision trees can be thought of as baseline models.

The most complex model was a **random forest** [4], which is an ensemble of decision trees. Using the default settings in [15], we used both bagging and random feature sub-setting to grow a forest of 500 trees. A recent comparison of gradient boosting algorithms included random forests as a comparison and nicely showed that they perform very well on a range of ML tasks and have the added benefit of not requiring hyperparameter tuning [3]. The disadvantage of random forests—as with many ML approaches—is that the internal mechanics that result in a prediction are not easily inspected (see our discussion around Figure 4 below).

The two other models were **ridge** regression and the **lasso** [10], which apply slightly different shrinkage terms when coefficients are estimated. The key difference between the two methods is that ridge regression will retain coefficients for all input features, while the lasso effectively performs feature selection (see section 6.2 in [12] for an introduction). This generally makes lasso models more interpretable. Both models have a single hyperparameter, λ, that was tuned for each iterative prediction using the cross-validation procedure implemented in [8] and all numerical features were standardized.

2.4 Simulation study and analysis

The approach to our simulation study can be summarized as follows: For each session $s = 1, 2, \ldots, 7$, train the models on data up to session s and issue predictions for the pre-test of session $s + 1$. We focused on pre-test scores because we were interested in predicting students' readiness to perform CPR compressions and ventilations, prior to additional training. The procedure was run for all 29 (combinations of) models described above and generated iterative predictions for sessions 2 through 8. The quality of predictions across the models will be compared by computing the mean absolute error (MAE), which summarizes how accurately, on average, each model predicts the scores recorded in the subsequent session. This yields $7 \times (4 + 20 + 5) = 203$ (i.e., number of predicted sessions times number of models) errors. For the sake of easier presentation of these results, we subsequently

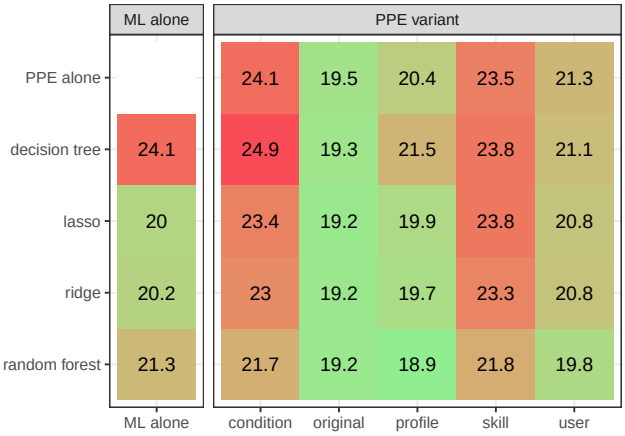

Figure 2: Average MAE across sessions for all models.

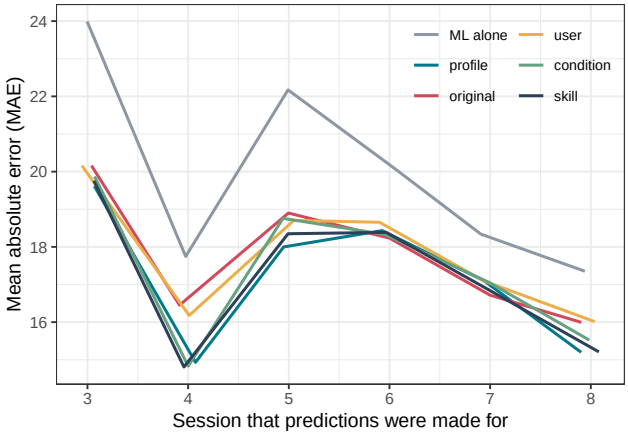

Figure 3: Comparison of all models in the "random forest" row of Figure 2, showing prediction errors for each session.

summarize the errors by (i) computing the average MAE for each model (Figure 2), and (ii) ranking the models based on their errors (Table 2). These overall results are elaborated on with additional figures and tables that highlight relevant details.

3. RESULTS

Figure 2 presents the average MAE for all 29 models and speaks to all three research questions posed in section 1.1. As detailed in section 2.4, the 203 prediction errors were aggregated across sessions and the average MAE for each combination of models is presented as a heatmap. The color-coding corresponds to the magnitude of the errors; lower values are better. By averaging across sessions, variations in predictive accuracy as a function of session (see Figure 3) is lost but it becomes easier to assess the model's relative performance in one glance.

First, we can look at the "PPE alone" row in Figure 2 to compare the five PPE variants that were tested. Overall, the original instantiation of the cognitive model as used in the CPR field study—if used alone—does indeed outperform the more constrained variants explored here. This is somewhat surprising since the original model exhibited signs of overfitting (i.e., fit MAE lower than prediction MAE) that were ameliorated for the constrained variants of PPE. However, it appears that despite overfitting the training data, the original variant of PPE did produce the best predictions after all.

Second, whether a number of off-the-shelf ML approaches would have yielded superior predictions than the cognitive model can be assessed by comparing the cell original PPE alone (MAE = 19.5) with the prediction errors in the "ML alone" column in Figure 2. All ML approaches yield average errors larger than 19.5 when applied alone, which suggests that the ML models tested here—if used by themselves—would not have resulted in better predictions overall. However, the differences in prediction errors are not large and the ridge and lasso regression in particular perform well on average.

And third, and most importantly, we turn to the PPE+ML combinations. These correspond to the larger facet labeled "PPE variants" in Figure 2. A number of notable patterns emerge: the average MAE for the original PPE is hardly affected by adding any of the ML models to predict its residuals. This might be because this variant of PPE is very flexible, which restricts the residuals in the training data that the ML can actually fit to. For all other PPE variants, we see a gradient from top to bottom, with average MAEs decreasing with ML models relative to PPE alone. The decision trees are an exception to this pattern and seem to worsen the performance more often than not. Otherwise, we generally see the lasso and ridge regressions improving on PPE alone and the PPE+random forest resulting in the best performance for all PPE variants.

Zooming in on the models using random forests, Figure 3 shows the session-by-session prediction errors of the random forest alone (ML alone) and the PPE+random forest combinations. We omitted predictions for the second session because they are quite poor for the random forests combined with the condition and skill PPE variants, which distorts the y-axis and obscures differences between models in the later sessions[1]. The figure highlights that the random forest alone consistently performs worse than all other combinations of models, in which the random forest is used specifically to learn PPE's residuals rather than observed performance. This suggests that the most promising approach is an ensemble of a PPE variant that captures the overall temporal dynamics to issue predictions that are subsequently fine-tuned by a random forest that can leverage all other available input features.

Another way to summarize these results is by ranking all 29 models' MAE within each session and computing the average rank for each PPE variant. These average ranks are shown

[1]Predictions for session 2 were generally much worse than for all subsequent sessions. We ran all analyses reported here without session 2 predictions to confirm that our conclusions do not depend on differences between models on session 2. If session 2 is omitted, the skill PPE variant performs a little better overall but results are not otherwise affected drastically.

Table 1: Comparison of PPE variants across all ML models.

PPE variant	average rank	average MAE
profile	11.9	20.1
skill	12.7	23.2
original	15.1	19.3
user	17.2	20.8
condition	18.4	23.4

in Table 1, and reveal that although the original PPE yields the lowest overall average MAE, both the profile and skill variants achieve better average ranks. This suggests that if ML models are leveraged to predict PPE's residuals, more constrained variants of PPE tend to perform better. However, even the lowest average ranks listed in Table 1 is relatively high, suggesting that no model consistently outperforms the others. This observation is confirmed by inspecting the models' MAEs in detail (not shown here), which reveals that for some sessions, most models perform effectively identically.

Lastly, we present the top 10 models in terms of their ranking in Table 2. Here, the ranks are computed as an average across the seven sessions each model made predictions for. The best-performing model is the PPE with parameters for each performance profile whose residuals are predicted by a random forest. Figure 2 corroborates this observations, showing that this combination of models obtains the lowest average MAE overall. Notably, all five instances of the original PPE and five out of six instances of random forests are represented in the top 10, confirming that these models perform very well in various combinations.

3.1 Peeking into the random forest

Space constraints limit the amount of model interrogation we can report here. However, we want to at least showcase one prominent example. Table 2 and Figure 2 show that the best model overall is the combination of the PPE variant with unique parameters for each performance `profile` and a random forest that learns its residuals. (This model is the blue line in Figure 3, which highlights that other models perform very similarly.) Figure 4A shows the normalized feature importance computed for each input feature (white and yellow arrows in Figure 1) for each iterative session that predictions are made for. Superimposed are the average importance and the spread (in black) and features are sorted from least to most important based on average importance. Notably, most time-invariant features (gender, age, etc.) are equally important across the seven iterations. The `session` counter, `stability`, and `model time`, on the other hand, become gradually more important as more sessions were included in the training data, while the opposite pattern is evident for `compvent` and users' performance `profile`.

Feature importance plots as shown here can be informative but should be interpreted with caution since they do not capture and visualize the potential intricate non-linear relationships between the various input features [17]. Furthermore, feature importance and their impact on predictions are not necessarily the same—more advanced approaches exist [19] but are beyond the scope of the current paper.

Table 2: The top 10 models overall sorted by average rank across the seven predictions made by each model.

	PPE variant	ML model	average rank
1	profile	random forest	5.3
2	skill	random forest	6.7
3	condition	random forest	7.9
4	original	lasso	8.1
5	original	random forest	8.3
6	original	decision tree	8.4
7	original	ridge	8.6
8	user	random forest	10.1
9	original	PPE alone	10.7
10	condition	ridge	11.9

Figure 4B zooms in on two important features and shows the predictions made for the profile PPE model for the fourth session against the residuals the random forest predicts for each instance. We generally see the most differentiation between models on Session 4, which is why we chose it—however, this figure is broadly representative of the profile PPE+RF dynamics for other sessions. Figure 4B suggests that ventilations are more often down-adjusted than compressions (i.e., more triangles below the equality line) unless PPE predicts near-ceiling performance. The fact that model time is consistently identified as the most important feature (see Figure 4A) but no clear relationship between the magnitude of the adjustment (i.e., distance from equality line) emerges in Figure 4B highlights the disadvantage of applying ML models—such as a random forest—that are challenging to interrogate.

4. DISCUSSION

The post-hoc simulation study reported here suggests that the original cognitive model used for prescriptive, adaptive scheduling in the CPR field study performed very well overall. In fact, in the aggregate, it resulted in lower average prediction errors than both the more constrained variants of PPE and the machine learning models included in the current comparison. Thus, it is unlikely that the tested off-the-shelf ML models would have performed better than the original PPE, although the regularized regression models (ridge and lasso) in particular achieved prediction errors similar to the original PPE. We expected the ML models to outperform the cognitive model because the latter's main "insights" (the estimated *model time* and *decay rate*) were included as input features to the ML models (yellow arrow in Figure 1. This suggests that the PPE, using much less information, was slightly better at extrapolating performance to the next session.

The current explorations also showed, however, that an ensemble cognitive and ML model has the potential to perform slightly better than either alone. Notably, the more constrained variants of PPE performed particularly well in this ensemble arrangement. One possible explanation is that the less flexible cognitive model operates as a smoothing function on the temporal information, which leaves the ML to learn under which conditions (i.e., [combinations of] input features) the general temporal dynamics should be adjusted to further improve predictions. This framing of the procedure is

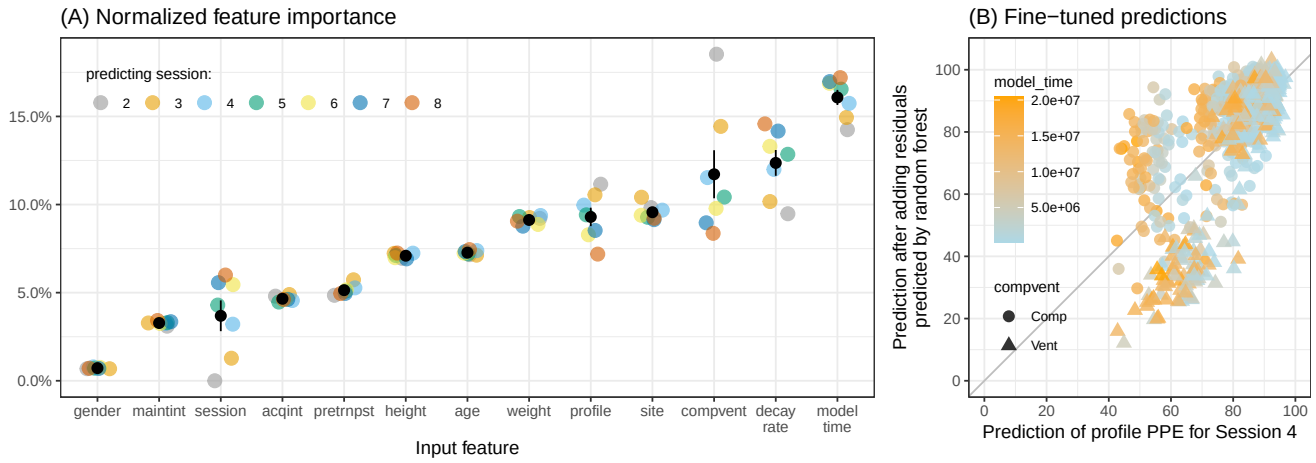

Figure 4: Details on the best-performing model. (A): The normalized feature importance for each iteration of the model with superimposed averages (black dots). (B): Initial PPE predictions for Session 3 (x-axis) plotted against fine-tuned predictions (y-axis); color-coding indicates the `model time` for each predicted instance and shape differentiates `compvent`.

conceptually akin to a two-step boosting algorithm [7] and the "fine-tuning" of predictions induced by the second step (the ML model in this case) is nicely illustrated in Figure 4B, which shows the results of the first step (the constrained cognitive model's predictions on the x-axis), against the results after the second boosting-like step (the PPE+ML predictions on the y-axis). In this process, the initial PPE prediction's quite restricted range is expanded by the random forest, which can—and does (cf. Figure 4A)—draw on various input features.

The ensemble approach outlined here has the added benefit of a modular structure. Thus, it is easy to make design decisions, particularly regarding (i) which constraints should be built into the parameter fitting procedure for PPE, and (ii) what type of ML model is most informative. The latter will determine where on the continuum of interpretability the ensemble will fall. For example, the dynamics of the random forest that predicts the profile PPE's residuals (highlighted in Figure 4), does not lend itself to straightforward model interrogation but the PPE+lasso and PPE+ridge combinations would not reduce the interpretability of the ensemble, while slightly reducing prediction errors relative to PPE alone (see Figure 2).

It should be pointed out, however, that the improvement in prediction errors relative to the original PPE alone is minor. Nevertheless, we consider these findings significant for two reasons: First, the small improvement vindicates that PPE's time-based mechanisms capture the majority of variance in this task domain. Second, the PPE+ML ensemble approach used here serves as a proof-of-concept that illustrates how the core mechanism of PPE can be preserved while incorporating an arbitrary number of additional input features. For example, some of the input features used here were specific to the field study's design (notably `acqint` and `maintint`) and would not be present in the hospital setting RQI systems are primarily deployed in. In such settings, however, other input features would be available (e.g., job title or department) and samples would be larger and more heterogeneous, which would conceivably introduce more variance that is not a function of time-based features alone. We expect that under these conditions, the ensemble approach's advantage over PPE alone would be more pronounced.

In the current effort, we choose to assess the models' ability to make session-by-session predictions. This approach meant that events did not line up chronologically (a student in the weekly acquisition condition will have completed the first four session before a student in the 3-month condition returned for their second session) but the amount of training data available for each student is equalized—only the lag between events varies. This reveals, for example, that predictions improve up to session 4 (the end of the acquisition phase; see Figure 3) and then get worse for session 5, which is when students switch to the maintenance phase. This suggests that the models get better at forecasting performance as more data from a consistent schedule becomes available, and that one should expect a dip in predictive accuracy as the temporal dynamics are altered.

Future work in this domain should validate the approach presented here in more naturalistic data that more closely resemble how medical professionals train and maintain CPR proficiency. We believe that cognitive models in particular—and a cognitive-machine learning ensemble specifically—hold great promise in moving towards a predictive framework that affords personalized, adaptive refresher training schedules that are tailored towards individual learning needs—either of an individual or groups of learners that exhibit similar performance profiles. Furthermore, the outlined predictive pipeline's potential value in adaptive, educational learning system outside of the medical domain should be explored.

ABSTRACT

We investigate encoder-decoder GRU networks with attention mechanism for solving a diverse array of elementary math problems with mathematical symbolic structures. We quantitatively measure performances of recurrent models on a given question type using a test set of unseen problems with a binary scoring and partial credit system. From our findings, we propose the use of encoder-decoder recurrent neural networks for the generation of mathematical multiple-choice question distractors. We introduce a computationally inexpensive decoding schema called character offsetting, which qualitatively and quantitatively shows promise for doing so for several question types. Character offsetting involves freezing the hidden state and top k probabilities of a decoder's initial probability outputs given the input of an encoder, then performing k basic greedy decodings given each of the frozen outputs as the initialization for decoded sequence.

Math Question Solving, Distractor Generation, Math Multiple Choice Questions, Mathematical Language, Math Education

1. INTRODUCTION

1.1 Problem Statement

Here we focus on the needs of mathematics educators in high school and early university education, One of the most tedious jobs for a teacher is to create exams and quizzes and grade them. The more time they spend on these tasks, the less time they spend teaching students. An automated system capable of creating reliable math questions of consistent difficulty level, creating solutions, generating distractors for them, and finally be able to grade them is the holy grail of educational automation. In this paper we focus on solving the math questions and generating distractors for Multiple Choice Questions.

Questions in mathematics are different from other subjects such as English, History, or Economics. In mathematics and by extension in all STEM fields, questions and answers not only are composed of natural text but are often accompanied by symbolic equations, expressions, inequalities or relational information. Ganeslingam [6] postulates in his work that these non-textual objects not only augment the context of the textual part but also derive their context from it. These non-textual objects are not part of the natural language and hence require special treatment. On the semantic level, mathematical questions require an underlying understanding of rules before a question can be solved. A mere comprehension is not sufficient. To solve a simple problem in arithmetic, the fundamental understanding of the four operators is necessary.

In this work we experiment with a network which has had historical success on natural language processing problems and test its ability to generalize mathematical knowledge from an open source data set contributed by [22] consisting of elementary focused question types. Alternatively as a second problem, for some question types, we examine whether models which fail to generalize to the test set may have their incorrect solutions leveraged as 'good' distractor options for multiple choice questions like those seen in multiple choice questions on a math quiz. As following with the precedent of the data set contributor [22], mathematical expressions are presented using Python's operator syntax.

In summary we show the following:

- Insight in the ability of an encoder decoder attentional GRU to extract semantic and syntactic meaning from mathematical expressions.
- Simultaneously test whether these model's incorrect predictions may be leveraged to auto generate multiple choice question distractors commonly seen in lower education exams. Continuing with this potential application, experiment with the practice of character offsetting–a modified greedy decoding schema which pushes the networks to predict four separate sequences instead of a single output thus providing a complete set of distractors.

*Both authors contributed equally.

- Qualitatively measure which question types show the highest potential for leveraging character offsetting for the purpose of multiple choice distractor generation.

2. RELATED WORK

Math Word Problems

Early applications of machine learning and deep learning based methods in math questions attempted to convert math word problems into equations [10]. Here we rely on the capability of neural network to identify the textual and equation parts from the question and model them correctly in order to solve them. Much of the work in math word problems relied on extracting equations from text and then solving them using symbolic solver libraries such as Sympy.

Subhro Roy and Dan Roth created expansion trees [20] and Unit Dependency Graphs [21] from arithmetic word problems. Kushman et. al. [11] mapped word problems to equations using canonical templates and handled ambiguity using probabilistic models. Tencent AI Lab [29] first used deep neural networks for solving math word problems. They used the Seq2Seq model with LSTM units for mapping math word problems to the equations. MathDQN [27] proposed using Deep Q-Learning to map math word problems to solvable equations. Deepmind [15] attempted to solve math word problems using the program induction technique, which would also generate a rationale for choosing an answer. This method did not involve mapping problems to equations but the reasoning in text form. Recent work focused on using recursive neural networks for evaluating equations [30] [28] mapped from word problems.

Polozov et. al. [19] and Liu et. al [16] proposed methods for generating math word problems. Liu et. al. [16] used Gated Graph Neural Networks with Variational Autoencoders to generate questions from knowledge graphs of mathematical concepts and symbolic expressions. [19] take programming approach for encoding requirements from tutors and students to create logical graphs with the help of ontology. This logical graph is then used to create expressions and sentences with the help of primitive templates.

Lample et. al. [12] showed solutions for questions in differential equations, differential calculus, and integral calculus and used transformer networks [26] to solve calculus questions and compared their results with traditional solvers like Mathematica and Matlab. In contrast, Saxton et. al. [22] created a codebase to generate math problems across fifty-six classes and solve them using deep neural networks. Saxton et. al. compared problem solving abilities of Seq2seq networks with transformers. Though transformers showed better results than the the recurrent models, but Saxton et. al. commented that the improvement in performance was largely due to the higher capacity of transformer networks to remember rather than their ability to solve.

Here we use the codebase created by Saxton et. al. [22] to generate math questions. Even though the codebase in its original form cannot generate distractors, it can be modified to create distractors using simple rules. In comparison to other datasets [15] which contain distractors, we chose to use the codebase since it provided more control over the generation of questions and also the templates used have a simpler language and an equation with each question.

In a classroom and tutoring settings math questions are more open ended. Erikson et. al [5] tested the capability of XGBoost, Random Forests and LSTMs in analyzing the open ended answers in mathematics. These models were created to assist the teacher rather than complete automated grading. Michalenko et. al [17] used LSTMs to solve polynomial factorization problems. They created their dataset from Wolfram Alpha. They use the trained network for automated grading and personalized feedback system.

Distractor Generation (DG)

In multiple choice questions, the options which are not the answer are called distractors, because their job is to distract a student from a given correct answer. Distractor generation has been studied for non-mathematical subjects, especially English (Susanti et. al. [23]) and other domain-specific tasks (Aldabe et. al. [2]). Distractor generation for scientific subjects like physics, chemistry, biology, and economics was explored by Linag et. al. [13]. They [13] used a two-stage model with a classifier and a ranker to filter out the relevant distractors. Linag et. al. [14] explored distractors for fill in the blank type questions using GAN networks.

Partial Credit Scoring

Similar in spirit to our partial credit scoring system, Pho et. al. [18] attempt to automatically score the *quality* of manually created English multiple choice distractors using various semantic and syntactic criteria including WordNet. This is fundamentally different from our problem however as we seek to automate the generation of the distractors themselves and simultaneously sought out a metric to help measure the fundamental reasonableness of those distractors.

3. EXPERIMENTS

3.1 Training Data

The data set used in this paper [22] had the express purpose of being a large scale training and testing framework for benchmarking models on mathematical reasoning. The framework consists of both training and testing sets. The training set consists of 39 different math problem types and variants of 17 of those add the element of mathematical composition to the problem's statements for a total of 56 question types organized into 8 different domains–probability, polynomials, numbers, measurement, comparison, calculus, arithmetic, and algebra. Each question type within a domain is split into three training sets, easy, medium and hard of 666,666 question answer pairs, for a total of 2 million examples per question type.

Difficulty measures the relative complexity of coefficients in the expressions generated. As an example compare from the polynomial evaluation set the easy: 'Let u(q) = q**2 - 6*q - 10. Calculate u(8).', medium: 'Let s(v) = v**3 + 47*v**2 +471*v + 142. Give s(-33)', hard: 'Let h(a) = -177071*a - 4957992. What is h(-28)?' and an actual related college algebra exam question [25]: 'Evaluate the function f(x) = 3 + (x-5)**(1/2) at x = 9.'. It is relatively clear that

examples from medium and hard are unlikely to appear on a low level math examination. For this reason the majority of experiments rely on the easy train set variants. It was our hypothesis that as the curriculum provided by these sets are much more in line with the expected complexity of questions appearing on actual low level exams that the models would thus be more likely to generate better distractors (or even the correct answer) when provided such an exam's questions as input.

The primary test method within the framework proposed by [22] is a data set referred to as interpolation. Every question type has an associated interpolation test set. The set consists of 10^5 question answer pairs *likely* unseen in either the easy, medium and hard train sets of the associated question. The guarantee of lack of repeated questions comes from a lower bound on the probability of a questions repeated generation. A training question at most has a 10^{-8} chance of reappearing in the test set. [22] also release a secondary test set referred to as extrapolation, which measures generalization of core concepts across multiple question types. However, as we specifically were interested in single question trained models for the express purpose of multiple choice question distractor generation this test set was unused.

3.2 Rule Based Distractor Generation

Evaluation of distractors is not an exact process. For a given question there can be any number of distractors, some good, other bad. There is usually a very loose concensus on what constitutes a good distractor. Also no algorithm exists that can gauge the "goodness" of distractor. However, expert educators have a keen sense of judging the distractor by their teaching and research experience. Educators usually know where students make mistakes, and leverage that to generate good distractors. For simple high school questions, we can simulate this process by creating rules that mimic the mistakes made by students. These rules then can be embedded with a mathematical solver to produce distractors for given question. A simple set of rules can be created to modify the solution steps to generate distractors for questions containing mathematical equality or inequality. Commonly used rules are:

- *Change One Sign* : Randomly pick one coefficient or constant in equality/ inequality and multiply by -1.
- *Change Two Signs* : Randomly pick two coefficients or constants of equality/inequality and multiply by -1.
- *Most Frequent Number* : Use the most frequent number in the equality/inequality as a distractor
- *Nearest Multiple* : Randomly pick a coefficient or a constant in equality/inequality and change it to the nearest multiple of 2, 3 or 5.
- *Random Drop* : Randomly drop one of the coefficients or constant in equality/inequality
- *Invert Range* : Invert the solution range of the inequality, e.g. change $[0, 1]$ to $(-\infty, 0) \cup (1, \infty)$
- *Trivial Solution* : For inequality problems, one of the distractors can be chosen from $\{\phi\}$, $(-\infty, \infty)$, or *No Solution*. For equations, choices are from 0, -1 or 1
- *Flip brackets* : Change an open bracket in answer to closed and vice and versa. In the question, order of operations can be changed by changing the position of brackets.

These rules can be coded as python functions and then selected one or two rules at random to modify the steps involved in solving the question. Symbolic library like sympy can be used for generating and solving the math questions. The library developed by deepmind [22] can create math questions across various domains with varying difficulty level. We modify their codebase to extend its capability to generate the distractors based on the stated rules. Table 1 shows few examples of rule based distractor generation.

Question	Answer	Distractors
Let $-\frac{2p}{3} - \frac{2}{3} \geq \frac{2p}{5} - \frac{4}{5}$. What is p?	$-\infty < p \leq \frac{1}{8}$	$\frac{11}{2} \leq p < \infty$ $3 \leq p < \infty$ $\frac{4}{23} \leq p < \infty$
Find all solutions to $\frac{3}{2} - \frac{w}{6} \geq -\frac{2w}{11} - \frac{14}{11}$.	$-183 \leq w < \infty$	$-\frac{61}{4} \leq w < \infty$ $-\infty < w \leq \frac{61}{4}$ $-\infty < w \leq \frac{47}{2}$
Solve the polynomial inequality: $51 - 3f \neq -f - \frac{1}{6}$	$f \neq \frac{307}{12}$	$f \neq -\frac{305}{24}$ $f \neq -\frac{305}{18}$ $f \neq -\frac{46}{3}$

Table 1: Distractors generated using rules

Distractors generated using rules act as a form of reference distractors. For qualitative evaluation of distractors generated by neural networks, we will look at both the distractors side by side in table 3.

3.3 Experiment Detail

Two principle experiments can be identified. An attentional [3] encoder decoder GRU [4] is trained on a single question type for the entire 666,666 easy train set. Keeping with the spirit of the framework released by [22] we after training a model on a specific question set test the models on their respective question's interpolate test rather than a subset of the train set.

Simultaneously, during the second round of data collection with the GRU, when the model is scored on the interpolate set we perform character offsetting (see 3.3.1) and ask the model to predict 3 distractors in addition to a primary solution sequence. Two different scores were calculated for a model's performance on the test set–the first, a complete binary accuracy where credit is assigned if and only if the entire primary greedy decoded sequence matches the true solution sequence. And second, a partial credit score which is calculated by subtracting from 1 the normalized Levenshtein edit distance between the predicted and true solution. Normalized in this context means the ratio of the edit distance to the max sequence length of either the true or predicted solution sequence. Thus for a given Levenshtein distance d for solution sequence S and prediction sequence P we have partial credit defined as

$$\text{partial credit} = 1 - \frac{d(P, S)}{\max(\text{len}(P, S))} \tag{1}$$

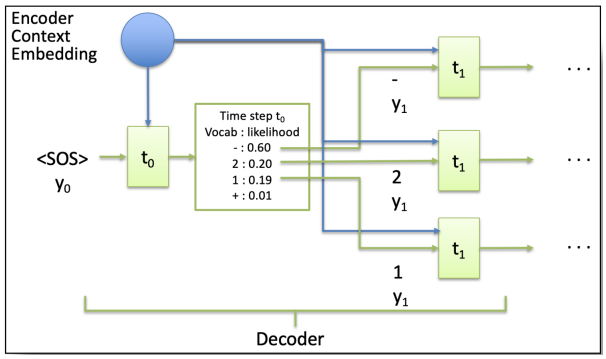

Figure 1: Example of character offsetting given an encoder's context embedding from the input question '-2 + 1'. Note decoder hidden states not shown in diagram. <SOS> signifies the start of sequence character.

It is important to acknowledge the widely different possible interpretations for what partial credit could mean in this context and why we choose the definition we did. In a typical educational setting, partial credit is assigned when the student demonstrates sufficient understanding of the problem albeit fail to arrive at the final correct solution. This is difficult to measure in model outputs–consider a correct sequence being -2 and a predicted sequence of 2, the partial credit score would be $1 - \frac{1}{2} = 50\%$. In real life a teacher may realize a student failed to report a final sign change and assign significant credit. Such thorough review is impossible given the $100,000$ examples within a single question type's test set (and also impossible considering the model's inability to provide secondary and tertiary decision making steps)–and so we formulate the above definition as an attempt to empirically measure the ability for a model to predict *similar* expressions to the correct one. We emphasize this is not any attempt to measure the models comprehension of the mathematics it is predicting on. As for why this is important; the ultimate goal is to generate multiple choice question distractors which generally exhibit some form of similarity to the correct solution. We discuss defining a good distractor more fully in section 3.3.2.

3.3.1 Character Offsetting

We propose a modified greedy decoding schema called character offsetting for generating multiple choice question distractors. In a typical greedy decoding scheme for an encoder decoder sequence to sequence model an input sequence (in our case, a string literal representation of a math problem) is given to the encoder which generates a context embedding [24]. Then character by character the decoder outputs a response sequence based on this context. At every time step of the output sequence's prediction, the previously predicted character and hidden states, as well as the encoder's context output, are re-fed into the decoder. The actual output of the decoder at any step is a probability array the size of the model's vocabulary [8]. The highest value corresponds to the most likely next character in the sequence, at least according to the model's weightings. In a greedy decoding at every step we simply take the most probable character and append it to the final output. Prediction is halted once the model outputs the end of sequence character as the most probable next step [8].

In character offsetting we freeze the initial decoder returned probability array and hidden states. We now ask the decoder to generate four total prediction sequences–one being your expected greedily decoded output, a second with the second most likely character from the frozen initial probability array as the sequence's starting character, and similarly a third and fourth. Each time a new sequence is attempted, we reset the hidden state to the saved initial hidden tensor. This was found for several question types to generate diverse and reasonable incorrect outputs. Table 4 provides a qualitative ranking based on question type for this task.

3.3.2 Difficulty in Defining a Good Distractor

Defining a good distractor is a non-trivial endeavor, and we make no claim to have accomplished this in this paper. Rather we discuss *qualities* typically considered when trying to formulate distractors for a multiple choice assessment.

Some qualities are readily apparent–general reasonability of a distractor as a possible solution to the question posed is perhaps the most fundamental requirement [7]. Measuring reasonability may be accomplished in several ways. Difference in value between a distractor and the true solution are potentially a good baseline–a distractor should be within a context specific similar magnitude as the true solution to avoid immediate exclusion. For lower level maths such as the the problem types discussed we believe this to be typically within a magnitude difference.

3.4 Model Parameters and Training Procedure

The model experimented with was an encoder decoder attentional GRU trained on a single NVIDIA 1080TI GPU for a single train-easy curriculum question type from the [22] data set. The models encoder and decoders had an embedding layer of size 512, with the decoder having 16 attentional heads. Initially what was attempted for a given training question type was an encoder decoder hidden size of 2048 on a batch size of 256. If the 1080TI GPU memory was insufficient given a training question type then we alternated between dropping encoder size and batch size. The parameters for a given question type are recorded in table 4. 150 training epochs were performed.

We follow most of the parameters used in [22]–the Adam optimizer [9] was selected for minimizing the sum of the log probabilities of the correct character with learning rate $lr = 6 * 10^{-4}$, and $\beta_1 = 0.9$, $\beta_2 = 0.995$, and $\epsilon = 10^{-9}$ and absolute gradient clipping of 0.1. The model leveraged teacher forcing during training and used 0.9/0.1 split of training data into a train and validation set.

4. RESULTS AND ANALYSIS

4.1 Attentional GRU on the Interpolate Set

4.1.1 Performance Considerations

It should be noted that these models have removed from them the greater context provided by the train-medium and train-hard data sets, of which interpolate attempts to test understanding for as well. It is possible as well that the hard or medium sets better generalize to interpolate for specific question sets. A small test seems to support this–we let the model train on the hard variant of algebra_linear_1d and scores improved from 3.9% to 44.3%.

Metric	Mean Score
Binary	0.065
Partial Credit	0.679

Table 2: Comparison of attentional GRU partial credit and binary scoring performance averaged across all questions not disqualified in 4.2.1. This includes low potential questions excluded in table 4.

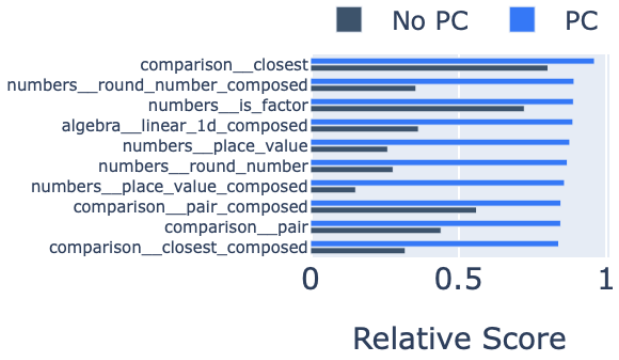

Figure 2: Top ten scoring questions when evaluated with the partial credit (PC) metric and no partial credit (binary) (No PC) score.

4.1.2 Analysis: GRU Performance Binary Scoring

Performance when scored with no partial credit varied widely. Of the top ten scoring question types 5 are from the comparison module type. Based on overall poor performance we are skeptical that the models extrapolate true mathematical semantic meaning–rather they likely just determine meta solution strategies. For example, one hypothesis for the comparison task success is that the notion of magnitude is readily apparent based on the length of the input sequence. Two observations about this–the first is that this requires the model to have gained the ability to isolate critical numeric subsequences within a larger question prompt. Secondly, providing contrary evidence to this hypothesis of sequence length metagaming, is that even for examples comparing long decimal sequences of lesser magnitude to short whole integers of greater magnitude we observe successful predictions. Lastly, the implication of signage in comparison was understood well by the models.

Generally it would appear that magnitude is an easier concept for statistical pattern recognition to abstract. Most difficult for the network was the evaluation of polynomials and other algebraic expressions, and arithmetic. Binary scores in all these categories were low–even given the considerations provided in section 4.1.1.

4.1.3 GRU Performance Partial Credit Scoring

Measurement with the partial credit metric (table 2, figure 2) demonstrates greater consistency and performance and shows promise for the ability of the attentional GRU to capture the essence of a reasonable response and work as a distractor generator for multiple choice questions–especially for types of problems the model performed poorly on using a binary scoring metric. However we note some flaws in the measurement. An example: in algebra_linear_2d_composed the model would frequently predict a single negative sign, a safe prediction and given the length of correct outputs is typically only one or two characters this led to a significant boost in score while answers remained meaningless. Interestingly in the question set's non-composed variant algebra_linear_2d the model's outputs are mostly meaningful and the partial credit score seemingly justified. To supplement the partial credit score, a qualitative examination of the reasonability of model's outputs compared to their empirical partial credit scoring is provided in table 4.

4.2 Multiple Choice Question DG

4.2.1 Considerations

The [22] framework releases a wide range of question types posed in diverse formats. Not discussed until now is that several formats are not conducive towards training models. Take for example questions from the comparison_closest set which are themselves posed as multiple choice questions–

'Which is the nearest to -955? (a) -3/4 (b) 0.2 (c) 17/3 (d) 3/5 (e) 0.5'

A model is supposed to predict either a, b, c, d, or e. Of the data sets released only four were found to use such a format for some or all questions within the set. A similar problem; six sets were either partially or fully posed as simple true and false questions. Naturally such questions are removed from consideration from our goal of distractor generation.

Partial credit was found to be an effective indication for many question types of whether a model's principle predicted sequence captures what a reasonable response should look like. Some faults exist however–consider the question type comparison_sort. An example: 'Sort -1, 0.3, -6, -24/11, 3, 5, 1 in descending order.' with primary prediction '5, 3, 1, -0.3, -1, -24/11, -6'. Observe the -0.3 in the prediction output–a value which is not even an option given in the problem statement! Such an example would not make a worthwhile distractor as it fails to test for the mathematical notion this question fails to over a high partial credit score. In table 4 we provide a qualitative review per question type of character offset predictions for multiple choice question distractor generation. By comparing to their respective partial credit score we find that generally a high score is an indicator for character offset predictions to also be reasonable.

4.2.2 Character Offset DG: Interpolate Sampling

The following are a couple of curated model responses–the order of the distractors matches the ordering of the probability of the initial character offset. So the first value listed is the model's primary greedily decoded prediction, the second is the sequence generated when we force the initial character to be the second most probable, and so on. If the model predicts the correct solution it is bolded.

'solve -2*s - 40 = -2*j, 53*j - 62*j + 245 = 4*s for s.'
output: **5**, -5, 4, 1

'let i(a) = -a**2 + 1319*a - 22130. calculate i(17).'
output: **4**, -4, 5, 14

Here we see a pair of ideal outputs from the algebra_linear_2d and polynomials_evaluate sets respectively. Not only did the model successfully predict the correct solution sequences of 5 and 4, but also produced noteworthy distractors. Observe the similar magnitude and the prediction of -5 and -4–sign changes of the true solutions and a powerful arithmetic skills check.

Quantitative measurement of the potential for character offsetting in generating multiple choice question distractors is a difficult endeavor due to the lack of formal definition of the problem. However, we observe general groupings of questions which seem to have potential for the use of character offsetting as a computationally cheap method of doing so. Table 4 is a qualitative ranking when given a random subset of outputs for each interpolate question type, whether offset predictions are not reasonable (low, not reported), whether at least one offset sequence is reasonable (medium), or whether most offset sequence predictions are reasonable (high). We view a prediction as unreasonable if it is mathematically meaningless or as mentioned in 4.2.1 either unreasonable given the problem's context or disqualified due to format. We find a higher partial credit score of the primary predictions frequently but not always aligns with whether offset predictions would also be reasonable.

Table 3 shows the comparison of the model generated distractors and rule based distractors for five questions. We generated four distractors for each question from the model and generated ten distractors from the rule based system. In the given table we show the most matching distractors. As we can see we get two matches each for questions (1), (4) and (5). There are three matching distractors for question (3) while there is no matching distractor for question (2). Despite being no matching distractor, our model gets the form of the distractors correct, and the predicted distractors at a glance can be used on a real quiz. In question (4), we can see that the model gets the multiplicity of 120 right and tries to stay around it. From the above examples we can see that our model first tries to get the form of the answer correct and then aims for computational compositionality.

4.2.3 Character Offset DG: Standard Exam Sampling

We sample several actual standardized exam questions from the SAT, ACT, and a college algebra midterm. Questions are altered before being fed to a model so that mathematical syntax matches Python's. Interestingly models appear resilient to significant changes in the question's formulation. Correct exam solutions are bolded, and generated options are in order of the probability of the initial character offsetting. The exam distractors are provided for comparison below but are removed before the question is fed to a model.

'What is the greatest common factor of 42, 126, and 210?
A) 2 B) 6 C) 14 D) 21 **E) 42**'
output: 42, 6, 21, 12

An interesting example [1] as the numbers_gcd data set only ever presents two values to find the gcd of, while the above presents three. Not only does the model predict the correct solution, but two distractors also used in the actual exam.

'Evaluate the function f(x) = 3 + (x-5)**(1/2) at x = 9. A) 1 **B) 5** C) 6 D) 7'
output: 5, 49, -5, 9

Again we observe relatively reasonable responses given question formulations which diverge significantly from the templates trained on. This question [25] is similar to a polynomials_evaluate type. However, the difference is no fractional powers exist in the train-easy set–yet even with the power symbol being replaced by the unknown character the model still generates valid distractors (and the correct solution, but this is clearly by chance as the model has no knowledge of roots).

5. CONCLUSION

5.1 Summary

Two experiments quantitatively showed that a GRU has mixed results when attempting to solve elementary math problems. Our alternative goal of multiple choice distractor generation for several question types typically found in pre-undergraduate education by applying a modified greedy decoding schema referred to as character offsetting was successful. Evaluation using an edit distance based partial credit scoring metric as opposed to a binary one demonstrates greatly increased consistency and performance for capturing a reasonable response. We found the following:

- Generally the easiest math problem types for a GRU is comparison tasks which is not surprisingly since this is a fundamental problem encountered early in education. It would appear the ability for GRUs to abstract mathematical knowledge is minimal.
- The ability for networks to capture the essence of a reasonable response for several question types is shown. Leveraging the proposed practice of character offsetting we show that these networks can cheaply generate distractor options for multiple choice questions.

5.2 Future Work

It would be interesting to compare a beam search decoding's non principle predicted sequences to those produced by character offsetting and whether for certain question types more worthwhile distractors are produced. The general capability for character offsetting to produce at least one worthwhile distractor for the medium potential questions listed in table 4 hint that with some refinements to the decoding schema or training parameters could potentially become high potential question types.

ABSTRACT

Collaborative dialogue is rich in conscious and subconscious coordination behaviours between participants. This work explores collaborative learner dialogue through theories of alignment, analysing inter-partner movement and language use with respect to our hypotheses: that they interrelate, and that they form predictors of collaboration quality and learning. In keeping with theories of alignment, we find that linguistic alignment and gestural synchrony both correlate significantly with one another in dialogue. We also find strong individual correlations of these metrics with collaboration quality. We find that linguistic and gestural alignment also correlate with learning. Through regression analysis, we find that although interconnected, these measures in combination are significant predictors of collaborative problem solving success. We contribute additional evidence to support the theory that alignment takes place across multiple levels of communication, and provide a methodological approach for analysing inter-speaker dynamics in a multimodal task based setting. Our work has implications for the teaching community, our measures can help identify poorly performing groups, lending itself to informing the design of real time intervention strategies or formative assessment for collaborative learning.

Dialogue, Gesture, Natural Language Processing, Alignment, Collaborative Learning

1. INTRODUCTION

Collaborative problem solving has long been a focus of educational research, and has been deemed an educational learning objective of critical importance in the 21st century workforce [12]. In the education literature, collaboration success is often analysed with respect to a *joint problem space* as created through learner interaction [31]. This joint problem space integrates learner shared goals, descriptions of the problem state, awareness of available problem solving actions and the associations between these aspects. The emergence of this shared conceptual space is constructed through shared language, situation and activity.

Alignment in dialogue, the language component of this interaction, is also commonly attributed to an automatic mechanism to achieve a shared understanding, or *situation model* [27]. This account of dialogue predicts alignment across various modes of communication, from word level to gesture and gaze patterns. Specifically in a task based setting, alignment is thought to aid mutual understanding [10, 27]. These theories of alignment and collaborative learning when taken together suggest that convergence at many levels of communication will take place in parallel over the course of collaborative dialogue, and that this alignment will be indicative of collaborative success. Additionally, the collaborative learning literature suggests that the effort necessary to build shared understanding is what actually leads to learning [40], thus alignment, already found to be predictive of student learning in a teacher student context [42], may also be indicative of this.

Investigating collaborative problem solving through the lens of alignment can give additional insights to this complex problem of convergence [38]. In this work, we examine the synchrony and convervence between students at both a linguisitic and gestural level, via inter-student metrics of linguistic alignment and movement synchrony. Of particular interest in this study is the separate coding of collaboration and learning in the learner dialogues. This allows for side by side comparison of the different modalities, and the analysis of their interaction with respect to these outcomes. Gestural and linguistic coordination between locutors has long been linked in dialogue, both properties having been individually explored for facilitating collaboration and learning in various settings.

We offer an exploration of theoretically motivated metrics to capture synchronisation and alignment at the levels of linguistic expressions and movement patterns. We explore correlations between the measures themselves and between collaboration and learning. Exploring the relationship between these measures we find strong correlations between modalities, in line with the collaboration and alignment literature. Finally we explore the combination of these modalities in their predictive power for both collaboration and learning, finding that although they are interrelated, each plays a significant role in prediction quality.

1.1 Research Questions

Motivated by the hypotheses we draw from the literature on collaboration, learning and alignment, we hypothesise that more successful learner dyads will converge in both their language use and their movement patterns to a visible degree, as the students align their mental models during the learning process. We also hypothesise that together, these aspects of interaction can provide useful tools in the analysis of student learning. We split our analysis into the following research questions:

RQ1: ***Evidence of Convergence:*** Are linguistic alignment, gestural synchrony and convervence effects between students higher than by chance task and vocabulary effects?

RQ2: ***Convergence Vs Collaboration & Learning:*** How do our measures of convergence correlate with collaboration and learning?

RQ3: ***Interaction: Linguistic Vs Gestural:*** Do these modalities correlate with one another?

RQ4: ***Multimodal: Do combined measures of synchrony predict learning and collaboration outcomes:*** are the measures in combination predictive of learning and collaboration?

2. BACKGROUND

Evidence of convergence. Experimentally, in a two person dialogue setting, speakers have been found to converge, each aligning to their locutor at many levels of communication: lexical, structural, gesture and conceptual[27]. Speakers have been found to spontaneously coordinate body postures and gaze patterns during conversation [35]. Behaviour matching in multimodal communication has also been found to be temporally synchronised in collaborative task-based activity, when participants are facing each other [22]. Imitation or mimicry between people unconscious of this behaviour has been found in incidental mannerisms such as the bouncing of a foot, or rubbing a nose [9]. People imitate one another in dialogue across many different modalities, including lexical choice [17], accent [18], pauses [7], speech rate [43] and syntax [30, 4, 26]. This imitation has been linked to having social benefits, for example, [9] find that speakers in those pairs where their incidental mannerisms were mimicked perceived the interaction as running more smoothly than those whose were not. In terms of collaboration, multi modal behaviour matching has been found to occur in a synchronous manner in a task based collaborative dialogue where rapport and its role in learning and convergence was investigated [22]. Acoustic prosodic entrainment has also been found to correlate with rapport, a social quality of the interaction, in collaborative learning dialogues [23]. Parallel to this, it has been argued that infants' early skills of joint attention is their emerging understanding that other people exist as intentional agents [8], as they develop theory of mind. In terms of learning, lexical entrainment has been shown to correlate with success in multiparty student engineering group project meetings [16], where higher scoring teams were more likely to increase their entrainment in project words over the course of a dialogue, while lower scoring teams are more likely to diverge. Alignment level has been shown to vary with student ability [36], and convergence of lexical and speech features from student to tutor in spoken tutorial dialogue corpora has been shown to be a useful predictor of learning [42].

Language and gesture in learning. Gesture has an important role in teaching and learning [32], as does language, which, at a structural level, has been shown to exhibit effects characteristic of both learning and implicitness, thought of as an aspect of alignment or coordination between interlocutors [15]. A wide range of lingusitic features derived from student dialogues have been found to be effective predictors of both learning gains and collaboration quality [29]. Categorising gesture in an educational setting often adopts the framework proposed by [24], of separating them into four basic types: beat (gestures devoid of topical content yet which lend temporal or emphatic structure i.e. hand tapping, head movement for emphasis), deictic (concrete or abstract pointing i.e. to match an object referred to as 'this' or 'that', or a concept in the past that is being referred to), iconic (also referred to as representational, i.e. making a gesture of putting a phone to ones ear), and metaphor (gestures to illustrate abstract concepts, such as moving hands together to illustrate mathematical convergence, or drawing a trend line in the air to demonstrate positive correlation). While gestures are pervasive, not all types are equally represented in particular speech events, and are very dependent on the dialogue context, however, various studies have found that gesture and speech together provide a better index of mental representation than speech alone, and to be an important aspect in learning [19, 11].

Table 1: Example dialogue excerpt. Expressions in bold indicate shared **lexical** constructions.

Experimental Setup. The experimental setup consisted of 40 pairs of undergraduate students participating in a collaborative problem solving task of programming a robot to traverse a maze. The participants had no prior programming experience. The participants sat facing a computer screen, and were recorded as they worked through the shared exercises. During the collaborative aspect of the task, the focus of our analysis in this work, participant dialogue was recorded and subsequently transcribed. Body movement data was also recorded via a Microsoft kinect sensor. This resulted in timestamped language and movement data for the 30 minute period of the task. The participants were individually given a pre and post test on a similar set of exercises, in order to evaluate the relative learning in the dyads. The learning assessment consisted of four short answer or fill-in-the-blank questions that assessed their understanding of basic computer science competencies (adapted from [5, 44]). Learning gains were computed by subtracting pre-test scores from post-test scores and divided by the total number of points to be gained minus the pre-test [13]. Collaboration was evaluated on a series of axes derived from the

collaboration assessment measures proposed in [25]: *sustaining mutual understanding, dialogue management, information pooling, reaching consensus, task division, time management, technical coordination, reciprocal interaction, and individual task orientation*[1]. Each dimension was given a score between +2 and -2 (each score was defined with concrete behaviors in a codebook). Researchers double-coded 20% of the sessions and had a Cronbach's alpha of .65 (75% agreement). An overall measure of collaboration was defined as the aggregate of all collaborative features. More details of the study, the data, experimental setup and coding of collaboration and learning scores can be found in Reilly et al. 2019 [29].

Dialogue transcripts. An example snippet from a dialogue with high collaboration score is provided in Table 1. The transcripts occasionally include some utterances from the facilitator, for whom we are not interested in measuring any alignment effects. The facilitator typically will speak most at the beginning of the dialogue, thus we remove all intial utterances (including participant) which interleave facilitator and participant. For the remainder of the dialogue, facilitator utterances are simply removed. Punctuation, although added at the annotators discretion, is retained, as it provides valuable information about the pace of the language used, and indicates the fragmented nature of these dialogues. The transcripts were tokenised before analysis using the nltk python package[2].

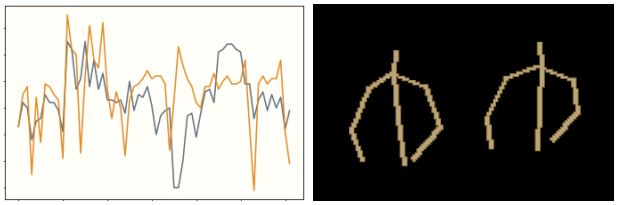

Figure 1: Example student movement pattern over time (left) and student geometries (right).

Movement Data. Student movement was processed using motion sensors from microsoft kinect, returning a series of geometries representing the students' body positions in space. An example of two students sitting at the table (which obsures the lower half of their bodies) can be seen in Figure 1. We only include data from the time period where the students were performing the collaborative activity, which corresponds to the transcript data of 30 minutes per session. In terms of pre-processing choices, our interest in the movement data is where the students mimic the gestures of their partner independent on their position relative to the camera or one another. This allows us to abstract from the postural shapes, relative size, and dominant hand of the participant's gestural patterns. We thus use averaged 30-second time slices[3] of the movement data (a measure of between frame positional difference). We further process this data to account for the differences in movement which the experimental setup introduces: we apply standardisation[4] to each participant signal in order that two signals of different means and standard deviations can be compared on the same axis. This grants us a measure of variance similarity, which captures better the elements of beat gesture patterns separate from absolute movement differences, as we know the students consistently display different mean movement levels across dyads.

3.1 Computing Lexical Alignment

We operationalise linguistic alignment in this work at the lexical (word) level, derived from the dialogue transcripts, extracting *shared expressions*, which we define as any sequence of tokens which contain at least one word (e.g. single punctuation marks are excluded). The automatic extraction of shared expressions per dialogue is an instance of the longest common sub-sequence problem [20, 3]. For each dialogue, we extract the inventories of shared expressions using the method proposed by Duplessis et al. [14]. For each of the two dialogue-specific inventories of shared constructions, we compute the following measures:

- *Expression Variety (EV):* The lexical diversity of the expression vocabulary.
- *Expression Repetition (ER):* The ratio of produced tokens belonging to an instance of an established expression
- *Vocabulary overlap (VO):* Captures the richness of the shared vocabulary, the ratio of shared vocabulary present in the dialogue between participants:

$$\frac{\#(words_{\text{speaker1}} \cap words_{\text{speaker2}})}{\#(words_{\text{speaker1}} \cup words_{\text{speaker2}})}$$

Individuals repeat and introduce expressions at different rates within dyads, thus we additionally calculate dyad level measures to capture the symmetry between interlocutors.

- *Expression Initiator (IE) Difference:* Difference in % of shared constructions introduced by each dialogue participant. *Initiator* describes the dialogue participant to first use a subsequently shared and repeated construction.

  $||IE(speaker\ one) - IE(speaker\ two)||$
- *Expression Repetition Difference:* The difference in proportion of an individual speaker's utterances which contain a usage of a shared construction:

  $||ER(speaker\ one) - ER(speaker\ two)||$

These measures capture the between speaker repetition within dialogue, which we use as a proxy for measuring the coordination or alignment between the speakers. An example of expression repetition can be found in Table 1

[1]Detailed descriptions of these measures used can be found in [25]

[2]NLTK[21] python package http://www.nltk.org

[3]Our choice of 30-second slices was in part informed by previous work [38], and through qualitatively examining the data at 5-second and 30-second slices, 30-seconds seems to be sufficient to capture interesting aspects of finer-grained hand movement, but not so fine as to render average total movement data meaningless

[4]Standardising a time series dataset involves re-scaling the distribution of values, also known as *Z-normalisation*

3.2 Computing Gestural Synchrony

We use Dynamic Time Warping [33] as the measure of similarity between partner movement patterns as it has been found to be a consistently robust measure of time series similarity [2], which although introduced as a method for analysing speech signal [33], has been employed successfully in the field of gesture recognition [1]. DTW is a technique to find the optimal alignment between two time series, through the stretching or compression of either series along its time axis. This warping can be used to find corresponding regions between two time series, and serve as a distance measure. This measure of distance allows us to capture slightly out of sync movement patterns, or those of slightly differnt phase length, to be deemed more similar than their difference in slope would suggest. Our main motivation for choosing DTW over other metrics demonstrated suitable for this task such as [38, 28] is our hope to capture the similarity of slightly asynchronus movement, which, if indeed movement and linguistic alignment is linked, should follow a similar mixed turn taking behaviour as dialogue [41]. As well as providing a robust distance measure between two time series, DTW returns a warping path which describes in what direction the time series needs to be moved in order to best align: in other words, the warping path can provide useful information about leader and follower dynamics which we exploit in our analysis.

Inspired by common measures of gestural synchrony/body language, we investigate the following dyadic behavioural properties:

- *Movement Difference (Mdiff):* Global mean movement difference in a pair. Calculated as the absolute value of the difference between the means of each participants.
- *Movement Synchrony (dtw_dist):* The synchrony between pairs in terms of their movement patterns, as measured by the Dynamic Time Warping (DTW)[33] distance
- *Leader Follower dynamics (diffLF):* The directionality of the alignment of the movement between the pair. This metric is derived from the DTW path.

Additionally, to measure whether these similarities become more pronounced as the session progresses, we divide the session in half by timestamp, and compute the measures per half. We use the difference between dialogue halves (*second - first*) as a measure to capture convergence. This results in three additional measures corresponding for those synchrony measures above: *Mdiff_change*, *dtw_dist_change* and *diffLF_change*. The aspects of the body geometries which we focus on consist of the points for *Head, Hands, Shoulders* and *Total* (average) movement. For hand and shoulder measures, these are defined as an average of the movement in the right and left points for each aspect.

3.3 Measure Validation - Baseline

A certain level of similarity between speakers will exist independently of their adapting to one another. Due to their performing the same task, vovabulary will necessarily be constrained by topic, and consistent across pairings. Due to the experiment configuration, task specific gesture patterns such as moving the robot, or interacting with the computer, as well as to which side of them their interlocutor is will also lead to movement similarities, e.g. turning to the right vs the left to speak. We thus create baselines for both dialogue and movement data which demonstrate the levels of similarity inherent to the task setup. For the dialogue baseline, we create a scrambled version of the corpus by retaining the utterances of one of the students and interleaving it with utterances randomly drawn from another pair, per speaker. For a partner specific movement baseline, the movement data from each student is randomly paired with the data from another student on the same side relative to them as their partner was (i.e for each participant on the right hand side, replace their partner with a participant from the left hand side). To further check task specific effects of the seating configuration, we pair students sitting in the same position with one another, in order to confirm that the role does not show more similarities than the origional student pairings.

4. RESULTS

4.1 Analysis 1: Measuring Convergence

Linguistic. We firstly hypothesise that there will be significant inter dyad repetition beyond what the task demands by chance, since alignment has been linked to both learning, as well as collaboration, and this same measure has found significant alignment levels in negotiation[14], as well as in second language tutoring dialogue[37], although this dialogue setting is different since both speakers are learners. Firstly we explore whether alignment is greater than by chance: we therefore compare the original dialogues to the shuffled baseline in the same manner as [14]. The expression variety is significantly higher for the original (mean=0.118, std=0.023) than for the shuffled dialogues (mean=0.110, std=0.015). Statistical difference is checked by a Wilcoxon rank sum test (U = 1141, $p = 0.03 < 0.05$, r = 0.21)[5] This indicates that there exists a richer and more dyad specific expression lexicon. The expression repetition is also significantly higher for the original (mean=0.509, std=0.123) than for the shuffled dialogues (mean=0.487, std=0.109) (U = 1079.5, $p = 0.014 < 0.05$, r = 0.25). This means that the level of repetition between student dyads is not simply incidental, and can be attributed to alignment or routinisation effects. Finally, as a measure of how task specific the vocabulary is, we find the vocabulary overlap between speakers significantly higher in the original (mean=0.509, std=0.123) than in the shuffled dialogues (mean=0.487, std=0.109) (U = 856, $p = 0.0002 < 0.001$, r = 0.41). This difference demonstrates that students share a much richer vocabulary than would happen by chance in performing this task. Overall, these results show that the collaborative student dialogues constitute a richer expression lexicon than they would by chance, indicating that the students align to one another, resulting in their langauge converging [10, 27].

Gestural. We hypothesise that our measures of movement matching will result in higher partner-specific synchrony than

[5]Following [14], for each test, we report the test statistics (U/W), the p - value (p) and the effect size (r)

in our baseline: i.e. lower distance between pairs collaborating than simply any student performing the same task with a different partner. We find that within dyad DTW similarity is significantly higher than in both the partner substitution baseline (t= -2.0401, $p < 0.05$), and the within side baseline (t = -2.0397, $p < 0.05$). This indicates DTW is a useful measure of movement similarity in this setting showing that this method is suitable for capturing partner specific effects of these movement patterns and can allow us to use this to compare similarities between dyads.

4.2 Analysis 2: Convergence Correlated with Collaboration and Learning

Lingusitic alignment. We hypothesise that alignment between students will correlate with learning, since in other tutoring settings, it has been found to correlate with both learning gains [42] and linguistic ability [36]. Additionally, global language features of collaborative dialogue have also found to correlate with learning gains [29]. To answer *RQ2*, we compare our linguistic alignment metrics with learning and collaboration scores. We find support for our hypothesis about collaboration and alignment correlating. We find ER (r 0.680 $p < 0.001$), EV (r 0.622 $p < 0.001$), and VO (r 0.663, p <0.001) all correlate with collaboration using Pearson's r correlation coefficient. This shows that inter partner repetition is important, and that students will converge even to less common language in a collaborative setting. We also find our between learner measures significantly correlated with collaboration, IE_diff (r=-0.570, $p < 0.01$) and ER_diff (r=-0.54, $p < 0.001$) meaning that smaller differences between learner initiation and repetition of shared expressions correlates with how well they collaborate. EV (r=0.442, p =0.026), ER (r=0.442, p =0.006) and VO (r=0.349, p =0.034) also correlate with learning, although to a lesser degree. An intuition as for why, is that in other studies reporting alignment correlation with learning analyse dialogues conducted in an asymmetric *tutoring* setting, where adopting the language of the teacher is a sensible learning strategy as it is assumed that this language is correct. In our case, since these dialogues are between *peer* learners, the learning outcome is somewhat dependent on the rapport within the dyad, and the information aligned to being correct. In other words, in some cases, the learners may be converging to a shared mental representation, but it may not be the correct one. In keeping with this observation of dyad rapport and equality, IE_diff (r=-0.487, $p = 0.002$) and ER_diff (r=-0.515, $p = 0.001$) both show strongly that more equal contributions from the students in terms of repeating one another, and in introducing words upon which to align correlate with learning.

Movement Synchrony and Convergence. We hypothesise that movement synchrony and convergence, as defined by DTW distance and its change over the interaction, will provide a robust measure of synchrony which will better distinguish between dyads with differing activity levels, which in turn should correlate with collaboration and learning, in keeping with previous results with other measures in task based dialogue [22, 32, 28]. We compare our movement similarity metric with learning and collaboration scores. Overall

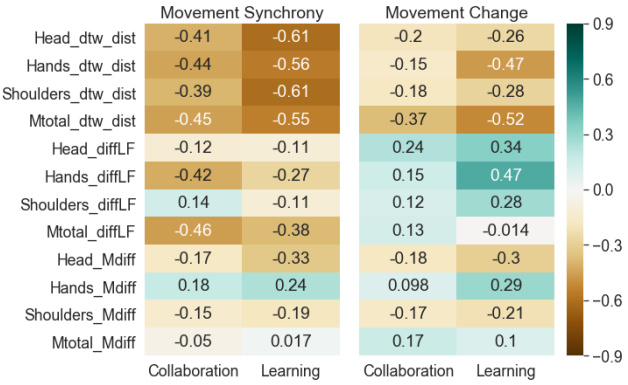

Figure 2: Gestural synchrony and convergence vs. Collaboration and Learning measures correlation with Pearson's r. Significant p values reported in the text.

as can be seen from Figure 2, we find average movement synchrony to correlate with both collaboration and learning. In terms of learning, DTW_dist measures for Head (r = -0.611, $p > 0.001$) Hands (r = -0.561, p = 0.002), Shoulders (r = -0.609, $p > 0.001$), and Mtotal (r = -0.611, p =0.006) all significantly correlate with learning to a strong degree. Convergence between dyads in terms of Mtotal (r=-0.519, p = 0.006) and Hands(r=-0.467, p = 0.014) also significantly correlate with learning. Finally, dyads becoming more dissimilar in terms of hand movement (having a stronger leader follower dynamic) also significantly correlates with learning: Hands_diffLF (r=0.471, p = 0.013). With collaboration, Head Hands Shoulders and Mtotal all significantly ($p < 0.05$) correlate. As does the diffLF for Hands (r=-0.42, p = 0.029) and Mtotal (r=-0.519, p = 0.006). Overall, the results are intuitive: we find that more synchronus pairs as measured by DTW distance significantly correlate with collaboration quality. We also find that convergence between dyads is present (negative correlation between *dtw_dist change* and *Mdiff change* show greater similarity between learners over time) and correlates with learning quite strongly for some movement metrics. We also see a positive correlation between the *diffLF change* features, particularly with learning, indicating that while convergence of behaviour is important, some aspects of turn taking and initiative are separate to this.

4.3 Analysis 3: Comparing Linguistic and Gestural Convergence

Comparing Linguistic and Gestural convergence, we hypothesise these aspects of communication will correlate with one another, as previous literature suggests [17, 4, 22]. To answer research question (*RQ3*), we contrast the modalities themselves. We split this comparison to compare gestural and linguistic coordination. We hypothesise that movement synchrony and linguistic alignment will correlate strongly, due to the process of speakers' alignment of shared mental representations taking place across various linguistic and paralinguistic levels [6, 27]: if dyads align at the lexical level, it is likely that the same process leading to this alignment will affect the gestural level also [27]. The DTW path allows us to capture the relationship between slightly offset movement patterns of beat gesture mimicry [24], and the

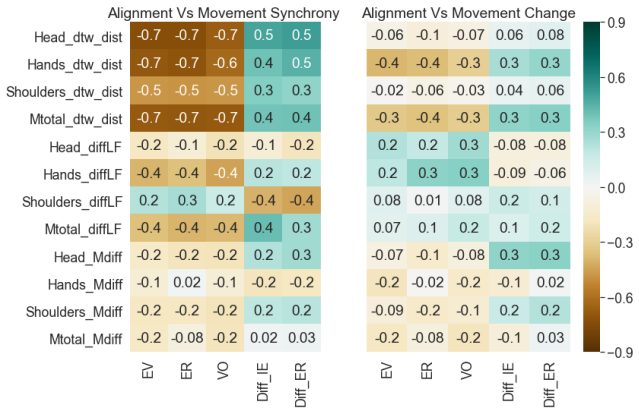

Figure 3: Movement measures vs. linguistic alignment measures. Pearson's r correlation coefficient.

case where linguistic alignment in turn taking utterances is low, which can lead to more synchronised patterns of movement [32]. Previous work has also found evidence of the coordination of of lexical alignment and gestural behaviour in a multimodal [35, 9, 22] context, we thus hypothesise that collaborative problem solving dialogues will also demonstrate this. We find significant correlation between linguistic alignment measures and movement synchrony across all movement patterns (Figure 3), with strongest effects for head (r = -0.735, p-value: 1.225) and hands (r = -0.706 p-value: 3.811), providing support that our hypothesis about lexical patterns influencing gestural alignment at the level of beat gesture and head nodding may be be true for this setting. In terms of convergence, there is a significant correlation with change in hand movement and expression variety (r = -0.387, p-value: 0.0458). Interestingly, the difference between speakers lingusitic (*Diff_IE*, *Diff_ER*) patterns positively correlates with both their difference in movement synchrony and speaeker divercence, indicating that asymmetric relationships between students are visible across modalities of communication. Inkeeping with our hypothesis we find strong negative correlation between between speaker difference in movement and divergence (strong correlation between similarity and convergence) with the linguistic measures of convergence, providing supporting evidence for the hypothesis that lingusitic and gestural convergence are part of the same underlying communicative process.

4.4 Analysis 4: Predicting Learning and Collaboration

Finally, in order to answer research question (*RQ4*), to find combined interaction effects of the various inter modality measures, we fit a series of mixed effect regression models[6]. We hypothesise that while each measure individually is strong, and although the measures themselves are correlated, each modality will provide its own distinct information contributing to learning and collaboration aspects. We perform backward step wise model selection to select the best predictors, firstly fitting each model with all relevant variables and stopping only when all remaining terms have significance $p < 0.05$. Although RMSE and r^2 values of predicted data are highest when combining all factors, we wished to discover the minimally significant descriptive set of criteria in order to find more interaction in our results.

[6]To fit the data and perform the statistical tests within this paper, we use the Statsmodels python package [34]

Table 2: Mixed effects Regression model multimodal results

Formula
Learning: **RMSE:5.48** r^2**:0.90**
*Learning ~ EV : ER + Diff_IE * Diff_IE + Handmean_movement_30_diffLFChange + Shouldermean_movement_30_diffLFChange*
Collaboration **RMSE:0.15** r^2**:0.999**
*Collaboration ~ EV * ER + Diff_IE * Diff_ER + Head_movement_30_dtw_dist + Handmean_movement_30_dtw_dist + Shouldermean_movement_30_dtw_dist + movement_total_30_dtw_dist + Head_movement_30_diffLFChange + Shouldermean_movement_30_diffLFChange + movement_total_30_diffLFChange + Head_movement_30_dtw_dist_change + Handmean_movement_30_dtw_dist_change + Shouldermean_movement_30_dtw_dist_change + movement_total_30_dtw_dist_change + Head_movement_30_diffLF + Handmean_movement_30_diffLF + Shouldermean_movement_30_diffLF + movement_total_30_diffLF*

Table 2 shows the minimal significant set of linguistic and gestural factors and their interaction in terms of their ability to predict the dependent variables of *learning* and *collaboration*. Each modality separately can form a good predictor of both alignment and learning in this setting. However, this analysis offers strong support for the multimodal modelling of collaborative problem solving, proving that although correlating with one another, both linguistic and gestural aspects have an independent role to play when predicting learning and collaboration. Broadly, from Table 2, the gestural features chosen indicate that both the measures of synchrony, and those for convergence (*_change* features) play a role in prediction. It is also clear that predicting collaboration in this case is easier than learning. This may be influenced by ceiling effects or ease of pre-test being a limiting factor. e.g. a learner with very good pretest score will have hit a ceiling by the end of the session.

5. DISCUSSION & CONCLUSION

We find significant levels of both linguistic and movement synchrony in our data (*RQ1*). In answer to *RQ2*, we find our measures of linguistic and gestural alignment correlate with collaboration. In terms of learning, we find that the difference in repetition between students negatively correlates with learning, that movement synchrony in general shows strong correlation with learning. In terms of *RQ3*, we find significant strong to medium effects when correlating measures of ER and dtw_dist with one another. This contributes to a growing body of evidence in support of theories of interactive alignment emerging across communicative modalities. Finally, via regression analysis combining our metrics (*RQ4*), we find that although separately powerful, a combination of modalities can best explain collaboration and learning outcomes. Our findings show the importance of analysing between speaker dynamics to capture nuances of learning. Our findings also suggest the use of a multimodal approach for the best understanding of these interactions. We also contribute interesting new evidence adding to work exploring the relationship between linguistic alignment and gestural and movement similarity. Our findings, while limited to a small specific setting, contribute evidence to support existing theories of human cognition and alignment.

ABSTRACT

Over the years, researchers have studied novice programming behaviors when doing assignments and projects to identify struggling students. Much of these efforts focused on using student programming and interaction features to predict student success at a course level. While these methods are effective at early detection of struggling students in the long run, there is also a need to identify struggling students during an assignment so that we can provide proactive intervention to prevent unproductive struggle and frustration. This work proposes a data-driven method that uses student trace logs to identify struggling moments during a programming assignment and determine the appropriate time for an intervention. We define a struggling moment as not achieving significant progress within a certain amount of time, relative to the amount of progress made and time taken in a sample student dataset. The paper describes how we determine significant progress and a time threshold for struggling students. We validated our algorithm's classification of struggling and progressing moments with experts rating whether they believe an intervention is needed for a sample of 20% of the dataset. The result shows that our automatic struggle detection method can accurately detect struggling students with less than 2 minutes of work with over 77% estimated accuracy. Our work contributes significantly to building proactive immediate support features for intelligent programming environments.

1. INTRODUCTION AND BACKGROUND

Computer programming is a challenging topic for novices. As a result, there has been an increasing interest in the early detection of struggling students for proactive intervention to reduce dropout rates and improve student learning in programming courses.

Researchers have collected and studied student problem-solving trace data during programming assignments from various perspectives. Most of this effort has focused on analyzing student programming actions to reveal their behavioral traits and programming patterns. This research typically uses manual inspection of the trace logs [4, 16, 9] or applies machine learning models [7, 3, 1] to categorize student behaviors and discuss the characteristics of each category and their potential impact on or relationship with student performance. The contribution of these studies usually lies in helping educators understand novice learning processes and promote positive behaviors. Another strand of research that analyzed student trace data focuses on student compilation behaviors [11, 19, 2] and syntax errors and bugs [21, 10] in student traces. This research used statistical inferences, machine learning methods, and visualization techniques to explore the relationship between specific patterns and student success and identify novice students' common mistakes. Some of these patterns are helpful for identifying students struggling with certain concepts.

However, we found that there has not been enough research that uses student trace log to model their progress and identify struggling moments during programming assignments. One major application of struggling detection is providing proactive hints in intelligent tutoring systems (ITS), as previous research has shown that novices, especially those with low prior knowledge or experience, may not request on-demand hints even when they need them [18]. Prior work identifying struggling students in traces generally focused on early detection of struggling students determined by the assignment outcome [12, 5, 6] and are not suitable for identifying struggle during programming assignments.

In this work, we propose a novel data-driven approach to

identify struggling moments from student trace data. We describe how we adopted the SourceCheck algorithm to model *student progress* during open-ended programming assignments and how to identify *progressing moments* and *struggling moments* from student progress. We used human experts to evaluate the progressing moments and struggling moments classified by our method. Our initial result shows that human experts had a decent agreement with our algorithm and that it is possible to determine if a student is struggling during programming assignments within two minutes. To the best of our knowledge, this is the first attempt to use a data-driven progress measurement to identify struggling students. We also discuss how our method may generalize to other domains that meet certain requirements.

2. DETERMINE INTERVENTION TIMES

In this work, we consider a student to be *struggling* during problem-solving when they could not make *enough progress* within a *typical amount of time*. As such, to determine the proper time to provide proactive intervention, we need to investigate: 1) how to measure student progress *during* solving a programming assignment, 2) what constitutes significant progress, and 3) how much time it typically takes a student to make significant progress, and finally, 4) what is the appropriate *time threshold* beyond which we consider the student is struggling and need help. This section describes how our algorithm models student progress and identifies potential progressing and struggling moments through these four steps.

2.1 Dataset

We analyzed a dataset collected from an introductory programming course for non-computer science major students in Fall 2017. Students learned to program by doing a series of open-ended programming assignments adapted from the BJC curriculum [8] in a block-based programming environment called Snap*!*.

We extended the Snap*!* environment to record all students' programming actions into *traces*. Each trace, identified by a project id, contains all actions a student performed during an assignment (e.g., creating or deleting a block) with timestamps. There are two types of actions in the traces, *non-coding* actions, and *coding* actions. Non-coding actions do not change the program scripts, for example, searching for blocks and running the program. Coding actions change the abstract syntax tree of program scripts, such as creating variables, creating custom blocks, and reordering blocks. Alongside every coding action, our Snap*!* environment also saves a code *snapshot* after the action, allowing us to reconstruct the steps a student took to build their final code and analyze their coding progress.

In this work, we focused on analyzing two assignments, Squiral and Guessing Game. Squiral is a homework assignment that asks students to create a procedure that draws a square-like spiral with a certain number of rotations specified by an input parameter. A correct Squiral solution typically contains 7 to 14 lines of code. Guessing Game (GG) is an in-class assignment that requires students to create a game that greets the players by their names, asks the player to guess the secret number, and tells the player if their guesses were too high too low until they guessed correctly. A typical Guessing Game solution contains 14 to 18 lines of code. These two assignments allow us to explore how well our method identifies students' struggling moments in assignments with different time constraints. Table 1 shows the descriptive statistics of the traces analyzed in the two assignments. We preprocessed the traces to remove any idle time of more than five minutes, during which the student did not perform any action.

Table 1: Descriptive statistics of the trace logs and grades of the two assignments.

	Traces	Rows	Time on Task	Avg Grade
Squiral	45	25160	29.6m	9.8/12
GG	59	22744	30.5m	11.7/12

2.2 Define Progress

The first step to identify struggling is to measure student progress in the assignment. Previous work used code compilation results [11, 19, 2], students' programming behavior patterns [7], and features completion [15, 13] to monitor student progress in an assignment. While these criteria are reliable indicators of how many assignment requirements the students have met, they did not use the student traces' full potential to identify struggling students at an action-level granularity during the assignment.

We adopted the *SourceCheck* algorithm [17] to measure student progress during an assignment. *SourceCheck* was initially designed as a hint generation algorithm to provide on-demand, next-step hints to help students move towards the closest correct solution to the student's current code. When generating hints, emphSourceCheck first compares the student's current code snapshot with a list of correct solutions (usually collected from past student data) and generates *mapping costs* from the student's code snapshot to each of the correct solutions. These mapping cost values represent how similar the correct solutions are to the student code – the more similar a correct solution is to the student's code, the lower the mapping cost is. *SourceCheck* picks the correct solution with the lowest mapping cost as the *closest correct solution* and generates next-step hints to move the student to that solution.

We adapted the mapping cost into a **similarity score** by reversing the mapping cost such that when a student moves closer to the closest correct solution, the mapping cost decreases, and the similarity score increases. One novel aspect of this paper is how we use the similarity score to measure student progress in the two assignments [1] We calculate a similarity score for every snapshot in a student trace using the *SourceCheck* algorithm. We define a snapshot's *progress* in an assignment as the similarity score *difference* between the *current* snapshot and its *previous* snapshot. As such, at a particular snapshot, we say a student is making a **positive progress** if the similarity score difference is positive and a **negative progress** if the similarity score difference is negative.

[1]Note that we assume a student is moving towards the closest correct solution at any given snapshot. Students do not know the prior student solutions used by *SourceCheck*, and we have no ground truth to identify what strategy a student may be using for their assignments.

We can visualize a student's progress in an assignment by plotting the similarity scores for each snapshot against the cumulative active time, shown in blue in Figure 1. The red line in Figure 1 represents what we call "absolute progress", which we define in the next section. The blue dots in Figure 1 represent the similarity score of every snapshot in a *Squiral* trace, and the blue line represents the progress (similarity change between consecutive snapshots) over time. Figure 1 demonstrates that the student made steady *positive progress* in the first eight minutes. Then, the student had a reduced similarity score for about four minutes, tearing the code apart trying to complete an objective of the assignment. Afterward, the student continued to make rapid positive progress until 14 minutes, stopped progressing for around three minutes, and finally reached their final submission at around 17 minutes.

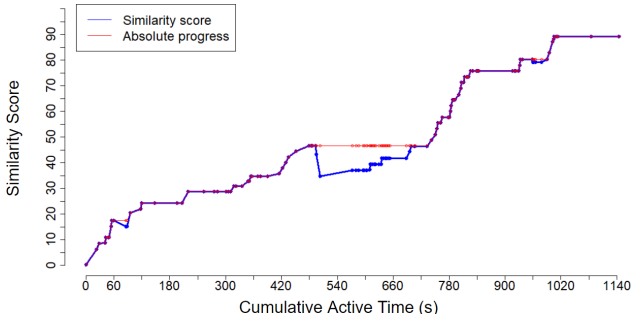

Figure 1: Similarity score (blue) and absolute progress (red) change over time in one student trace of Squiral.

2.3 Determine Significant Progress

Through inspecting multiple students' traces and comparing them with their corresponding progress plot (e.g., Figure 1), we found that not all positive progress represents a significant change to the program. Some minor similarity score increases were due to reordering code that does not change the code semantics but slightly reduces the mapping cost. This observation means that using *any* amount of similarity score increase for making progress *may not* be sufficient. Thus, it is important to determine how much similarity score increase can be considered *significant progress*.

To determine significant progress, we first define *absolute progress* for a student s_j at time t_i. We define $S_{max}(s_j, t_i)$ to be the maximum similarity score achieved by student s_j in an assignment between time t_0 and t_i, $S_{max}(s_j, t_i) = max_{k=0}^{i} S(s_j, t_k)$. We then define **absolute progress** as the difference in the maximum similarity scores between t_i and the previous snapshot time t_{i-1}, $P_{absolute}(s_j, t_i) = max(S_{max}(s_j, t_i) - S_{max}(s_j, t_{i-1}), 0)$. To visualize absolute progress, we plot the highest similarity scores achieved since the beginning of the trace (S_{max}), as shown in red in Figure 1. The absolute progress is *positive* whenever S_{max} increases between two consecutive snapshots.

We then calculated and sorted the absolute progress values from all the student traces for each assignment in increasing order and plotted all *positive absolute progress values* by percentile (using the quantile function in R), as shown in Figure 2. We used the 25th percentile of absolute progress values as the threshold for making **significant progress**. This choice was also used in another work identifying struggling students in a MOOC programming assignments [20]. The intuition is that if a student's absolute progress is no more than three-quarters of all the absolute progress, we consider the student is not making enough progress. Figure 2 shows that the significant progress threshold is 1.25 for Squiral and 1.5 for Guessing Game.

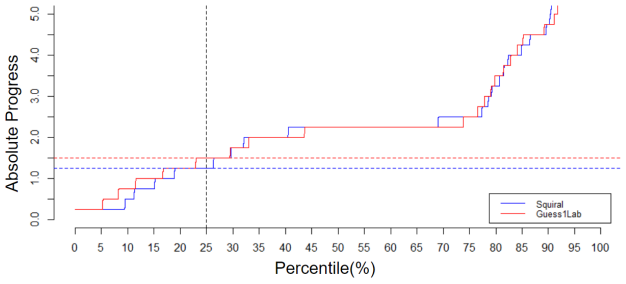

Figure 2: Positive absolute progress in all traces by percentile

2.4 Determine Typical Time

Now that we have determined the significant progress for each assignment, the next step to identify struggling moments is to extract the *typical time* for students to make significant progress. To do this, we first split all the traces into *code chunks* whenever the student makes significant progress–each code chunk contains multiple snapshots. This gave us 648 code chunks from Squiral and 1207 code chunks from Guessing Game. Then, we calculate the elapsed time between the first and the last snapshot in each code chunk and organize the elapsed times in ascending order. We plot the ordered elapsed times in Figure 3 where the y-axis is the elapsed time, and the x-axis is the percentile of the elapsed time distribution. The green line in Figure 3 marks the third quartile of time used to make significant progress. Note that the elapsed time to make significant progress grows almost exponentially after the third quartile. Therefore, we chose to use the third quartile as the cutoff for the *typical time* to make significant progress. The third-quartile time (dashed green line) in Figure 3 intersects with the Squiral progress (solid blue line) at 105 seconds and intersects with the Guessing Game significant progress (solid red line) at 85 seconds. We use these times as the typical time for the students to make significant progress in Squiral and Guessing Game. There are several dashed lines on Figure 3, which we explain in section 3.

2.5 Determine Progressing and Struggling Moments

The last step of this process is to use the typical time to make significant progress in identifying progressing and struggling moments for each assignment. To do this, we took all the code chunks generated in the third step and divided them into two groups, *struggling moments* and *progressing moments*. Recall that we define a student as struggling if the student does not make enough progress within a typical amount of time. Therefore, struggling moments are defined to be code chunks that have elapsed time greater than our struggling time threshold (75th percentile of time for significant progress), meaning that in this code chunk, even though students spent a long time, they did not make

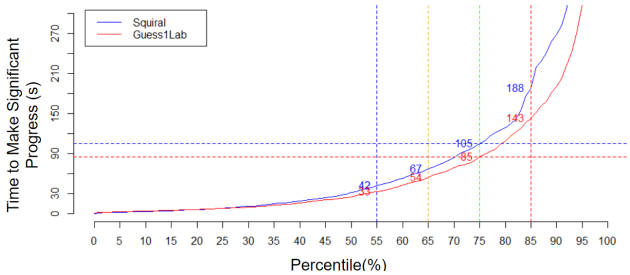

Figure 3: The elapsed time for all code chunks to make significant progress by percentile. The green, yellow, blue and red dash lines mark the proposed, earlier, even earlier, and later intervention times, respectively.

significant progress. Conversely, progressing moments are defined to be code chunks that took equal or less time than the 75th percentile of the typical time to make significant progress. Table 2 summarizes the significant progress, typical time for significant progress, and the number of code chunks generated for each assignment.

Table 2: A summary of products generated by our algorithm for the two assignments.

	Squiral	GG
Sig. Progress	1.25	1.5
Typical Time for Sig. Prog.	105.3s	84.5s
# Code Chunks	648	1207
# (%) Struggling Moments	131(20.2%)	269(22.3%)
# (%) Progressing Moments	517 (79.8%)	938(77.7%)

3. EVALUATION

Our evaluation is driven by the following research questions:

RQ1: To what extent the human experts agree with the progressing moments and struggling moments identified by our method?
RQ2: What are the common causes that the human experts do not agree with the progressing and struggling moments identified by our method?

We invited three expert raters, all included as authors, to participate in the rating of whether an intervention is needed for given code chunk samples. All three experts are computer science graduate students, two with extensive experience analyzing Guessing Game traces, and all three with extensive experience analyzing Squiral traces for research.

We first created the *struggling rating sample dataset* by picking a random struggling moment from each trace until the rating dataset contains 20% of all struggling moments for each assignment. Then, we created the *progressing rating sample dataset* by selecting the progressing moments immediately before each struggling moment in the struggling rating sample dataset. Finally, three redundant progressing moments were excluded from the progressing rating dataset because they were shared by consecutive struggling moments in the same trace. As a result, our rating dataset ended up with 29 struggling moments and 29 progressing moments for Squiral (out of 131), and 57 struggling moments and 54 progressing moments for Guessing Game (out of 269).

The experts were told to imagine themselves as TAs when rating. They used a customized interface that allowed them to visually step through the students' code changes in the rating moments to decide whether an intervention is needed. The experts used the time elapsed between actions and the type of the actions to inform their rating decision. They were asked to avoid using *hindsight*, which means that they should not justify their decision for intervening at an earlier time using student's later actions.

When rating the struggling moments, to make it easy to compare expert ratings, the experts were given five intervention timing options. The five options corresponds to potential intervention times marked by the colored vertical lines shown in Figure 3, which correspond to suggesting an intervention at time: blue or before (quantile(0.55)), yellow (quantile(0.65)), green (quantile(0.75), the typical time to make significant progress), red (quantile(0.85)), or "not now" (after red, or never). We chose these candidate percentiles to gain insights into expert preferences of intervention times for future analysis. For struggling moments, experts were shown the code changes from the start until the last action before the 85th percentile time for significant progress (red) to decide when an intervention would be most appropriate, or "not now." For progressing moments, experts were shown the entire progressing moment (all code changes within the time period where significant progress was achieved) and asked the expert to rate whether the moment "needs intervention" or "not now." Aside from rating the struggling and progressing moments, experts were also encouraged to take notes on why they believed an intervention is needed whenever they rate a sample as "needs intervention" for both the struggling and the progressing rating sample datasets. These notes will help us understand the experts' point of view when inspecting the disagreements between the experts and our algorithm.

Before formal rating, the experts practiced rating on a training dataset by immediately discuss their ratings after rating each sample until they were comfortable with the rating process. Then, the experts rated the struggling moments independently in three rounds, each round rating a third of the samples in the dataset. After each round, the experts gathered and discussed the differences in their ratings to share perspectives and resolve disagreements caused by oversight. We did not require the experts to reach a complete consensus on the rating because experts sometimes have different opinions on handling specific situations. Finally, after rating the struggling sample dataset, the experts independently rated the progressing dataset and were asked to check disagreements to correct rating errors caused by oversight.

4. ANALYSIS AND RESULT

To evaluate our RQ1 considering to what extent the human experts agree with the struggling moments and progressing moments identified by our algorithm, in this analysis, we merged the five rating options the experts used in the rating of the struggling chunks dataset into two options, "need intervention" and "not now." Specifically, we merged "at blue or before," "at yellow," and "at green" options into "need intervention" and merged the "at red" and "not now" options

into "not now." These two option labels are identical to those used when rating the progressing moments to directly compare how much the experts agreed with the generated struggling and progressing moments. Splitting and merging the options at green where the proposed time is at allows us to determine if our proposed typical time to make significant progress is appropriate and enough for the experts to decide whether they believe an intervention is needed.

Our analysis of expert ratings focuses on their ratings after discussion because those ratings are after the effort to remove personal error or bias. However, we report the inter-rater reliability (IRR), calculated with Fleiss Kappa, both before and after discussions to demonstrate the impact of the discussions. To determine how well the experts agree with the algorithm, we turned each expert's ratings into binary scores of 0s and 1s depending on whether the expert rating agrees with the rating dataset. Specifically, for struggling moments, the score is 1 if the expert rated "need intervention" and the score is 0 otherwise. For progressing moments, on the other hand, the score is 0 if the expert rated "need intervention" and the score is 1 otherwise. We then take the average of all expert ratings to calculate a *combined rating score* for each sample such that a combined rating of 0 or 1 represents that the experts reached an agreement and anything in between 0 and 1 means the two or three experts had different opinions, even after discussion, on whether the student was making progress or struggling. Finally, we calculate the *agreement rate* for each rating dataset by summing up all the combined rating scores in that rating dataset and divide the sum by the total number of samples in the rating dataset for that assignment.

4.1 RQ1: Expert Agreement

Table 3 shows the percentage of progressing moments and struggling moments that the expert ratings agreed with the algorithm after discussion, as well as the corresponding inter-rater reliability before and after discussions. Looking at the agreement rate between the expert and our algorithm, we see that for both assignments, over 77% of the time, the human experts agreed that an intervention was needed when the algorithm determined the student was struggling. Over 85% of the time, the human experts agreed that an intervention was not needed when the algorithm determined the student was making progress. This suggests that our method was able to identify struggling moments and progressing moments from the trace data with decent accuracy.

Table 3: Human expert agreement with the algorithm identified struggling moments and progressing moments

	Struggling Rating			Progressing Rating		
	N	Need Interv.	IRR (B/A)	N	Not Now	IRR
Squiral (3 raters)	29	77.0%	0.805** /0.847**	29	85.2%	0.853**
GG (2 raters)	57	83.3%	0.539** /0.646**	54	85.1%	0.819**

Looking at the expert agreement with each other, we found that the experts had excellent inter-rater reliability for progressing moments ratings on both assignments and for struggling moments ratings on Squiral. However, the experts were only able to reach a moderate agreement, even after discussion, for struggling moments on Guessing Game. We explored reasons that might cause experts to disagree with each other by manually inspecting the traces and their notes. We found that in four out of five struggling moments that the experts disagreed, students did not have errors in their snapshots but only performed less than six actions, which is way below the average number of 12 actions of all rated struggling moment samples. In such cases, one expert prefers to hold off on any intervention until seeing more student actions, whereas the other expert believes that the student needed a nudge telling them what they should do next. We did not see such a case in Squiral because all the rated struggling moments with few student actions had relatively apparent flaws in the student codes that warrant intervention. We will talk more about this in the discussion section.

4.2 RQ2: Common Causes of Disagreement

We manually investigated the ratings on which the human tutors and our algorithm disagreed. We present some common causes of disagreement for struggling moments and progressing moments, respectively.

Disagreement in Struggling Moments

Solution Matching: A decreased similarity score does not always mean the student is making negative progress. Due to characteristics of the SourceCheck algorithm, in some cases, a reduced similarity score can also be caused by the SourceCheck algorithm mapping the student's previous snapshot and the current snapshot to different correct solutions because the student added a particular code block. In such cases, if the student similarity score does not surpass the maximum similarity score since the beginning within an expected amount of time, our algorithm will determine the student is struggling, even though the student is making progress (having an increasing similarity score). However, the student may just be using a different approach to solve the problem from the expert's perspective.

Few Coding Actions: Since our algorithm focused on students' progress over time, sometimes students might not have taken enough actions for experts to determine if the student is struggling or not. There are several possible reasons why students have few actions, including trying to reason with their code, running their code, evaluating the result, or being off task. Disagreement in this situation did not only occur between experts and our algorithm but also happened between expert raters, causing a relatively lower inter-rater reliability of struggling moments in the Guessing Game assignment.

Disagreement in Progressing Moments

Logic Errors: The experts are good at catching critical logic errors in the student code and tend to intervene if there is a critical logic error in student code that might prevent them from completing the feature they are working on. For example, in Guessing Game, both experts decided to intervene when a student set the secret number to a boolean value and was trying to use the secret number to give player feedback on their guesses because the student would not be able to test the feedback feature properly without correctly setting the secret number first. In contrast, our algorithm considered that the student was making progress because

the students added blocks seen in the correct solutions.

Human Factors: Sometimes, when deciding on intervention, the experts assess the natural language in students' code to infer information about student intention in a way that is not possible for our algorithm. For example, in the Guessing Game assignment, experts pointed out that an intervention is needed when several students used an if/else block instead of combining the say block and the join words block to greet the players. However, since the if/else block was used for giving player feedback in many correct solutions, our algorithm determined the student was making progress, despite the student using the if/else block incorrectly for a different purpose.

5. DISCUSSION

RQ1: *To what degree do the experts agree with the algorithm on struggling and progressing moments?* For Squiral, the experts agreed that an intervention was needed for over 77% of the struggling moment samples and agreed that no intervention was needed for over 83% of the progressing moment samples. However, the experts have a relatively lower disagreement with each other in Guessing Game ratings, caused by different opinions on whether an intervention is needed when a student has few actions within the time frame. Since the expert raters were not pedagogical experts and had experience level on par with experienced teaching assistants (TAs), we do not know how an experienced instructor would react to this or other scenarios. Nevertheless, our results show that our method of identifying struggling moments by measuring whether a student could make significant progress within a typical amount of time aligns well with opinions from our experts who have at least as much experience as highly qualified TAs. We believe this shows great potential to determine when to give proactive interventions to students in intelligent tutoring systems for programming.

RQ2: *What are the common cases that our algorithm does not handle well?* We listed four common causes that led to disagreements between the experts and our algorithm. The first cause, "solution matching", rests in the adoption of SourceCheck as a progress measure. Since the SourceCheck compares student solutions to multiple model solutions, sometimes, adding a code block to a snapshot could cause SourceCheck to pick a different solution as the closest solution with a lower similarity score. This calls for investigation on how we may wish to smooth out the abrupt progress change when mapped to different correct solutions between consecutive snapshots. "Logic errors" and "human factors" are problems that are difficult to solve by using distance-based similarity measures alone, since similarity measures merely compare the mapping cost between two pieces of code and do not assess the semantics in natural language or programming logic. Thus, these two causes may require obtaining knowledge from other types of analysis to identify. Previous research has used compilation error [11, 19, 2], and feature detection [14] to detect if there are specific errors and determine if the student is struggling. Incorporating these methods could provide richer information in the decision-making for struggling moments. Lastly, some expert disagreements with the algorithm in struggling moments were caused by dealing with "few actions" within the time frame of the code chunks. Our inter-rater reliability for Guessing Game shows that even experts had a hard time agreeing on if an intervention is needed in this case. There seem to be multiple factors that may affect the expert decision, including if there are errors in the snapshot, the type of actions performed, and the assignment requirements that are completed and incompleted. Potential solutions to this problem may include consulting experienced teachers and incorporating sequence pattern analysis [7].

It's worth pointing out one important contribution of this work is that our method of using a data-driven approach to identify struggling moments has the potential to be generalized into any other domain that meets the following criteria.

1.Student Performance: Good student performance on the task, meaning that the majority of the students achieve correct or mostly-correct final solutions.
2.Trace log data: having time-stamped trace logs that documents students' snapshots during an assignment.
3.Progress measure: A score, or a combination of correct solutions and a distance metric between snapshots and correct solutions, as we devised from SourceCheck.

There are two major ways our method can benefit future research. First, our method of identifying progressing and struggling moments provides a new way for researchers to study novice problem-solving behaviors and identify common misconceptions. Second, the significant progress value and typical time to make significant progress can be incorporated into intelligent tutoring systems for providing proactive feedback to struggling students.

This work has some clear limitations. First, we only used three expert raters to evaluate the sample result. The expert raters were not pedagogical experts and had experience levels on par with experienced TAs. Hence the evaluation result may be different if rated by experienced instructors. In addition, our work is limited by a small sample size with only two programming assignments. We need further investigation to determine if our result holds for assignments with even more varied complexity or in other problem-solving contexts.

6. CONCLUSION

This work presented a novel, data-driven approach to use a similarity measure to model student progress in programming assignments and identify progressing and struggling moments from trace log data. To evaluate the performance of our algorithm, we asked human experts to evaluate a sample of 20% of the algorithm-identified progressing and struggling moments from trace logs from students solving two programming assignments and rated if the experts agree with the algorithm. Our result shows that the expert agreed with over 77% of the struggling moments and over 83% of the progressing moments, which shows great potential. Our algorithm can be generalized to different domains if they have good student performance, trace log data, and a progress measure for in-progress student solution attempts.

ABSTRACT

Automatically detecting bugs in student program code is critical to enable formative feedback to help students pinpoint errors and resolve them. Deep learning models especially code2vec and ASTNN have shown great success for *large-scale* code classification. It is not clear, however, whether they can be effectively used for bug detection when the amount of labeled data is limited. In this work, we investigated the effectiveness of code2vec and ASTNN against classic machine learning models by varying the amount of labeled data from 1% up to 100%. With a few exceptions, the two deep learning models outperform the classic models. More interestingly, our results showed that when the amount of labeled data is small, code2vec is more effective, while ASTNN is more effective with more training data; for both code2vec and ASTNN, the more labeled data, the better. To further improve their effectiveness, we investigated the potential of semi-supervised learning which can leverage a large amount of unlabeled data to improve their performance. Our results showed that semi-supervised learning is indeed beneficial especially for ASTNN.

1. INTRODUCTION AND BACKGROUND

When students encounter difficulties during programming, they are often caused by systemic procedural errors, or "bugs" [9], which can occur repeatedly across problems [38, 8]. For example, a student may confuse when it is appropriate to use the `and` and `or` operators, or fail to consider a boundary case in a condition, using `>` instead of `>=` [17]. These bugs are rarely directly addressed by the compiler or test-case feedback employed in most computer science (CS) courses, which are generally limited to suggesting syntax errors, or which correct input-output pairs the program fails to replicate. Historically, tutoring systems in a variety of learning domains have detected these bugs automatically (e.g. through a *bug library* [9, 4]). The detection can be used to offer tailored formative feedback [34] that address bugs directly [22], and can also help instructors to be more informed about student learning process [25]. The detection of bugs often requires experts' manual definitions, with distinct rules for detecting the bug on different problems [4]. This can make it impractical to use bug detection in practice. Most current automatic grading systems for student code are mainly based on test cases, which provide a score and failed test case information to students [15, 16, 37]. Nevertheless, the relationship between code's output and the presence of specific bugs in student code is not clear, since a given erroneous output could be caused by various errors in student code. An automatic bug detection system for student code could be useful to fill in the gaps for students.

Machine learning (ML) algorithms are powerful tools for data analysis, which have been commonly used for automatic programming code analysis [10]. Classical machine learning methods, such as support vector machines [13] and XGBoost [11], are capable of classifying program code [12, 21, 18]. Recent advances in machine learning have leveraged structural information in code to accurately classify and label it [2, 3, 41, 28]. For example, Alon et al. explored path representations on code represented as trees [2], and designed the code2vec model to learn the representations using deep neural networks [3]. Abstract Syntax Tree based Neural Network (ASTNN) by Zhang et al. applied recursive neural networks in the structure, outperforming Tree-based Convolutional Neural Networks [28] and other state-of-the-art models [41].

However, to apply the models to detect student program bugs, two challenges need to be addressed. First, these deep models were originally designed for *professional programs* which are fundamentally different than code written by students [39]. Some recent work has applied these techniques to educational domains [33, 19, 26, 30, 6], but they either used base models years before, [28, 19], or are not specifically used for bug detection [33, 26, 30, 6]. Second, deep learning models are traditionally "data hungry" [1], using large, labeled

training datasets (e.g. [19] was trained on 270k samples). However, in most educational settings, datasets can be much smaller (e.g. ∼100 students), and labeling (e.g. to identify bugs) can take extensive expert effort [14]. This suggests the potential of leveraging a *semi-supervised* learning strategy, using a mixture of labeled and unlabeled data [42]. Semi-supervised learning, such as the Expectation-Maximization (EM) method, uses unlabeled data for model improvement [42]. However, studies show that the usage of unlabeled data may not always help [35]. Thus, an empirical evaluation, suggested by recent studies [29], to investigate whether semi-supervised learning with unlabeled data actually helps is needed.

To address these challenges, in this paper, we evaluate two state-of-the-art deep learning methods: code2vec [3] and ASTNN [41], on the task of automatically detecting programming bugs in student code. We manually labeled three bugs in ∼1800 code submissions from 410 students in a Java programming course, where each bug occurred in 4-6 distinct problems. Our results show that, when using *all available training data*, the ASTNN model performs best at detecting all three bugs, outperforming code2vec and two classical baseline models (support vector machines and XGBoost).

Furthermore, we investigate whether a semi-supervised learning approach can improve the code2vec and ASTNN performance without requiring additional labeled data. More specifically, we investigated how the deep and baseline models performed with different amounts of labeled training data through a "cold start" analysis [32]. We found that all models benefited from more data. However, despite deep models' reputation as "data hungry," we found the top-performing model was generally a deep model, regardless of training data size. However, *which* model performed best depended on the data size, with code2vec outperforming ASTNN when less labeled data was available. We also found that semi-supervised learning generally improves both code2vec and ASTNN by using unlabeled data. This effect was most consistent for ASTNN, where semi-supervised learning consistently improved the model performance by 5% to 20% on all splits. For code2vec, we also found that it required very little data (5%) to achieve 80% of its peak F1 score.

The major contributions of this paper are addressing three research questions (RQs):

- RQ1: How well do state-of-the-art deep learning models for programming code perform in a student bug detection task?
- RQ2: How are deep learning models' performance impacted by the amount of available training data?
- RQ3: To what extent does semi-supervised learning improve the performance of the deep learning models?

2. APPROACHES

In this section, we introduce how we build code2vec and ASTNN for program classification; and how we applied the semi-supervised learning strategy on them to leverage unlabeled data.

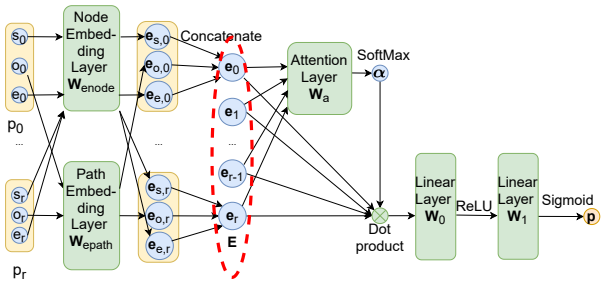

Figure 1: Code2vec model structure: model takes a set of paths as input, and through embedding layers, attention layer, then detect if the input code has bugs (1) or not (0).

2.1 Code2vec

One primary technical challenge in applying machine learning to program code lies in code representation. Code is often represented using an abstract syntax tree (AST) [7], while most learning algorithms expect a fixed-length vector. To solve this issue, sub-components of the ASTs are used as inputs for deep learning models. In the case of the code2vec model, it learns a code embedding through leaf-to-leaf paths, represented as strings. Strings of nodes and paths are mapped into numbers by tokenizers, where different strings are mapped into different numbers. These numbers are used as the input of a code2vec model, shown in Figure 1. Assume we have a code snippet that produces R paths $(p_0, ..., p_r)$ to be fed into the code2vec model. These numbers are embedded into e-dimensional vectors through node and path embedding layers ($\mathbf{W}_{enode}$ and $\mathbf{W}_{epath}$) respectively, and these node and path vectors are concatenated together into one vector for each of the paths $(\mathbf{e}_0, ..., \mathbf{e}_r)$. These vectors form a matrix $\mathbf{E}$, where $\mathbf{E} \in \mathbb{R}^{e \times R}$. Then these path vectors pass through a soft attention layer $\mathbf{W_a}$ [40], where they calculate the soft attention weight α for each of the paths: $\alpha = SoftMax(\mathbf{W_a}^\top \mathbf{E})$, $\mathbf{W_a} \in \mathbb{R}^{e \times 1}$, and thus α has scalar weights α_r for each of the paths, normalized by a SoftMax operator. Then the embedded path vectors $\mathbf{E}$ take the dot product of the calculated attention weights, showing which paths are more important in a code snippet. Then the weighted average vector passes through two fully-connected layers to make the bug classifications. In the training process, all the $\mathbf{W}$ weights are updated using Adam [23] optimization algorithm, while in the evaluation and validation processes, the weights in model are not changed.

2.2 ASTNN

Different from the path-based inputs for code2vec, ASTNN utilize the statement-level ASTs to learn a vector for the code. Specifically, we split the large AST of a code fragment by the granularity of the statement and extract the sequence of statement trees (ST-trees) with a pre-order traversal, and feed them as the raw input of ASTNN. Suppose that we have a set of ST-trees $(s_1, s_2, ..., s_T)$, our goal is to learn a vector representation z for the original code. The detailed architecture of ASTNN is shown in Figure 2.

Statement Encoder: Each ST-tree is composed of a root node and its child indices from a limited vocabulary of up to V symbols. For a ST-tree s_i, we first represent all nodes with

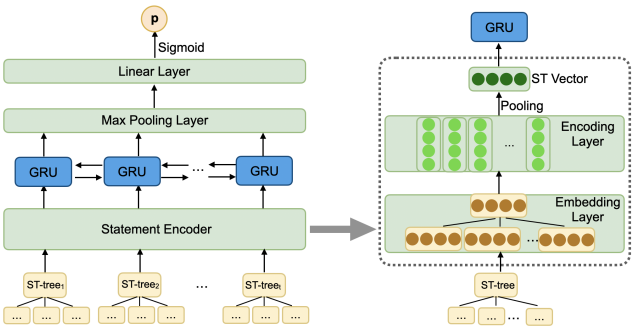

Figure 2: ASTNN model structure: model takes a set of statement trees as input, and through encoder layer, Bi-GRU layer, max-pooling layer, then to detect if the input code has bugs (1) or not (0).

the pre-trained embedding matrix $\mathbf{W}_{embed} \in \mathbb{R}^{V \times d}$ where V is the vocabulary size and d is the embedding dimension. Thus the initial vector of a node n can be obtained by:

$$\mathbf{v}_n = \mathbf{W}_{embed}^{\top} \mathbf{x}_n \tag{1}$$

where x_n is the one-hot encoding of node n. Next the ST-tree will go through a Recursive Neural Network [36] based encoder layer to update the vector for each node:

$$\mathbf{h}_n = \sigma(\mathbf{W}_{encode}^{\top} \mathbf{v}_n + \sum_{i \in child} \mathbf{h}_i + b_n) \tag{2}$$

where $\mathbf{W}_{encode} \in \mathbb{R}^{d \times k}$ is the encoding matrix and k is the encoding dimension. v_n is obtained from Equation 1 and b_n is the bias term. σ is the activation function and in this work we followed the original paper to set σ as identity function. After recursive optimization of the vectors of all nodes in the ST-tree, we sample the final representation e_i for s_i via a max-pooling layer.

Code Representation: Based on the sequences of ST-tree vectors, bidirectional GRU [5] is applied to track the naturalness of statements sequence $(e_1, e_2, ..., e_T)$, where T is the number of ST-trees in the AST:

$$h_i = [\overrightarrow{GRU}(e_i), \overleftarrow{GRU}(e_i)], i \in [1, L] \tag{3}$$

The statement representation $h_i \in \mathbb{R}^{L \times 2m}$, where m is the embedding dimension of GRU. Finally, similar to Statement Encoder, a max-pooling layer is used to sample the most important features on each of the embedding dimensions. Thus we get $z \in \mathbb{R}^{2m}$, which is treated as the final vector representation of the original code fragment. Finally $\mathbf{z}$ vectors pass through a linear layer to make the final classification of the bugs.

2.3 Semi-supervised Learning Strategy

While we explore the potential of machine learning models using insufficient labeled data as training inputs, unlabeled data can also serve as an important resource for the models to learn the structure of code. We applied a semi-supervised learning strategy to utilize these unlabeled data to help the model update. Specifically, in our experiments, we used Expectation-Maximization (EM) method [42] as an exploratory attempt.

EM method is iterative, and it contains two steps for every iteration: 1) In expectation steps, the model infers on the unlabeled dataset, getting a probability score, which will be served as the pseudo-label in the next step, for each of the unlabeled code snippets; 2) In maximization steps, the model is retrained using all the labeled training dataset and the unlabeled set with the pseudo-labels from expectation step. After retraining, the model is used for the next round of expectation step. In our case, deep learning models are designed to output probability scores, but SVM and XGBoost models make classifications without clear scores or probabilities. We implemented the regression versions of the models, assuming they would output a continuous probability as the regression result. We then used 0.5 as the probability threshold to binarize the output, serving classification results. Every model uses a unified 10 iterations of EM steps, assuming the models are able to converge after a certain number of iterations and retraining.

3. EXPERIMENT SETTINGS

3.1 Dataset and Bug Labeling

We performed bug classification on a publicly available dataset, collected from an entry-level Java programming class in Spring 2019[1]. It was collected from the CodeWorkout [15] platform and stored in ProgSnap2 [31] format. Since Java compiler can already detect bugs from code that failed to compile (due to syntax errors), and this code cannot be converted into an AST, we excluded uncompilable code from our analysis. We also did not use code that passed all test cases, as this code is correct and therefore is very unlikely to have bugs. There are 410 students, who attempted in total 50 problems from 5 assignments. Typical solutions for these assignments range from 10 to 20 lines of code. In order to determine the common set of bugs across different problems, two authors examined student code from six distinct programming problems from the first assignment and identified common bugs that arose. They then selected 3 prevalent ones after calculating the coverage of bugs from each problems, and identified in prior CS education literature [17, 20]. This included 2 logical bugs and 1 syntax bug: `comparison-off-by-one` (logical), `assign-in-conditional` (syntax), and `and-vs-or` (logical), defined below:

`comparison-off-by-one`: This bug occurs if, in a conditional expression (e.g. in an `if` or `while`), the student's code uses a greater/less-than comparison operator (`<=`, `>=`, `<`, `>`) incorrectly, and this error can be resolved by adding or removing the '`=`', (e.g. `<` becomes `<=`). The direction of comparison (i.e. `<=` vs `>=`) should already be correct. This often indicates an "off by one" error, and it is contextual, dependent on the number of literals being compared. If there are multiple bugs, including this bug, we still count it.

`assign-in-conditional`: This bug occurs if, in a conditional expression, a student uses the `=` *assignment* operator in their code when trying to compare a variable with another value, rather than the correct `==` *comparison* operator. This is a syntax-based bug, but it is not detected by the compiler, since the assignment is logically a valid operation.

`and-vs-or`: This bug occurs if a student uses the logical

Table 1: Detection performance for four classifiers on three bugs.

	Method	Accuracy	AUC	Precision	Recall	F1 Score (Std)
comparison-off-by-one	SVM	0.753	0.658	0.731	0.100	0.173 (0.045)
	XGBoost	0.505	0.541	0.384	0.547	0.334 (0.088)
	Code2Vec	0.736	0.746	0.500	0.556	0.522 (0.058)
	ASTNN	0.785	0.704	0.606	0.533	**0.560 (0.090)**
assign-in-conditional	SVM	0.943	0.959	0.918	0.627	0.733 (0.099)
	XGBoost	0.847	0.877	0.494	0.726	0.563 (0.112)
	Code2Vec	0.917	0.907	0.725	0.688	0.672 (0.119)
	ASTNN	0.970	0.901	0.961	0.807	**0.868 (0.094)**
and-vs-or	SVM	0.722	0.674	0.534	0.173	0.256 (0.078)
	XGBoost	0.503	0.669	0.350	0.784	0.470 (0.045)
	Code2Vec	0.758	0.821	0.570	0.663	0.609 (0.078)
	ASTNN	0.880	0.837	0.820	0.739	**0.773 (0.064)**

operator `and` instead of `or` in their code, or vice-versa, such that the opposite operator would produce correct code. This is also a logical bug that requires contextual information but is easier to detect than `comparison-off-by-one`. It requires the literals, but does not depend much on problem requirements.

Two authors started by labeling 20% of the data, following the same set of initial bug definitions. The labeling process was iterative: the two authors first labeled 20% of the data independently and then calculated Cohen's Kappa scores κ. If on any of the three bugs, the two authors did not achieve a score higher than the 0.8 [24], then the authors discussed and resolved the disagreements, refined the definitions, and continued to another round of independently labeling 10% of the data. This process continued until the authors reached high agreement ($\kappa > 0.8$) on all three categories of bugs, which occurred after labeling 40% of the data. The first two rounds of labeling did not achieve a high κ score, both due to the low scores on the `comparison-off-by-one` bug, suggest that this bug may be more difficult to consistently detect for humans. On the third round of labeling, the two authors achieved 0.81, 0.97 and 0.84 κ scores on the three bugs. Then the authors divided the rest 60% of data by 35% for each person to label, overlapping on 10% of the data for verification. These 10% of data achieved 0.78, 0.98 and 0.95 κ scores, indicating moderate to near-perfect agreement [27]. The finalized labeled dataset has a biased distribution, as only 30% of the submissions have `comparison-off-by-one` bug, 28% of the submissions have `and-vs-or` bug, and 13% have `assign-in-conditional` bug. In total, we spent around 20 hours and labeled 1867 code snippets from 296 students.

3.2 Splits in Experiments

Since our dataset included multiple attempts from a given student, we split our data into training and testing sets by student. This ensured that a given student's code showed up in either the training *or* testing set, but not both. In our experiment, we have 20% of the data as the test set, and the rest 80% are used for model generation. To check the performance of models with limited labeled data, we further split the 80% of data into labeled data and unlabeled data. We use only labeled data for supervised learning, and use both labeled and unlabeled data for semi-supervised setting. All these splits were stratified according to the class label and number of submissions, ensuring that a similar proportion of buggy/non-buggy programs were in each split. This is necessary, since splitting by students can create very biased distributions, especially when we only have small labeled training sets. The stratification uses thresholds for 1) the ratio of bugs and 2) averaged submission numbers for students in respective bug groups. We argue that in practice, we should be able to select a similarly representative sample by manually checking several submissions to see if the distribution is fundamentally different. To ensure we evaluate our model performance with fair comparisons, we created 10 different splits, generated randomly. All models use the same training/testing splits, and average performance metrics are reported as the results. For semi-supervised setting, we varied the size of labeled/unlabeled data to evaluate the performance of models. In order to perform fair comparisons, all semi-supervised models have the same labeled/unlabeled splits. Also, all models are tested on the same test sets, regardless of the model, the amount of training data, or supervised vs. semi-supervised. These settings ensured fair comparisons across different models.

3.3 Model Settings

SVM and XGBoost Parameters: We performed grid search on hyperparameters for SVM and XGBoost models using cross-validation on the training sets. In the SVM setting, we searched linear and Radial Basis Function (RBF) kernels, with C parameters in a range of (0.1 - 1), stepping by 0.1. In the XGBoost setting, we searched through situations that sub-sample portions from 0.1 to 1, stepping by 0.1, using 5 to 100 estimators in the model. To prepare numerical input, we used TF-IDF feature extraction on the code submissions for both models.

Code2vec and ASTNN Parameters: Since deep learning models are more time- and resource-consuming, and our cold start experiments required many repeated runs ($\sim$ 100 runs), we did not perform automatic grid search; rather, we used default settings of the hyper-parameters and did manual changes. In code2vec, after observing the training and validation loss, we set the maximum training epochs as 200, with the *patience* of early stopping set to 100, and set the learning rate to 0.0002. Linear layer and embedding dimensions were kept at the default value of 100. To ensure the highest efficiency of the model, we set the batch size as the full batch. These parameters are tuned with different numbers, but little change in validation accuracy is observed. We also manually padded the number of paths to 100 over all code submissions. In ASTNN, we padded the statement sequences to the maximum length to accommodate the longest sequence before feeding to Bi-GRU. During training, we used 32 as batch size, 0.001 as learning rate, and keep the max training epoch as 50. The encoding dimension for the statement encoder was 128, and hidden neurons for Bi-GRU were 100. The weights were learned during training using the Adam optimizer for code2vec and ASTNN models.

4. RESULTS

4.1 Bug Detection Model Performance

In this subsection we address RQ1: *How well do state-of-the-art deep learning models for programming codes perform in a student bug detection task?* Table 1 shows the results of the classifiers in the task of detecting bugs across problems. We use accuracy, Area-under-curve (AUC), Precision (P), Recall (R), and F1 score as the evaluation metrics for the

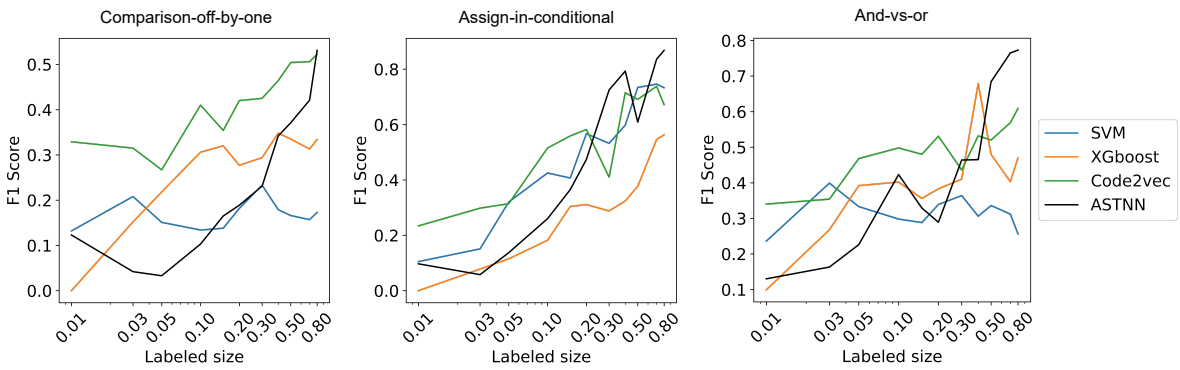

Figure 3: F1 score of models using supervised strategy with different portions of labeled data in detecting bugs.

detection. Across the three bugs for detection, we observe that the top-performing model (ASTNN) achieved 0.560, 0.868, 0.773 F1 scores on detecting `comparison-off-by-one`, `assign-in-conditional`, and `and-vs-or` respectively. The F1 scores indicate that the models achieved a higher performance on detecting `assign-in-conditional` compared to `comparison-off-by-one` and `and-vs-or`. In all bug detection tasks, ASTNN achieved the best F1 score on all bugs. On the two logical bugs, ASTNN achieved at least 0.226 higher F1 score than SVM and XGBoost, while Code2vec also achieved at least 0.139 higher, showing deep learning models are more preferable for detecting the two logic bugs across the six problems. On the detection of the `assign-in-conditional` bug, ASTNN achieved a high F1 score of 0.868, while a simple SVM model is able to achieve a 0.733 F1 score, which is not much lower than the ASTNN model. However, the recall of SVM is low (0.627), which indicates a limited capability of detecting the bugs out of submissions with bugs. Code2vec model did not achieve better F1 or AUC scores than SVM or ASTNN model in this case, showing that in the detection of syntax issues, paths features might be overly complicated. SVM might have a good performance when the real rule to learn is just "If it has `=` instead of `==` in the code, it has the bug," since there is little contextual information to learn. Generally speaking, when using all 80% labeled dataset ($\sim$ 1493 programs on average), deep learning models have a better performance than traditional machine learning models in detecting logical bugs, showing the advantage of leveraging structural information in the feature extraction step.

4.2 Bug Detection with Limited Labels

We address RQ2 in this subsection: *How are deep learning models' performance impacted by the amount of available training data?* From Figure 3, we see the F1 scores of the four models in supervised strategy using a subset of labeled data. The x-axis is the log-scaled labeled data size, and the y-axis is the F1 score that models achieved across the 10 different splits. The lowest portion of labeled data we use is 1%, which contains around 15 students, while the highest portion is 80%. The general trend of the supervised models shows that when more data is used, better F1 scores can be achieved by models, especially ASTNN. We also observe some interruptions in the increment of the performance as more data is available, meaning that it is not guaranteed that more data generate better models. For other baseline models, such a data-performance relationship is weaker, but still more data can generally produce better models.

While the models expect better performance given more data, we would like to note that among all supervised models, code2vec achieved better results than other models using a small subset of labeled data, showing a property of warm starting. With 10 percent of labeled data, code2vec has at least 7.5% higher F1 scores than any other models on all the three detected bugs. When more data is used, ASTNN outperforms other models, showing that there is generally at least one deep learning model more preferable than baseline models. When comparing code2vec with ASTNN, we find that deep learning models are not always "data-hungry": although both models are are sensitive to data size, code2vec starts higher than baseline models in classifying all three bugs. To achieve a good detection result, using 30%-40% (560-747) less labeled data would create models achieving 80% of the F1 score.

With these results we are able to conclude the answer for RQ2: For code2vec and ASTNN, more data would produce models with better performance. However, the relation is not linear: ASTNN is more "data-hungry" than code2vec, but these deep learning models do not require lots of data points to perform better than baselines.

4.3 Application of Semi-supervised learning

This subsection addresses RQ3: *To what extent does semi-supervised learning improve the performance of the deep learning models?* Figure 4 shows the semi-supervised learning results for all four models and the comparisons to supervised ASTNN and code2vec models. The labeled training data for each split is exactly the same as ones used in supervised settings. While the results give a mixed signal about whether semi-supervised learning is beneficial for all models, we have two observations. 1) semi-supervised learning enhanced the learning of *deep models*, especially ASTNN in all three bugs. Comparing the black lines, we found that solid lines are always higher than dashed ones. It suggests ASTNN, as a more "data-hungry model", is favored by the semi-supervised strategy more than in other models. Typically, an ASTNN model trained with a semi-supervised learning strategy achieves 0.05 to 0.2 higher F1 scores than

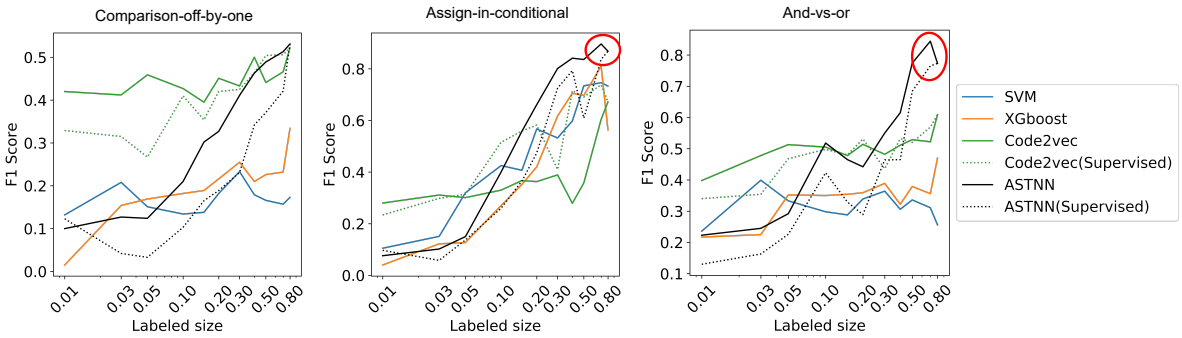

Figure 4: F1 score of models using semi-supervised strategy with different portions of labeled data in detecting bugs. Red circles noted places when semi-supervised strategy outperformed supervised training with full data.

those trained in supervised learning strategy, using the same training dataset. In code2vec, which is also a deep learning model, semi-supervised learning does not always help. It helps code2vec achieve better F1 scores when using a lower portion of data, but when given more data, a supervised learning strategy provides better performance. Semi-supervised learning does not help much for the other two classical models, compared with deep models. 2) In semi-supervised learning scenario, ASTNN achieved a better performance when using 70% labeled data than using all 80% as training in detecting two bugs, `assign-in-conditional` and `and-vs-or`, by 2.8% and 7.1% respectively (red-circled in Figure 4). While this may reflect the fluctuation of data performance, we did run the models 10 times. This suggests that the model may be harnessing the semi-supervised learning strategy to infer labels for unlabeled sets, and achieve more consistent labels than the authors, or some outliers present in the unlabeled set. We assume that the model then learned on these automatically inferred labels and achieved better results than learning from all expert labeled data.

Our conclusion for RQ3 is that semi-supervised learning often improves performance, especially when little training data is available. It enables the models to achieve an expected performance with less labeled data than the supervised scenario. Specifically, semi-supervised learning helped all cases in the learning of ASTNN models, and helped code2vec overall as well, especially when data size is low.

5. DISCUSSION CONCLUSION

Our results suggest three primary conclusions: **1) The two deep learning models generally outperformed baselines, and ASTNN had the best performance.** Our results from Subsection 4.1 show that deep learning models can detect simpler bugs, but still have a limited effectiveness on more complicated bugs (detailed in Subsection 3.1). The complexity of the `comparison-off-by-one` bug may be due to the difficulty of the labeling process, or its dependency on the problem context. **2) Deep learning models may still be successful when labeled data is limited**. From the results in Subsection 4.2, we learn that even if training with small data size such as < 100 data points in complicated programming data, the code2vec model is still able to outperform baseline models. **3) Semi-supervised learning has the potential to help deep learning models perform better.** Semi-supervised learning helped code2vec to achieve a higher performance, but only when a small number of data points are labeled. One may assume the difference between the two deep learning models come from the structures, but it may also come from the feature extraction process. Code2vec uses paths based features but ASTNN uses node based features, and recursively processed by neural networks.

Our results can have other potential applications in educational program analysis tasks as well. For example, as features are automatically extracted from student code during code2vec or ASTNN training, these features can be used to help instructor discover *new bugs*, as suggested by [33], which can help shape instruction. If more features such as problem requirements and test case inputs are available, we can apply these features to the model introduced by [30] to propagate instructor feedback to all students who would benefit form it.

This work also has a couple of caveats or limitations as of the current stage. 1) We only performed extensive experiments on three bugs and used them to generalize to conclusions. This is because the dataset labeling is time consuming, requiring the authors to label $\sim$ 1800 data points. The conclusions here may not generalize to other bugs or code classification tasks. 2) Similarly, these bugs also come from one programming assignment near the beginning of the course, focused on if conditions, and thus may be biased to this specific type of problem. 3) In the splitting process, we performed stratified sampling, requiring that test, labeled, and unlabeled data be a similar distribution of class labels and the number of attempts. 4) Since we only compared our models with two classical model baselines, there may be other better models existing for better performance. We used our best effort to select representative models that achieve state of the art performance, but there might be better models available for the task as well. This work's primary goal is to lay the foundation for using deep models in this task by exploring if the "data-hungry" property also applies here, and potential applications of semi-supervised learning. It serves as a step towards future model designs specific for automatic student bug detection, and provides guideline for situations when labeled data is limited.

ABSTRACT

The quality of exams drives test-taking behavior of examinees and is a proxy for the quality of teaching. As most university exams have strict time limits, and speededness is an important measure of the cognitive state of examinees, this might be used to assess the connection between exams' quality and examinees' performance. The practice of randomization within university exams enables the analysis of item position effects within individual exams as a measure of speededness, and as such it enables the creation of a measure of the quality of an exam. In this research, we use generalized linear mixed models to evaluate item position effects on response accuracy and response time in a large dataset of randomized exams from Utrecht University. We find that there is an effect of item position on response time for most exams, but the same is not true for response accuracy, which might be a starting point for identifying factors that influence speededness and can affect the mental state of examinees.

Keywords

exam quality, computerized testing, item response time, item position effect, speededness, speed-accuracy trade-off

1. INTRODUCTION

The quality of standardized high-stakes tests can be seen as a driver of test-taking behaviors and mental states of test takers. The structured format of these tests, with strict time limits and high consequences attached to the test result, lead test takers to a situation in which they feel more or less comfortable [19]. With the introduction and spread of computerized testing in high stakes tests, more data can be collected on high-stakes tests than in the past. These data can be used to monitor the quality of measurement instruments of individual items and exams as a whole. Among the collected data, an important source of information are response times. Response times can be used to gain more information on the test-taking behavior of the examinees [17, 1] and the functioning of the exam and exam questions. As a proxy for exam quality, higher education institutions commonly use reliability measures such as the Cronbach's alpha [5], although literature showed that this indicator, if speededness is present in the exam, might be underestimated leading to reliability concerns [2]. However, reliability is not the only measure of exam quality: test takers behavior, in particular speededness, might be relevant to lecturers and test creators. Thus, investigating the presence of speededness in a test is not only important to know whether the commonly used reliability measure can be trusted, but it can also be used to propose a new indicator of exam quality that takes into consideration the cognitive state of examinees, relating tests' quality and examinees' performance.

Traditional measures of speededness only take into account whether examinees provide responses to all exam questions and are not missing a large proportion of items at the end of the exam [13]. However, fully missing responses at the end of the test is not the only way in which speededness manifests itself [16]. An important way in which time pressure can be observed is the increase of speed and decrease of accuracy close to the end of the test [11]. This behavior can be operationalized as the effect of item position on response time and response accuracy. When exam items are administered to all students in the same order, as often is in the case of traditional high-stakes achievement tests, the effect of item position cannot be separated from the effect of item properties. However, since for test security reasons exams are now more often administered with a randomized item order, it becomes possible to study item position effects separately from item effects.

We have a large data set of computerized exams administered at Utrecht University between January 2015 and June 2020. Using these data, we want to study the overall effect of item position on response time and response accuracy. Furthermore, for each exam we want to quantify the effect of item position on test performance which can be used as an indicator of test quality and of the mental state of test takers. To answer these questions, we focus on three key points. First, we uncover that responses to later items in exams have an increased speed, in conformity with previous studies on anxiety and test strategies within high-stakes

tests [19, 8]. Second, we notice the lack of a relationship between item position and accuracy that, if analyzed in parallel with our first finding, might give us indirect evidence that increased response speed does not seem to have the expected negative effect on accuracy. This might show that successful test-taking strategies might include increased response speed towards the end of a test, as previous qualitative analyses already seem to show [18, 10], and that performance-reducing mental states do not appear to influence response speed.

1.1 Problem Statement

Currently, most tests used in European higher education institutions are non-adaptive computerized tests, that often have a large number of multiple-choice items, no penalty for incorrectly responded items and use a test-based time limit instead of a section-based time limit, as is usual in adaptive assessments. High-stakes non-adaptive computerized tests have not been researched and investigated as frequently as their adaptive counterparts and datasets on these tests are not widely available. Thanks to the advance of computerized testing within Dutch higher education institutions, we now have a multitude of data available that were not available before concerning high-stakes tests. Among these data, response times for each examinee on each item and the (randomized) item positions are saved. As test developers, when developing their tests, must find a balance between testing time requirements and difficulty and given that this balance depends on the type of the test and the needs of lecturers and students, we believe that exam-specific effects of item position on response time and response accuracy can provide them with useful information. Therefore, using the dataset at hand we set out to answer the following questions:

1. What is the effect of item position on response time and accuracy?
2. What can be inferred concerning test-taking behavior by analyzing the influence of item position on response time and accuracy?

1.2 Contribution

Answering our research questions, we make several contributions to the field: (1) using generalized liner mixed models that make use of item position in a dataset of university exams, we analyze the effect of item position on response time and accuracy; (2) we provide indications concerning the relation between examinees' response time and response accuracy within randomized high-stakes tests.

This paper is structured as follows: in section 2, we provide the background from which this work stems. Section 3, describes the data and the models used in the analysis. Section 4 continues comparing the results of the models fitted. Section 5 discusses the results of the models and provides the ground for the conclusion in section 6.

2. BACKGROUND

This research revolves around data collected at a higher educational institution concerning the results of tests administered using computers. The computerized collection of students' answers enables the creation of a dataset containing, among other data, the response time data of each student on each test item. We want to make use of this information to help us better understand response processes and, as a consequence, improve measurement instruments.

Interest in response time as a method of revealing information about mental activity has a long origin [15] and other research aims to be relatively comprehensive on the domain [6]. Here, we focus on the specific features on the approach relevant to our data and findings. Recently the role of response time modeling rose to a central position with novels works on the interplay between accuracy and response time [21, 9] and on item position [7]. Traditionally, two main effects of item position have been distinguished: a learning effect when items in later position become easier and a fatigue effect when items become instead more difficult [7]. In both cases, item position effects refer to the impact of the position of an item within an exam on the response time and on the response accuracy. Research commonly assumes that an increase in the speed of response will result in a decrease in accuracy [9]. This relationship, called speed-accuracy trade-off (SAT), is understood as a within-person phenomenon in which the accuracy of response varies with the time taken to produce it [11]. Our empirical findings provide some evidence that might enhance our understanding of the SAT and specify cases in which this relationship is more unclear than what previously thought.

On the other hand, the psychology and education literature has long been interested in developing test designs that generate fair results and thus studied examinees' test-taking behavior to investigate the effect of test designs. Among many domains, this literature also focuses on the effects of anxiety, motivation and test-taking strategies on performance when taking a test [19, 8, 3], finding that high achievers are more likely to engage in effective test-taking strategies compared to low achievers and identifying differences between genders in risk-taking behaviors and anxiety levels. Studies in this area identify risk-taking as an important strategy when taking a test, in particular in multiple-choice tests under strict limits [3]. These guessing strategies are found to potentially lead to better results regardless of ability level and compared to students at the same ability level not using these types of strategies [8]. Our empirical findings provide some evidence also in this aspect, not finding a negative relationship between speeded behavior and response accuracy.

3. METHODS

3.1 Data

We use data from Utrecht University that comprises all exams carried out using the online platform *Remindo Toets*[1] between 2015/01/01 and 2020/06/01. Given our goal of investigating the effect of item position, we select exams in which *response randomization* was applied (i.e., the position of the questions given to examinees changes from examinee to examinee). Therefore, the starting dataset of exams is filtered on the following conditions: (1) duration of the exam: less than 240 minutes. (2) Number of examinees: at least 100. (3) Number of items per examinee: at least 10. (4)

[1] *Remindo Toets* is a software product developed by Paragin, a Dutch education company, which provides educational institution with a platform to create, administer, review and grade exams.

Types of questions in the exam: "choice", "inline-choice", "order", "match". (5) Maximum response time: less than 600 seconds, to reduce outliers in the dataset. (6) Finally, we only analyze exams in which the item order is fully randomized. After filtering, the dataset contains 599.519 item responses. In the final dataset, tests are composed by an average of 204 students, 34 items and the average duration is of 106 minutes.

For each question, lecturers are provided with the so-called p-value, as a measure of "difficulty" of the item, and the estimates of commonly used metrics the item-test correlation (RIT) and the item-rest correlations (RIR) [20]. These variables are available along with item responses and response times. On the dataset at hand, the mean response time is of 91.18 seconds while the average accuracy rate is of 63.19%.

Due to privacy reasons, this dataset was anonymized. Because of this, we are only able to provide a general overview of the exams used in this analysis and not a complete overview of the underlying students population. The dataset at hand consists of 90 unique exams across 6 faculties within Utrecht University. In order, the largest faculties are Science, Veterinary Science and Social Sciences. Finally, as we selected courses with more than 100 examinees and due to the difference in the average class size between bachelor and master courses at Utrecht University, the wide majority of selected exam were from bachelor programs which are typically taught in Dutch. The predominance of the exam in Dutch (90%) indicates that the majority of students attending these courses courses are Dutch, implying that the results of these analyses might be culture-specific.

3.2 Selected variables

In the context of our analysis, we make use of the following variables:

- *Student*: factor variable identifying each individual student. Total number of factors: 18.476.
- *Test*: factor variable identifying each individual test. Total number of factors: 90.
- *Item*: factor variable identifying each individual item. Total number of factors: 5.089.
- *Response time*: continuous variable referring to the total time, in seconds, spent by an examinee on an item. The response time is the summed response time across all attempts made in answering that item. Clear extreme outliers in item were eliminated by setting a cutoff in the filtering process of the data.
- *Accuracy*: binary variable referring to a right or wrong answer by an examinee on an item.

Additionally, we create the following two variables: *item position* and *available time per item*. The first variable, *item position*, is used to identify the location in which the item appears within a test and it is divided within 10 blocks representing 10% of the exam. For each response of person i to item j in exam k, $z_{ijk} \in [0:9]$ denotes the block in which the item was presented to the person. We also create a set of dummy variables $z_{1ijk}, \ldots, z_{9ijk}$, where z_{sijk} if $z_{ijk} = s$, in order to model nonlinear relationship between item position and exam performance. The second variable, *available time per item*, is created dividing the total allotted time for a specific exam by the number of items in that exam. This variable is created as the exams available in the dataset are heterogeneous and do not have a common time limit. As we cannot compare exams having different time limits, we create a variable that represents the time limit at an item level. Across all exams, the *available time per item* has a mean allotted time of almost 3 minutes (177 seconds).

3.3 Models

Before discussing the results of our models, we make a brief note of the reason underlying their creation. A key necessity in our models is the ability to quantify the effect of item position on response time and on response accuracy. Therefore, to build models we turn to generalized linear mixed models (GLMMs). We choose GLMMs as we aim to develop models that create a reliable and easily repeatable analysis to increase the reach and applicability of the model results to datasets from other educational institutions.

In both models, to study the effects on response accuracy and response time, we consider three predictors. We allow for random variability across students incorporating this effect as random effect (θ_{1ik} for the effect on response accuracy, and θ_{2ik} for the effect on response time). We consider fixed item effects (β_{1jk} and β_{2jk} for the effects of item j from exam k on response accuracy and response time, respectively). Finally, for each of the item position dummy variables we consider fixed effects on response accuracy (γ_{1sk}) and on response time (γ_{2sk}), which are estimated for each exam separately. We include fixed item position effects only in the second variation of both models in order to enable us to evaluate whether their addition is significant.

3.4 Modeling response time

We construct the models concerning response time using the logarithm transformation of response time. For response time, we focus on the following linear mixed effect regression ($LMER$) models:

$$\begin{aligned} y_{ijk} &= \beta_{2jk} + \theta_{2ik} \\ \theta_{2ik} &\sim N(0, \sigma^2_{1k}) \end{aligned} \tag{1}$$

$$\begin{aligned} y_{ijk} &= \beta_{2jk} + \sum_{s=1}^{9} \gamma_{2sk} z_{sijk} + \theta_{2ik} \\ \theta_{2ik} &\sim N(0, \sigma^2_{2k}) \end{aligned} \tag{2}$$

wher y_{ijk} is the log-transformed response time of person i on item j in exam k, and σ_{2k} is the variance of the person random effect on response time in exam k. Model 1 does not contain the fixed effects of item position.

3.5 Modeling response accuracy

For response accuracy, we focus on the following generalized linear mixed effect regression on a binary variable (GLMER):

$$\begin{aligned} logit(x_{ijk}) &= \beta_{1jk} + \theta_{1ik} \\ \theta_{1ik} &\sim N(0, \sigma^2_{1k}) \end{aligned} \tag{3}$$

where x_{ijk} denotes response accuracy of person i on item j in exam k, and σ^2_{1k} is the variance of the random effect.

The model is extended with the effect of the item position dummy variables:

$$logit(x_{ijk}) = \beta_{1jk} + \sum_{s=1}^{9} \gamma_{1sk} z_{ijks} + \theta_{1ik} \qquad (4)$$
$$\theta_{1ik} \sim N(0, \sigma^2_{1k})$$

4. RESULTS

We first analyze the results of response time models from equation 1 and 2, before moving to the results of the response accuracy models from equation 3 and 4. Because of limitations due to the size of data at hand, in particular due to the number of fixed effects, all models are fit on each exam individually and their effects are shown as the gray lines in Figure 1 and Figure 2. After fitting each individual model, the item position effects estimates are pooled together with a random-effect meta-analysis in which we the exam-specific effects are assumed to come from a distribution with a common mean and variance [4]. The means of the effect and the ± 1.96 times the standard deviation of the effect boundary are shown as the blue and light blue lines in Figure 1 and Figure 2. The estimates of each of the item position effects of the pooled model of *LMER 2* and *GLMER 4* are given in Table 1 and Table 2 in the Appendix.

4.1 *LMER* on log response time

Concerning *LMER* models on response time, we see that across exams the ANOVAs between model 2 model 1 are significant in 79 out of the 90 cases. Respectively 72 exams at the .1% significance level, 5 at the 1% significance level and 2 at the 5% significance level. The average additional proportion of explained variance of model 2 on model 1 is 0.0084.

Analyzing response time behavior and the effect of item position, we observe a significant negative effect of item position on response time. In particular, we observe an increase in the effect over the course of the exam, which is typically defined as response acceleration. This can be seen in Figure 1 as each item position relates to the effect size compared to the baseline of item position 0, which represents the first 10% of the exam. The blue line represents the pooled estimates of the item position effects across all exams, while the gray lines represent individual exams.

4.2 *GLMER* on response accuracy

With respect to *GLMER* models on response accuracy, we see that model 4 does not significantly outperform model 4. The ANOVAs between model 4 and model 3 are only significant 5 times at the 1% significance level and 11 at the 5% significance level. This shows that the response acceleration found previously and shown in Figure 1 either is not strong enough to influence response accuracy or does not have any influence on it. Hypothesis on the reason underlying this finding are discussed in section 5.

4.3 Proportion of explained variance and available time per item

After running a likelihood-ratio test on each exam individually, we select model 2 as significantly better than model 1 while we further investigated the additional proportion of explained variance of model 2 regressing it on the *available time per item* for each exam. Figure 3 shows that there is a relationship between the available time per item in an exam and the additional explained variance from the model with item position effects (linear correlation $-.37$). This is an indicator that on exams that have less time available, response acceleration is indeed happening and the inclusion of a variable to take into account the position of the item help us explain better the behavior of students. However, as it is visible in Figure 3, the additional explained variance of model 2 is relatively low. This result is important as it provides us with a tool to support the results of response acceleration.

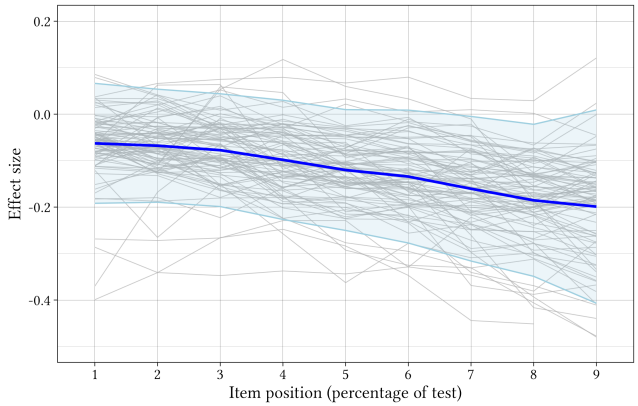

Figure 1: Item position effects on response time

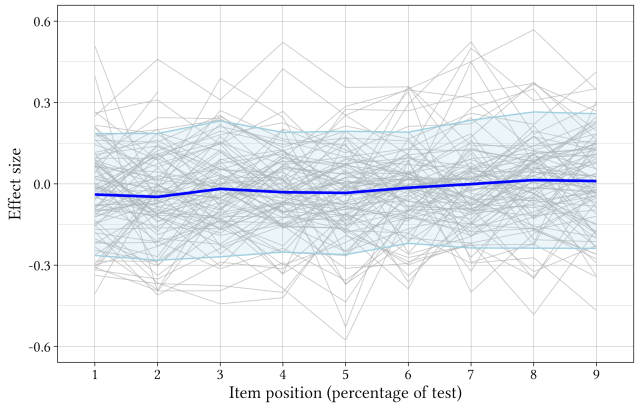

Figure 2: Item position effects on accuracy

5. DISCUSSION

5.1 Discussion of findings

Using a collection of item responses and response times from higher education tests during a five-years time span, we analyze the relationship between item position and response time and between item position and response accuracy. We show that item position is associated with response acceleration while we find that the connection between item position and response accuracy is unclear. Finally, we also find that the available time per item is negatively correlated with the additional explained variance when comparing the model relating item position and response time.

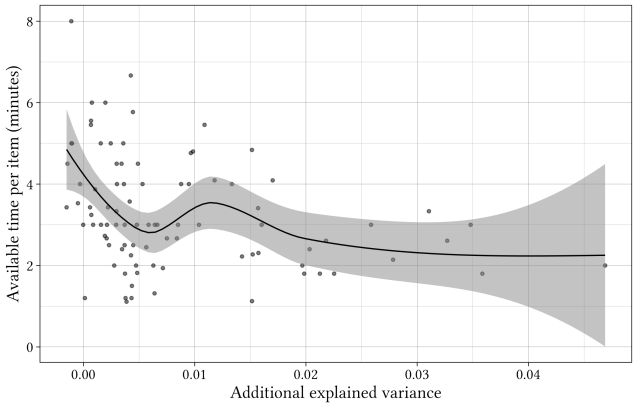

Figure 3: Regression between mean duration of item and additional explained variance for model 2

Concerning the significant effect between item position and response times, we see that the effect is not as strong as we initially expected. The presence of this effect might stem from increased respondents' fatigue or decreased interested in the exam, as highlighted by previous work on this topic [22, 9]. However, previous literature focuses on adaptive tests in which items becomes more or less hard in relation to respondent's performance, while in our dataset this is not the case. Comparing the differences between these two modalities of testing and understanding the difference in the response behavior might be an attractive opportunity for future research.

With regards to the interaction between response accuracy and item position, literature tends to show that later items are more difficult [14, 22] and therefore might decrease the rate of correct responses. We find no significant relationship between response accuracy and item position. The lack of this relationship might be explained by a few hypotheses. First, we might hypothesize that the response acceleration shown is the representation of students reaching their natural speed on the exam. Students might take some time to enter in the mental state that allows them to take an exam and they might be initially slowed down by the need of understanding how the exam is structured. This might explain the increased acceleration of response at the same level of accuracy between earlier and later item in the test. Secondly, we might hypothesize that there is an negative effect of response acceleration on response accuracy, but it is not shown because of the relatively heterogeneous dataset of exams at hand and because of the need of accessing more data. Concerning the second hypothesis, more work on a larger dataset of similar exams is needed before drawing any conclusion. Finally, the lack of this relationship might also be explained by the presence of increased response speed within effective test-taking strategies among high achievers, as found by previous qualitative literature on this topic [18, 12]. This result might be caused by an increased willingness to guess using effective elimination processes, leading to an effective guessing strategy on high-stakes multiple choice tests, when compared to the choice of picking an answer option at random.

Finally, we demonstrate that there is a relationship between the additional explained variance and the available time per item. When the model with item position effects is significantly more informative than the model without these effects, this correlation might also provide backing to a potential quality indicator to be provided to lecturers and test creators to inform them about their tests. In the presence of high additional explained variance, an indicator that would take this relationship into account might be used to provide lecturers with information about the quality of their tests and to identify exam-specific factors that influence speededness and the test-taking strategies of examinees.

5.2 Limitations

When carrying out the modeling part of our research, due to the size of data and factors at hand, we realized that the current statistical methods available to analyze this quantity of data create computational problems. As a matter of fact, we were interested in analyzing the effect of item position on response time and accuracy across the entire dataset but, due to computational limitations, we decided to fit the models on individual exams and later pool the effects estimates using a meta-analysis. To avoid this obstacle, two parallel path might be taken: (1) extending the current statistical libraries to include the possibility of using sparse matrices in computing fixed effects estimates and (2) adding more computational power to the tools used in the analysis.

Further, we also need to take into consideration both the dataset used in this research and the filtering actions taken on it. First, the dataset stems from a higher education institution (*wetenschappelijk onderwijs*) and therefore the results of our analyses might be dependent on the educational level of the students' population. Secondly, because of the filtering actions carried out on the dataset (2), we can assume that Dutch students are more represented in the dataset than international students. This might imply that the results stemming from our analyses are highly dependent on the Dutch test-taking "culture".

An important distinction between our work and previous studies on speededness, such as [9], is that we attempted to remove the effects of very long answers, but not of answers given during *rapid guessing behavior* [15]. As a matter of fact, the validity of test scores of such tests are threatened by what [23] call *noneffort*, which is associated with the guessing behavior of an examinee who does not try to solve items. The effect of such mechanism is an underestimation of his or her actual level of proficiency, threatening the validity of test score by adding a source of construct-irrelevant variance [23]. An analysis about the presence and the methods to identify *noneffort* in this dataset might reveal pathways to either take it into account or eliminate it from the dataset, paving the way for an analysis that compares the estimates of ability accounting only for *truthful* response acceleration.

5.3 Future research

Expanding dataset. As noted in section 5.2, we believe expanding the dataset at hand, including most recent data, and including other universities, would help providing more information on the relationship between response time and accuracy and thus the creation of more accurate indicators for lecturers. Moreover, as there might be differences in

the "culture" of examination between countries and between educational levels, a larger dataset comprising of multiple countries and different educational levels might help clarifying these questions.

Creating a metric to provide recommendations. As we did not see a clear effect of item position on accuracy, a future path for research might assume that, in the presence of similar results, students are given too few items for the time allotted on a specific exam. This would open a path for creating experiments to increase the total number of items on an exam and analyze the cutoff value at which effects on accuracy start appearing. An experiment increasing the number of test items would not only clarify the values at which effects appear, but would also improve domain coverage for that specific exam and, improving its reliability metric, and would allow us to study changes in test-taking strategies within the test.

6. CONCLUSION

This research evaluates methods to investigate the effects of item position on response time and accuracy. We find that, thanks to the advancement in the technologies used in exam settings and the wide application of these technologies in high-stakes tests, these analyses are not only feasible but are also promising if applied on larger datasets. We believe the overall results of the models can be of use within the educational sector, in particular thanks to the creation of an additional and reliable indicator of the quality of an exam. Using the results presented in section 4, we can now answer our research questions:

1. We find a small but significant effect of item position on response time, while we fail to find any effect of item position on accuracy. Section 5 provides a discussion on the findings.

2. We believe our results stemming from modeling item position and response time and the subsequent regression of the additional explained variance of this model and the available time per item, could evolve into a practical indicator providing more information concerning the quality of a test and the test-taking behavior of students.

Grouping Source Code by Solution Approaches — Improving Feedback in Programming Courses

Frank Höppner
Ostfalia University of Applied Sciences
f.hoeppner@ostfalia.de

ABSTRACT

Various similarity measures for source code have been proposed, many rely on edit- or tree-distance. To support a lecturer in quickly assessing live or online exercises with respect to *approaches taken by the students*, we compare source code on a more abstract, semantic level. Even if novice student's solutions follow the same idea, their code length may vary considerably – which greatly misleads edit and tree distance approaches. We propose an alternative similarity measure based on *variable usage paths* (VUP), that is, we use the way how variables are used in the code to elaborate code similarity. The final stage of the measure involves a matching of variables in functions based on how the variable is used by the instructions. A preliminary evaluation on real data is presented.

Keywords

source code distance, semantic analysis, variable usage paths

1. INTRODUCTION

Learning a programming language requires a lot of practice. Students gain knowledge and experience from both, homework and in-classroom exercises. It is, however, very important to give students feedback, e.g. discuss different solution approaches with them. Both, those who have and have not yet succeeded, will benefit from such discussions, either it widens their view (because they may not have thought about alternative approaches yet) or encourages them to try the exercise at a later point in time once more (once they got a glimpse on how to solve it). The sharing of different solution approaches and discussing the pros and cons of different approaches improves their algorithmic thinking skills. However, it is quite common in many programming courses, that the only (automatic) feedback consists of the number of passed or failed unit tests. Achieving a positive feedback then requires an already well developed solution and no credit is given for, say, getting the code structure right – which may frustrate novices noticeably.

Frank Höppner "Grouping Source Code by Solution Approaches — Improving Feedback in Programming Courses". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 461-467. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

We thus address the following research question: Can we support the lecturer in providing meaningful feedback about the solution approaches taken by the students? This requires automation as a lecturer does not have the time to review all solutions manually, especially not in online teaching situation. Providing meaningful feedback requires some kind of insight in the solution approach a particular student was following (semantics), how common the approach is, how many different approaches have been followed in the course, etc. We intend to achieve this by providing a similarity measure for source code that does not focus on results (as unit tests do) but to reach a higher semantic level by assessing the more abstract code structure: different solution approaches manifest themselves in different code structures.

Such a measure would be useful in many ways. For instance, during an in-classroom teaching situation it would enable the lecturer to pick two (or more) submissions following different approaches to start a discussion about their pros and cons. It could also support a lecturer in browsing the spectrum of approaches that were followed by the course members (how many different approaches were chosen how often) without having to check every solution manually. It may enable the lecturer to pick a solution that follows the same approach as a solution that has been discussed already, but did not pass all unit tests, thereby representing a live challenge to the course members ("spot the error"). Note that we are not aiming at grading the source with respect to its correctness, but leave this to the unit tests. As tests do not provide any useful feedback to students that do not yet have an appropriate code structure, the desired measure may close this gap, as it would allow us to differentiate code submissions that are far from working from those that follow a reasonable solution approach and got the code structure right, but only the tiny details prevents them from passing the tests. Such a more detailed inspection would enable a much more sensitive (automatic) feedback.

2. RELATED WORK

Similarity or distance measures for source code have been investigated for a long time. Many approaches have in common that they start from an abstract syntax tree (AST) that represents the code. Code is then compared by calculating some kind of *tree distance* on the corresponding ASTs: the minimal number of steps (node deletion, insertion, and relabelling) to transform one AST to the other. A survey on tree edit distance can be found in [2]. A tree, however, has no conscience about *variable identity*: the very same vari-

able occurs over and over again as a new node in an AST. To reflect which variable change affects other code, program dependency graphs (PDG) may be used. But comparing graphs is even more complicated than comparing trees, a survey on graph edit distance is given in [6]. To simplify the comparison, the AST may also be linearized such that much simpler string comparison measure (edit distance) may be applied (cf. [5, 7, 9]).

An extremly fast approach is to define a hash function on (possibly pre-processed trees) such that a similarity is detected when hash codes are identical [1]. The flexibility of such an approach is, however, very limited, as the similiarity measure is a binary one. It may nevertheless be useful for clone detection (plagiarism) or may be enhanced by calculating multiple hashes [4]. Tree edit distance has been used in, e.g., [10] to detect similar source codes. In [3] a distance measure for source code has been proposed, that transforms the AST into a sequence of tokens on which Levenshtein or edit distance is applied.

In many related papers the goal is to compare (student's) code to a (lecturer's) reference code; the higher the similarity, the closer is the student's submission to the correct solution. In this work, however, we want to identify source codes that are semantically similar, that is, they follow the same solution approach. Especially when novices start to code, their solutions are often more lengthy and redundant than those of an experienced programmer. This affects measures such as edit distance or tree distance dramatically. The approach in [3] did not work out as well as expected, and the authors hypothesized about one of the reasons that the length of the code dramatically influences the edit distance. While longer code may be less readable and more redundant, it is neither more likely wrong nor does it necessarily follow a different solution approach. As an example, consider codes (a) and (b) from Fig. 1. The task was to calculate the mean of all positive array elements. Both codes follow the same approach, but (b) uses a single loop instead of two and is thus more compact. But semantically, we consider both solutions as being identical. We are not aware of any source code similarity measure that tries to reflect that.

It is also common in the literature to replace variable names by a constant string (possibly depending on the variable's type), which eases matching sources that use different variable names. In plagiarism detection (see [5, 9] and references therein) this is considered as a countermeasure against disguising plagiarism by variable renaming. However, the way a single variable is used throughout the code is crucial for a solution approach. Fig. 1(d) utilizes the same statements (e.g., array-access in conditional statement of a for-loop), but does not calculate anything meaningful and thus does not represent the same solution approach as codes (a-c).

3. COMPARING SOURCE CODE BY VARIABLE USAGE PATHS

We argue that two solutions follow the same approach if they use variables in the same way. In the subsequent sections we show how we grasp variable usage in the code and then define similarity measures on this representation.

```
public double avg(double a[]) {
  if (a==null) return NaN;
  int n = 0;
  for (int j=0;j<a.length;++j) {
    if (a[j]>0) ++n;
  }
  double sum = 0;
  for (int j=0;j<a.length;++j) {
    if (a[j]>0) sum+=a[j];
  }
  return sum/n;
} // (a) [TwoLoopQuickExit]
```

```
public double avg(double a[]) {
  if (a==null) return NaN;
  int n = 0;
  double sum = 0;
  for (int i=0;i<a.length;++i) {
    if (a[i]>0) {
      ++n;
      sum+=a[i];
    }
  }
  return sum/n;
} // (b) [OneLoopQuickExit]
```

```
public double avg(double a[]) {
 if (a!=null) {
   int n = 0;
   double sum = 0;
   for (int i=0;i<a.length;++i) {
     if (a[i]>0) {
       ++n;
       sum+=a[i];
   } }
   return sum/n;
 } else {
   return NaN;
} } // (c) [OneLoopGuardedIf]
```

```
public double avg(double a[]) {
  if (a==null)
    return NaN;
  int n = 0;
  double sum = 0;
  for (int i=0;i<a.length;++n) {
    if (a[i]>0) {
      ++i;
      a[i]+=sum;
    }
  }
  return sum;
} // (d) [Disordered]
```

Figure 1: Responses to a simple programming exercise: Write a function avg that yields the mean of all positive values in the array. Left: Code (a) uses two loops, while code (b) only one. While the main code is organized *after* an if-statement in (a) and (b), it is embedded in the conditional statement in (c). Code (d) uses similar instructions, but the variable usage is screwed up and does not solve the problem.

3.1 Variable Usage Paths

Solving a programming exercise requires to combine programming instructions such that a handful of variables jointly build up the final result (and return it to the caller). The key to a solution are thus the variables and how they are embedded in the (possibly nested) instructions. Code analysis often starts with an abstract syntax tree (AST); there, every variable usage is represented by a new node in the tree. This occludes important information: Where in the source code is the same variable used? We therefore rearrange the AST to a graph, where a node is unique for each variable and subsequent usages of the variable link to the same node. Fig. 2 shows an example for the code of Fig. 1(b). All variables are marked in red color. From the paths between the variable `sum` and function `avg`, we can see that the variable `sum` is declared, occurs in a conditional statement that is embedded in a loop, and finally occurs in the return value. We consider these paths (shown in blue in Fig. 2) as a kind of *fingerprint* for the role of this variable: code following the same approach requires variables with the same roles.

We thus do not operate directly on the graph, but paths from variable nodes to the enclosing function node. After applying some transformations to simplify the graph somewhat (e.g. removing *body* or replacing *for*, *while*, etc. by a subsuming label *loop*), we end up with string representations of the three blue paths like *sum/expression/return/avg*, *sum/dec-*

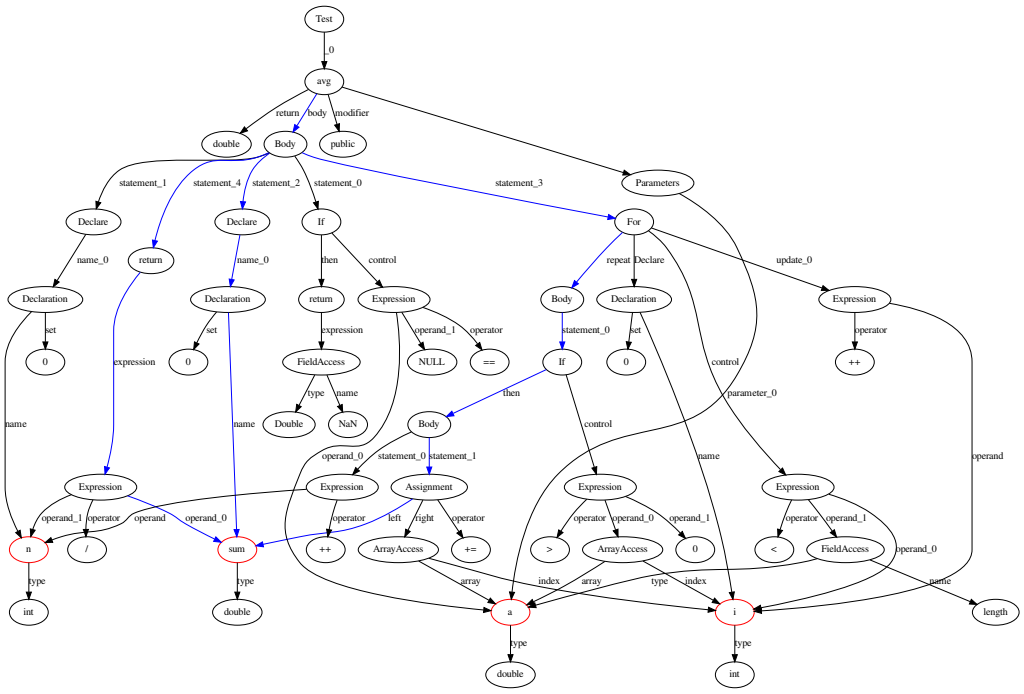

Figure 2: Graph representation of code in Fig. 1(b) (red: variable nodes; blue: VUPs of variable 'sum').

laration/declare/avg and *sum/assignment/if/loop/avg*.

Definition 1. Let I be a set of code instruction labels (such as *if*, *loop*, ...). For a given source code C (single class), let V_C be a set of variable-identifiers[1] and F_C the set of methods declared in C. A **path** $p = (v, i_1, \ldots, i_n, f) \in V_C \times I^* \times F_C := \mathcal{P}$ reflects that a variable v is used by instruction i_1, which is itself used by instruction i_2, etc., in function f. The **VUP-representation** (variable usage path) of code C is a set $P_C \subseteq \mathcal{P}$ of all paths occurring in C.

We thus intentionally drop many details from the original source code, e.g. numerical constants or full expressions. From the fact that two codes that are structurally identical (same VUP representation) we cannot conclude anything about the number of unit tests both codes may pass. But as we have mentioned earlier, we seek for a common code skeleton, which may indicate that the programmers were guided by the same underlying idea. The skeleton includes the information which variables need to be used in which instructions — but there are many different ways of coding expressions equivalently, so we simply stick with unit tests to check their correctness.

3.2 Simplified Set Similarity

Given two source codes (a) and (b) from Fig. 1 and the corresponding VUP-representations P, Q. Code (a) determines the number of elements first before it sums the relevant values, while code (b) does both in a single loop. While the choice of one or two loops may affect the efficiency, they are semantically equivalent and thus *similar*. At first glance the variable usage paths (of, say, the loop counter) in all loops seem identical such that a set comparison (where duplicate elements are not counted) appears just right. However, the loop counter is named `j` in code (a) and `i` in code (b). Furthermore, (a) defines two variables with the same name `j` (one for each loop). Let us ignore these details by introducing a simplification (and revisit the problem later):

Definition 2. From a VUP representation P we obtain a **SVUP representation** (simplified VUP) representation P' by replacing all variable identifiers and all method identifiers by a constant identifier `vn` (generic variable name) and `fn` (generic function name), resp. ($I = \{vn\}$, $F = \{fn\}$).

Standard methods to measure set similarity may then be used to compare source code. For given SVUPs P and Q we use the F_1 measure[2]:

$$F_1 = 2 \cdot \frac{p \cdot r}{p + r} \quad \text{where} \quad p = \frac{|P \cap Q|}{|P|},\ r = \frac{|P \cap Q|}{|Q|}$$

Fig. 3 shows a dendrogram for an average-linkage clustering using this measure (actually $1 - F_1$ to obtain a distance measure). Codes (a)-(d) correspond to TwoLoopQuickExit, OneLoopQuickExit, OneLoopGuardedIf and Disordered. Additional examples include: Nonsense (similar set of instruction

[1]Note the variable names themselves are not valid identifiers, as the same variable name may occur more than once in the same function, e.g. variable j in code (a) of Fig. 1.

[2]although based on asymmetric precision p and recall r, F_1 itself is symmetric and thus a similarity measure

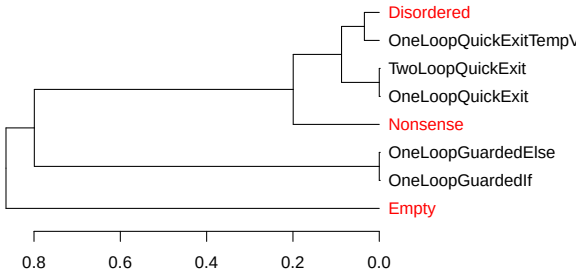

Figure 3: Dendrogram for source codes of Fig. 1 based on F_1-measure on VUP representation.

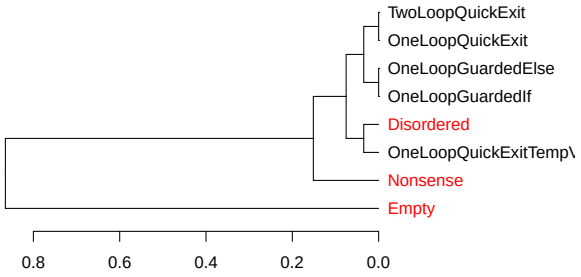

Figure 4: Dendrogram for source codes of Fig. 1 based on F_1-measure on SVUP representation.

Table 1: Example of comparing P and Q (see text).

			d	m(d)
P	1	vn/expr/if/loop/fn	if	(1,6), (2,7)
	2	vn/assign/if/loop/fn	assign	(3,8)
	3	vn/declare/fn	declare	(4,8)
	4	vn/assign/fn		
	5	vn/return/fn		
Q	6	vn/expr/loop/fn	step	un- / assigned
	7	vn/assign/loop/fn	0	1,2,3,4,6,7,8 / 5,9
	8	vn/assign/declare/fn	1	3,4,8 / 1,2,5,6,7,9
	9	vn/return/fn	2	4 / 1,2,3,5,6,7,8,9

set but variables are mixed randomly), OneLoopQuickExitTempVar (the mean value is assigned to a temporal variable before it is returned) and OneLoopGuardedElse (same as OneLoopGuardedIf (Fig. 1(c)) but inverted if-condition). From the dendrogram we learn that codes TwoLoopQuickExit and OneLoopQuickExit become identical as desired. But we can also see that code OneLoopGuardedIf, where a conditional statement encloses the main code, is recognized as very dissimilar. The additional *if*-statement occurs in *all* paths and the simple Jaccard similarity finds this code to be completely different. We address this problem next.

3.3 Reflecting Instruction Embedding

A single conditional statement may introduce an new element in many paths turning them all different (as in codes (a),(c) in Fig. 1). For compensation we could measure a partial similarity between paths (e.g., 80% of path p is contained in q), but a *single instruction* (such as the conditional statement in (c)) would then still weaken *all path similarities*. We therefore propose a different approach in the fashion of edit distance, where we pay a constant cost for a missing path element, which may then be used in many paths.

Given two SVUP representations P, Q, we compare all paths $p \in P, q \in Q$ to identify missing path elements $\delta(p,q) \in I^*$. (For example, δ(*vn/loop/if/fn*,*vn/loop/fn*)=*if*). Many different path combinations may lead to the same $\delta(p,q)$, so by $m(d)$ we denote the set of all pairs $(p,q) \in P \times Q$ with $\delta(p,q) = d$. The matching of paths in P to paths in Q is done iteratively: In the first iteration, we match all paths from P and Q that are identical ($\delta(p,q) = ()$). To match the SVUP representations at minimal cost, in subsequent iterations we identify the missing path element d that unifies the largest number of paths (that is, choose $d = \text{argmax}_x|d(x)|$). Before entering the next iteration, all pairs are removed from $m(\cdot)$ that have been assigned already. We reflect the cost of adding a missing path element by adding it as a *virtual path* to the SVUP P or Q (depending on where it was missing).

Table 1 shows a detailed example. The table on the left shows the paths belonging to SWUP of P and Q. All paths have been numbered for easier reference. The initial map $m(\cdot)$ is shown on the top right; for instance, the path element *if* unifies path #1 of P with #6 of Q, as well as #2 of P with #7 of Q. At the bottom right each line corresponds to an iteration of the matching process. In step 0, paths #5 and #9 are already identical. In the second iteration the path element *if* is chosen from map $m(\cdot)$, because it unifies 2 paths (all others only one). We have thus matched 6 paths in total (step 1 of bottom right table), and only #3, #4, #8 remain unassigned (gray). The map $d(\cdot)$ now offers two alternatives (*assign* and *declare*, both $|m(\cdot)| = 1$), we arbitrarily choose *assign* as the second missing path element for the third iteration. This leaves only path #4 unassigned. The choice of $m(declare)$ has covered paths #4 and #8, so we remove all pairs from $m(\cdot)$ containing any of these (already covered) paths. This ends the matching phase (all $|m(\cdot)| = 0$). We had to add the first missing path element *if* to paths in Q; likewise we had to add the second path element *assign* to P to match #3 against #8. As a penalty for the missing path elements we add them to the respective SVUP, that is, P becomes $\{1,2,3,4,5,assign\}$ and $Q = \{6,7,8,9,if\}$. Taking the established identity of paths into account, this gives us an F_1 value of

$$p = \frac{|P \cap Q|}{|P|} = \frac{4}{6},\ r = \frac{|P \cap Q|}{|Q|} = \frac{4}{5},\ \text{so } F_1 = 2 \cdot \frac{16/30}{44/30} = \frac{8}{11}.$$

Fig. 4 shows the resulting dendrogram. Now OneLoopGuardedIf (Fig. 1(c)) became much more similar to One/TwoLoopQuickExit (Fig. 1(a-b)). But we are still dissatisfied with the high similarities towards Disordered: it uses the same set of embedded instructions (causing the high similarity), but the variable usage is mixed up. The instructions may look identical, but the author did not get the role of variables right and that should degrade the similarity.

3.4 Matching Variables

So we finally revisit the simplification of definition 2. We have hypothesized that similar solution approaches use variables at specific places in the code skeleton. Up to now, we have mixed the usage paths of different variables in the SVUP representation. This will be sorted out next.

Definition 3. Let $\pi_{(v,f)} : \mathcal{P} \to \mathcal{P}, P \mapsto \{p \,|\, p = (v, i_1, \ldots, i_n, f) \in P\}$ be a filtering function that returns only those paths that refer to variable identifier v and function identifier f. From a VUP representation P with a set V of variable identifiers and F of function identifiers, we obtain a **GVUP representation** (grouped VUP) $P' = \{\pi_{(v,f)}(P) \,|\, v \in V, f \in F\}$. That is, a GVUP is a set of VUPs, one VUP set for each variable in each function.

For instance, the code in Fig. 1(b) consists of 4 variables in one function, so the GVUP representation is a set of four VUP representations (one set for each variable). Now, as the GVUP representations P and Q of two source codes are sets of sets, how do we generalize the F_1 calculation? Consider the following example, where we use abbreviated instructions $I = \{a, b, c\}$:

$$P = \{\{x/a/c/f, x/b/c/f\}, \{y/a/f, y/c/f\}, \{z/b/f\}\},$$
$$Q = \{\{x/a/f, x/c/f\}, \{y/b/f\}\}$$

Formally, a direct calculation of $|P \cap Q|$ yields 0 as none of the sets in P is contained in Q. But this does not meet our intention. Note that variable y in P plays the role of x in Q (same for z in P and y in Q). Variables may be renamed without changing the semantics, in fact $|P \cap Q|$ should be 2. The desired semantics is to match variable and function names appropriately, rename them accordingly and calculate the F_1 measure on the obtained $\bigcup_{X \in P} X$ and $\bigcup_{Y \in Q} Y$.

How do we match the sets $X \in P$ against $Y \in Q$? All paths in X or Y refer to the same variable and function name, so we can safely transform the VUP to a SVUP representation and use the measure from section 3.3 to construct a pairwise cost matrix. We employ the Munkres algorithm [8] to find the optimal assignment based on this cost matrix. As the Munkres algorithm performs a 1:1 least-cost assignment, some variables may not get assigned. We match them afterwards in a second pass to the least costly counterpart. (This allows us to match multiple identifiers in one program to the same variable in another, as required when comparing codes (a) and (b) of Fig. 1.)

As an example, for the abovementioned P and Q we would create a cost matrix of all pairwise F_1-values (P-paths in rows, Q-paths in columns):

$$\begin{pmatrix} 0.67 & 0.50 \\ \mathbf{1.00} & 0.50 \\ 0.50 & \mathbf{1.00} \end{pmatrix}$$

The Munkres algorithm optimally assign two of the P-paths to two of the Q-paths (bold face). The third P-path is then associated with the first Q-path, which matches best according to the higher F_1-value. We have thus assigned the variables x and y of P to variable x in Q and may think of renaming all these variables in both codes to, say, u. In the same fashion we may rename the variables of the second assignment to v; reunifying all SVUPs leads us to:

$$P' = \{\ u/a/c/f, u/b/c/f, u/a/f, u/c/f,\ v/b/f\},$$
$$Q' = \{\ u/a/f, u/c/f,\ v/b/f\}$$

The final similarity is obtained by applying the calculations of Sect. 3.3 to both sets P' and Q' (this time with different variable names rather than just generic variable names vn). Although the example did not include different function names, it works in the same way. Fig. 5 shows the resulting dendrogram. As desired, the similarity of code Disordered (Fig. 1(d)) is now worst among all solutions that follow the same solution approach.

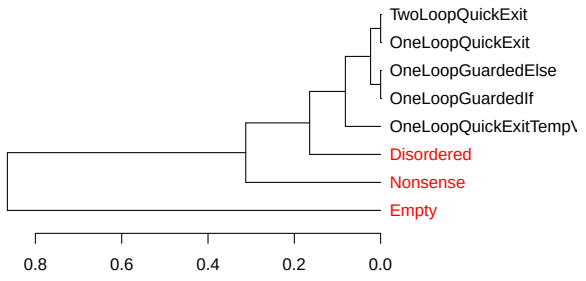

Figure 5: Dendrogram for source codes of Fig. 1 based on F_1-measure on GVUP representation.

4. EXPERIMENTAL EVALUATION

We started to evaluate the proposed approach on real student code submissions and demonstrate its performance on some examples. The submissions were inspected manually and grouped by approach (defining ground truth). While the author of an exercise may have a specific solution in mind, a group of students usually finds multiple ways to solve the exercise. The real data contains nearly identical submissions (potential plagiarism) as well as submissions that appear somewhat chaotic, have superfluous declarations and calculations, or contain artefacts indicating a change in the solution approach over time. Most codes can nevertheless be assigned to solution approaches, but the strong variation in novice's code length misleads edit- and tree-distance such that resulting dendrograms do not match the approaches.

We show results for two exercises, the first exercise asks for the most frequently occurring element in an integer array. To inspire the students to elaborate on different solutions, an additional restriction was given that all values v in the array satisfy $0 \leq v < 10000$. The two main solution approaches were: (1) iterate over all elements in an outer loop, count the frequency of the current element in an inner loop, remember the element that occurs most often; (2) instantiate an array of size 10000 (associating a counter with each possible element in the original array), increment the respective counter while looping over the array and identify the largest entry in the counter array. Apart from these two dominating solutions, three solutions (3) sorted the array first, such that identical values are grouped together, which simplifies frequency counting in a single loop over the array.[3] Finally, (4) there are some exotic solutions which may be considered as a mixture of the discussed solutions. Possibly students became aware of the other approaches by discussing approaches among each others, but had difficulties in solving the task and switched back and forth between them. Usually, elements of all other solutions can be found in them. Fig. 6 shows average-linkage hierarchical clustering

[3]However, when this exercise was handed out, sorting algorithms were not yet discussed (so this solution required background knowledge or a student's own initiative).

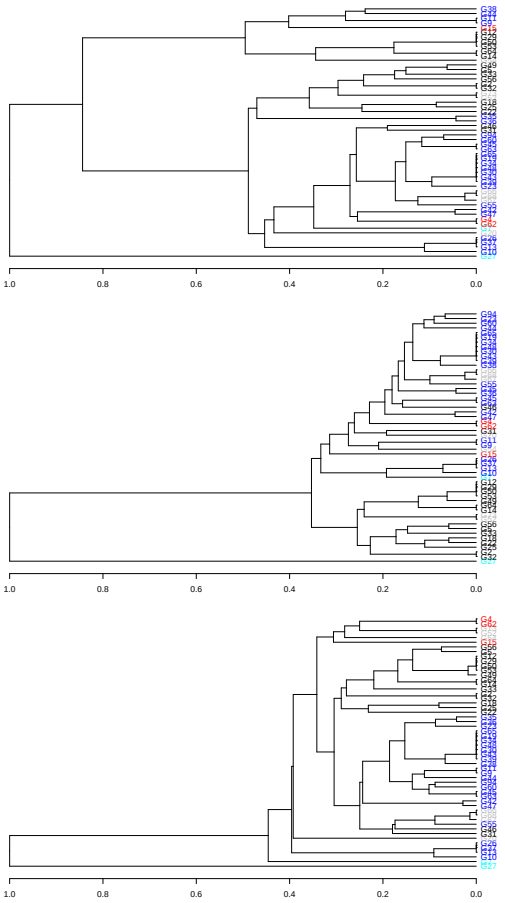

Figure 6: Dendrogram for exercise 'most frequent element' based on F_1-measure (measure from Sect. 3.2, 3.3, and 3.4 from top to bottom).

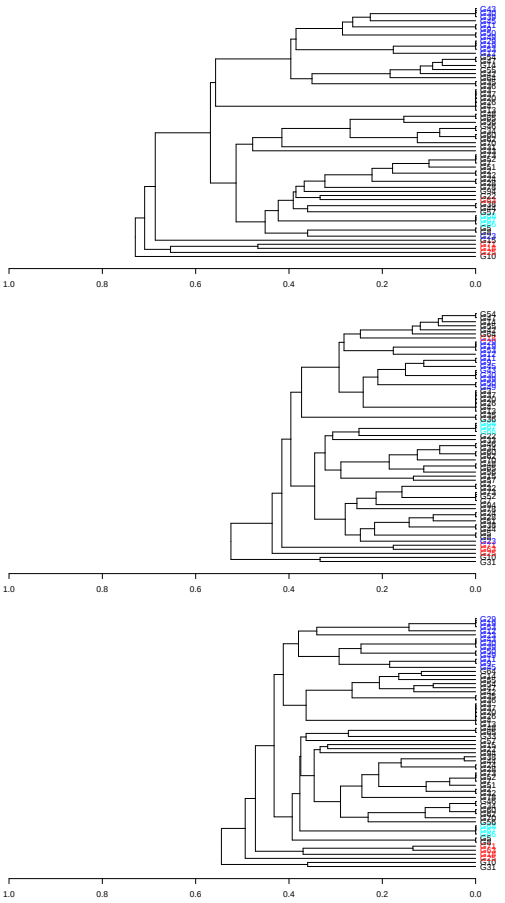

Figure 7: Dendrogram for exercise 'happy number' based on F_1-measure (measure from Sect. 3.2, 3.3, and 3.4 from top to bottom).

results for the similarities from Sect. 3.2, 3.3, and 3.4 from top to bottom. The ground truth is shown by means of the node colors: 1: black, 2: blue, 3: red, 4: gray, incomplete / unfinished: cyan. While the clusters in the top clustering mixes even the two large approaches (1) and (2), the clustering in the middle is much better but does not separate solution (3). This is only achieved by the GVUP-clustering (bottom), which corresponds best to the ground truth. The bubblesort used in (3) uses very similar loops as the main task, so it was crucial to distinguish the role of variables as done in the GVUP-approach.

A second exercise deals with the identification of *happy numbers*[4]. The calculations require the sum of squares of each digit and the submissions differ mainly in the way how this is solved. The intended solution (black) was a loop that successively splits the last digit (using integer division and modulo). Another popular solution is based on string-conversion (blue), a few (somewhat restricted) approaches (red) dealt with different numbers of digits individually (avoiding a loop). Again, the average-linkage clustering for all three proposals is shown in Fig. 7 and the GVUP-approach separates them best. The modulo-approaches (black) subdivide into two major branches, which differ in the way intermediate variables are used. Approaches that use the same kind of utility variables (e.g. to store digits, square of a digit, etc.) are closer matches than approaches that use different sets of utility variables.

[4]`https://en.wikipedia.org/wiki/Happy_number`

5. CONCLUSIONS

Assessing the variety in student's solutions to a programming exercises without having to inspect all codes manually can help a lecturer in many ways. We have proposed a measure that captures how variables and instructions are coupled by means of *variable usage paths*, and use this *fingerprint* to match code from different solutions while at the same time being tolerant to code repetitions. The approach needs to be evaluated further, but the first results appear promising. The nature of the comparison is set-based, which allows us not only to assess similarity (using F_1), but also to use recall and precision. This enables further applications, for instance, we may assess *partial solutions* by the degree how many elements of a *complete solution* they contain (using recall only) or assess the student's degree of programming maturity by investigating the amount of superfluous statements (using precision only).

ABSTRACT

Bayesian Knowledge Tracing, a model used for cognitive mastery estimation, has been a hallmark of adaptive learning research and an integral component of deployed intelligent tutoring systems (ITS). In this paper, we provide a brief history of knowledge tracing model research and introduce pyBKT, an accessible and computationally efficient library of model extensions from the literature. The library provides data generation, fitting, prediction, and cross-validation routines, as well as a simple to use data helper interface to ingest typical tutor log dataset formats. We evaluate the runtime with various dataset sizes and compare to past implementations. Additionally, we conduct sanity checks of the model using experiments with simulated data to evaluate the accuracy of its EM parameter learning and use real-world data to validate its predictions, comparing pyBKT's supported model variants with results from the papers in which they were originally introduced. The library is open source and open license for the purpose of making knowledge tracing more accessible to communities of research and practice and to facilitate progress in the field through easier replication of past approaches.

Keywords

Bayesian Knowledge Tracing; Intelligent Tutoring Systems; Educational Software; Python Library

1. INTRODUCTION

Knowledge Tracing [6] has been a well researched approach to estimating students' cognitive mastery in the context of computer tutoring systems [23]. Tutoring systems take a problem-solving, or active approach to learning [2, 1] that often resembles the personalized mastery learning approach researched by Bloom [4]. The model was not originally described using a particular statistical framework; however, the mathematical expressions in the original work are consistent with Bayes Theorem [26], and the canonical model was subsequently coined Bayesian Knowledge Tracing (BKT).

Anirudhan Badrinath, Frederic Wang and Zach Pardos "pyBKT: An Accessible Python Library of Bayesian Knowledge Tracing Models". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 468-474. https://educationaldatamining.org/edm2021/

In spite of its growing popularity in the research community, accessible and easy to use implementations of the model and its many variants from the literature have remained elusive. In this paper, we introduce pyBKT[1], a modernized Python-based library, making BKT models and respective adaptive learning research more accessible to the community. The library's interface and underlying data representations are expressive enough to replicate past BKT variants and allow for new models to be proposed. The library is designed with data helpers and model definition functions, allowing for convenient replication and comparison to BKT model variants and subsequently better scientific progression and evaluation of new state-of-the-art knowledge tracing approaches.

The Bayesian Knowledge Tracing model can be described as a Hidden Markov Model (HMM) with observable nodes representing students' known binary problem response sequences obs_t and hidden nodes representing students' latent knowledge state at a particular time step t. Using expectation maximization, pyBKT fits the learn (transmission parameter), and guess, and slip (emission) parameters from historical response logs, with the parameters defined below.

$$\text{prior} = P(L_0)$$

$$\text{learn} = P(T) = P(L_{t+1} = 1 | L_t = 0)$$

$$\text{guess} = P(G) = P(obs_t = 1 | L_t = 0)$$

$$\text{slip} = P(S) = P(obs_t = 0 | L_t = 1)$$

Note that while $P(L_0)$ denotes the prior parameter, we also define $P(L_t)$ as the probability that the student has mastered the skill at time step t. Bayesian Knowledge Tracing updates $P(L_t)$ given an observed correct or incorrect response to calculate the posterior with:

$$P(L_t | obs_t = 1) = \frac{P(L_t)(1 - P(S))}{P(L_t)(1 - P(S)) + (1 - P(L_t))P(G)}$$

$$P(L_t | obs_t = 0) = \frac{P(L_t)P(S)}{P(L_t)P(S) + (1 - P(L_t))(1 - P(G))}$$

The updated prior for the following time step, which incorporates the probability of learning from immediate feedback and any other instructional support, is defined by:

$$P(L_{t+1}) = P(L_t | obs_t) + (1 - P(L_t | obs_t))P(T)$$

The standard BKT model assumes no forgetting:

$$P(F) = P(L_{t+1} = 0 | L_t = 1) = 0$$

2. RELATED WORK

Since the introduction of the standard BKT model by Corbett and Anderson [6], many variants of BKT have been proposed which multiplex, or condition the four parameters of prior, learn, guess, and slip on different factors such as question type or student. KT-IDEM (Item Difficulty Effect) [20] captured item performance variance within skill by allowing different guess and slip values to be fit per item. Baker et al. [3] proposed a hybrid model using regression to help determine if a student's response was a guess or a slip based on context.

Other modifications focused on conditioning the learn rate and prior knowledge parameter [19]. Yudelson et al. [30] explored student-level parameter individualization, finding that the learn rate provided better predictive performance than prior when individualized to each student. Learn rate has also been conditioned based on the item [17], educational resource (e.g., a video in an online course) [21], or type of instructional intervention seen by the student at each opportunity [13] or order in which items or resources were seen [18]. The assumption of no forgetting was relaxed in Qiu et al. [25], finding that response correctness decreased based on time elapsed since the last response. This decrease was better modeled in BKT with conditional forget rates than with increased slip rates. González-Brenes et al. [9] created a hybrid BKT model that factored in a variety of features, including response time. An overview of other variations of BKT and logistic approaches to learner response prediction can be found in Pelánek [23].

Neural network approaches to knowledge tracing have gained in momentum since the introduction of Deep Knowledge Tracing (DKT; [24]). Some have explored the reasons for DKT's apparent accuracy improvement as compared to BKT and have attributed its success to its high dimensional hidden space and ability to observe interleaved skills in a single model [14]. However, most papers using neural approaches compare only to the standard BKT model proposed in the 1990s and not to the more modern variants. A noteworthy result of caution was reported in Khajah et al. [11], in which it was found that simply enabling the forget parameter of standard BKT led to performance on par with DKT on several datasets.

There has been a brief history of BKT implementation frameworks. Several BKT variants have used Kevin Murphy's Bayes Net Toolbox (BNT) for MATLAB [15], with a subsequent wrapper for that toolbox releases catering to knowledge tracing [5]. Yudelson et al. [30] produced a C++ implementation[2] of BKT with a command line interface that included support for individualized parameters. Finally, Xu et al. [29] created a C++ implementation of BKT with a MATLAB interface and support for parallelization and conditioning of all parameters based on both problems and passive resources (e.g., a learning rate for a video).

3. PYBKT LIBRARY DETAILS

The pyBKT library builds off of xBKT developed by Xu et al. [29] and is released under an MIT license. The library is compatible with all platforms (Linux, Windows, Mac OS), primarily utilizing NumPy [28] for computation. It is available on the Python PyPi repository, with installation accomplished through a pip one-liner: `pip install pyBKT`. To increase performance, we additionally supply routines which utilize C++ libraries and Eigen/LAPACK, which is an optimized linear algebra package with OpenMP support. This accelerated version requires a C++ compiler and is currently only tested on Linux and macOS.

We created a Scikit-learn style [22] Model class abstraction and accompanying data helpers that further facilitate the accessibility and expressive power of pyBKT. With one-line fit, predict, evaluate, parameter initialization, and cross-validate methods, pyBKT offers ease of use in ingesting response data and applying BKT models and supported variants. We explore the interface to these methods in the next subsection. We then detail the internal data structures, computations, and motivations behind the development of the two implementations of pyBKT, in pure Python and the accelerated C++/Python, along with runtime evaluation.

3.1 Interface

pyBKT's interface is modeled after Scikit-learn's accessible frontend interface for machine learning models [22]. The ease-of-use in the pyBKT Model class abstraction allows for increasingly expressive BKT code without the usability sacrifices of past BKT libraries. We aim for the library to be easy to learn for beginners while still useful for experienced users conducting knowledge tracing research. Further, it provides a gateway into exploring multiple model extensions from the literature, which have been shown to be capable competitors to DKT [11] and able to address inequities in unmodeled differences in learning and prior ability between students [7]. Supported BKT extensions include: KT-IDEM [20], KT-PPS (Prior Per Student) [19], BKT+Forget [11], Item Order Effect [18] and Item Learning Effect [17, 21]. These model extensions are referred to as `multigs`, `multiprior`, `forgets`, `multipair`, and `multilearn`, respectively, in the model interface.

The Model class abstraction supports creating, fitting, predicting, cross-validating and evaluating BKT models using any combination of supported extensions. Additional features include specifying model parameter initialization before fitting, custom cross-validation fold assignment, and multiple accuracy and error metrics - including support for generic user-defined or Scikit-learn imported metrics. Common dataset formats are made easier to ingest through automatic detection of familiar column headers seen in Cognitive Tutor [12] and ASSISTments datasets [10]. Defaults for all customizable parameters such as random seed, parallelization, model variants, and evaluation metric(s) are provided when they are not specified.

We demonstrate a few of the library's basic capabilities in parameter initialization, fitting, and parameter output in the below code snippet using the learned parameters of the "Polynomial Factors" skill from the 2009-2010 ASSISTments dataset[3]. Note that all parameters of all skills found in the dataset are fit unless otherwise specified.

[2] https://github.com/myudelson/hmm-scalable

[3] `https://sites.google.com/site/assistmentsdata/home/assistment-2009-2010-data`

```
>>> from pyBKT.models import Model
>>> model = Model()
>>> model.fit(data_path = 'assistments.csv')
>>> model.params().loc[('Polynomial Factors')]
param   class      value
prior   default  0.17452
learns  default  0.13378
guesses default  0.25502
# ...
```

The internal data helper functionality converts any response-per-row comma or tab separated file into the internal pyBKT data format. It is designed to convert input columns using default column mappings for skill name, student identifiers, correctness, etc. automatically for Cognitive Tutor/ASSISTments data and configurable with one line for any other dataset. It provides increased flexibility to the user, allowing for consistency across fit and predict/evaluate phases.

The included evaluation metrics are root-mean squared error (RMSE), accuracy with a threshold of 0.5, and area under the ROC curve (AUC). Custom metrics in the format of two-parameter Python functions are supported for evaluation and cross-validation, such as the regression or classification metrics from `sklearn.metrics` or `keras.metrics`.

The cross-validate function provides a one-line interface for fitting and evaluating any combination of model variants with one or more error metrics. For the following example, we specify a particular column to use for the multilearn (answer type) along with a multigs model trained on the default template ID for ASSISTments. A skill or combination of skills can be specified along with the seed and number of folds (optional).

```
>>> model = Model(seed = 42, parallel = True)
>>> model.crossvalidate(data_path = 'assistments.csv',
      skills = ['Circle Graph', 'Box and Whisker'],
      multigs = True, multilearn = 'answer_type', metric =
      ['auc', sklearn.metrics.mean_absolute_error])
skill                mean_absolute_error      auc
Circle Graph                     0.41565 0.72782
Box and Whisker                  0.33906 0.67991
```

3.2 Internal Implementation Details

The pure Python and C++/Python implementations of pyBKT both make use of optimized programmatic methods, efficient internal data and model representation, multithreaded model fitting, and optimized linear algebra libraries. The model fitting consists of a typical Expectation Maximization (EM) function for a Hidden Markov Model performing forward and backward passes over the sequential data to continuously update BKT parameters. We implement these passes using a parallelized iterative dynamic programming approach on the input data.

3.2.1 Model Representation

In the context of model variants with multiple learn, guess, slip, or forget rates, a subscript $P(T_i)$, $P(G_i)$, $P(S_i)$, $P(F_i)$ denotes the corresponding probability, or rate, for class $i = 1...m$, respectively.

Initial and fit BKT model parameters are represented using a Python dictionary. Inside of this dictionary, we store A, which is a collection of matrices with each 2x2 matrix corresponding to the learning and forgetting probabilities for each learn class in order to aid in efficient matrix multiplication during fitting. A has the format where m is the total number of learn rates:

$$\left[\begin{bmatrix} P(\neg T_1) & P(F_1) \\ P(T_1) & P(\neg F_1) \end{bmatrix}, \cdots, \begin{bmatrix} P(\neg T_m) & P(F_m) \\ P(T_m) & P(\neg F_m) \end{bmatrix}\right]$$

We define α as a set of 2-length vectors each corresponding to $[P(\neg L_t), P(L_t)]$ for all time steps for a specific student. Similarly, π_0 stores information about the prior, in the format of $P(\neg L_0), P(L_0)$.

3.2.2 EM and BKT Algorithm

We use Expectation Maximization to fit model parameters, shown to provide desirable convergence properties, given plausible initial parameter values [16]. Inside the EM and inference algorithms, we use several intermediate data structures and vectorization to improve computational efficiency in fitting the models. To calculate $\alpha[t+1]$ given $\alpha[t]$, we multiply it by the part of the learn/forget transition matrix A corresponding to the learn class of time step t. We element-wise multiply by the vector likelihoods which consists of $[P(G), P(\neg S)]$ or $[P(\neg G), P(S)]$ for the corresponding guess class of time step t, depending on whether the student answers correctly or not, respectively. Finally, normalizing this vector results in $\alpha[t+1]$. We demonstrate the algorithm for an example iteration of the BKT algorithm with learn class 1, guess class 1, and an incorrect response observed ($obs = 0$) at time step t.

$$\begin{bmatrix} P(\neg L_{t+1}) \\ P(L_{t+1}) \end{bmatrix} = \begin{bmatrix} P(\neg T_1) & P(F_1) \\ P(T_1) & P(\neg F_1) \end{bmatrix} \left(\begin{bmatrix} P(\neg L_t) \\ P(L_t) \end{bmatrix} \circ \begin{bmatrix} P(\neg G_1) \\ P(S_1) \end{bmatrix} \right)$$

$$= \begin{bmatrix} P(\neg T_1) * P(\neg L_t | obs_t) + P(F_1) * P(L_t | obs_t) \\ P(T_1) * P(\neg L_t | obs_t) + P(\neg F_1) * P(L_t | obs_t) \end{bmatrix}$$

At the end of this α calculation, we perform the E-step of the EM algorithm by recursively calculating an expectation γ for each time step by backtracking through the learned latent states. We can then take the global average of the expectations of the learn/forget transition matrices, guess/slip vectors, and priors during the M-step and use these as the parameters for the next iteration of EM. In terms of the number of students S and the typical sequence length for each student T, the model fitting algorithm's asymptotic time complexity for standard BKT is $\Theta(TS)$.

3.2.3 C++/Python Implementation Details

We use a C++ extension to perform the EM iterative updates and matrix multiplication for the model fit and prediction process. This allows us to use efficient linear algebra libraries in C++[4] and benefit from greater support for multithreading through OpenMP.

We use Eigen to perform the matrix operations. There are many technical advantages of using Eigen with a linear al-

[4]Boost was previously used as a connector between Python and the C++ extension, but it has been deprecated since pyBKT 1.2.2, resulting in a 3-5x performance increase.

gebra heavy model such as pyBKT. Eigen provides efficient, thread-safe matrices and arrays, while being a relatively portable package distributed along with pyBKT. It allows for lazy evaluation, expression templates and compiler optimizations.

We use OpenMP for parallelizing the demanding model fitting process. OpenMP is a universally accepted multithreading library for C/C++ that exploits multicore processors with low overhead. With a shared memory space for forked threads, OpenMP avoids overhead for inter-process communication (IPC) unlike Python's multiprocessing. With Eigen's explicit support for OpenMP-based multithreading, heavy matrix operations and iterative processes are further optimized in pyBKT.

3.2.4 *Pure Python Implementation Details*

We wish to maintain the accessibility of pyBKT across all platforms while maintaining as much efficiency as possible. To do this, a pure Python implementation, without C++ extensions, is included. This implementation provides quick access to any user, including on Windows, wishing to run a BKT model without the hassles of compilation and complex dependencies. We relax this version of the library's requirements to include mostly native modules along with the widely supported NumPy.

NumPy is used for the matrix operations in the pure Python build of pyBKT as it is the most efficient and widely used numeric computational library in Python. Technically, it provides impressive single-threaded performance. Similarly to other optimized mathematical libraries such as Eigen, NumPy employs code vectorization, efficient memory mapping techniques for sparse matrices, and compiler optimizations.

Since NumPy is primarily a single-threaded application with little support for multicore scaling, we use Python's native multiprocessing library for parallelizing the model fitting. It provides native CPython support for multicore scaling to bypass the Global Interpreter Lock (GIL), which allows only one running thread of execution within a process. Although different Python implementations (i.e JPython) exist to disable the GIL or remove the memory overhead, we use a native module for simplicity and speed.

3.3 Runtime Evaluation

We compare the runtime performance of the pure Python and C++/Python implementations of pyBKT on five typical model fitting and prediction tasks. We present two sets of tasks, fitting and prediction on synthetic data, that additionally showcases the way in which the runtimes scale with the size of input data for both implementations of pyBKT. Each of the tasks are averaged over several runs for both implementations of pyBKT on a machine with 2 x Intel(R) Xeon(R) CPU E5-2620 v3 CPUs at 2.4Ghz with 256GB of system RAM. The results are shown in Table 1.

We evaluate the runtimes using two metrics. The scaling factor is defined as the ratio of the runtime of the larger input and the smaller input for a set of prediction or fitting tasks. The speedup is defined as the ratio of the runtime of our C++/Python implementation to our pure Python implementation.

The first four tasks perform synthetic data generation for 500 students and 5,000 students respectively with a sequence length fixed at 100 followed by prediction or fitting. These tasks illustrate a typical medium and large workload for model fitting and prediction tasks. The generated synthetic data is fit or predicted using a standard BKT model. It is clear that as the number of students scales, the pure Python implementation of pyBKT performs and scales more poorly with the number of students. The C++/Python implementation shows a nearly 150-600x speedup for fitting and 15-30x speedup for prediction as compared to the pure Python version. In comparison to its predecessor xBKT (MATLAB), the C++/Python version of pyBKT gains a 3-4x speedup across all fitting and prediction tasks. In Xu et al. [29], it is noted that xBKT outperforms BNT by 10,000x, which suggests a 30,000-40,000x speedup of pyBKT as compared to BNT.

The final task performs a cross-validated prediction task for a selected skill in the Cognitive Tutor dataset. We use a variety of models (standard, multigs, multiprior) to test predictive accuracy and measure its runtime. This task is around 65x slower in the pure Python implementation.

While the runtimes and the overall scaling of the pure Python port with respect to the size of input data are significantly poorer for each task, that is an expected trade-off with regards to accessibility and portability. For an end-user that is training and testing moderately-sized BKT models or evaluating models, they would benefit from a portable and universal BKT model which can handle a moderate input size with relative efficiency. For heavier research-oriented or production-oriented tasks, the C++/Python implementation is recommended since it generally performs much more efficiently.

4. DATA SUFFICIENCY ANALYSIS

We examine the data sufficiency requirements of the standard BKT model by exploring trade-offs between input size and parameter error and mastery estimation accuracy. We define the input size as the magnitude of the number of students and the average sequence length. Through the first analysis, practitioners may gain an intuition for the minimum cohort size and minimum number of questions answered per student per skill to effectively apply BKT. Our second analysis in this section focuses on mastery estimation accuracy, also using synthetic data. This analysis depicts how the worst-case expected mastery estimation accuracy decreases as a function of sequence length for a given set of prior, guess, and slip parameters.

For the following analyses, we generate synthetic data, both responses and mastery states, from pyBKT using ground truth parameter values set to common values seen for Algebra skills[5]. In doing so, we are able to calculate the error of the fit parameters and accuracy of the mastery estimation.

[5]prior=0.08, guess=0.15, slip=0.05, forget=0 and learn=0.3 for the first analysis and variable for the second

Table 1: Comparison of runtimes, scale factor and speedup between Python and C++/Python implementations of pyBKT.

Test Description	Pure Python		C++/Python		Speedup
	Runtime	Scaling	Runtime	Scaling	
Synthetic Data Generation, Model Fit (500 students)	160.12s		1.07s		149.64x
Synthetic Data Generation, Model Fit (5,000 students)	1,596.30s	9.97x	2.62s	2.45x	609.27x
Synthetic Data Generation, Model Predict (500 students)	8.02s		0.50s		16.04x
Synthetic Data Generation, Model Predict (5,000 students)	67.08s	8.36x	2.42s	4.84x	27.71x
Cross-validation, Cognitive Tutor	320.28s	-	4.79s	-	66.86x

4.1 Synthetic Model Fit Accuracy

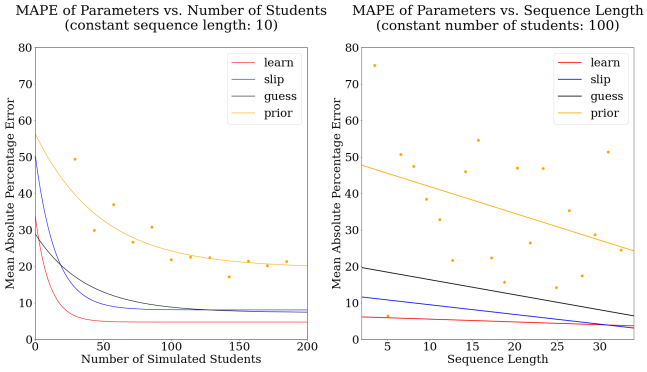
The synthetic generation of data is performed for input sizes from 10 to 200 students for all sequence lengths from 2 to 35. While 200 is not an uncommon number of students to have in a cohort, more than 30 responses to a single skill would be unusual for a student. Each combination of input size is averaged over five fits, each of which includes the best model over 20 random EM fit initializations.

The error of the model's fit parameters are analyzed using the mean absolute percentage error (MAPE) in relation to predefined ground truth generating parameters. We plot the fitting error of the learn, slip, guess, and prior parameters as a function of the number of synthesized students (Figure 1, left) and length of synthesized response sequences for each student (Figure 1, right). While all data points cannot be visualized on a single plot, we show the data points for the prior parameter as an example.

For all parameters, there is a clear negative and exponential error decay with respect to the number of students. This is consistent with an expected asymptotic behaviour when increasing the number of students in the fitting procedure. Learn and slip parameters asymptote at around 50 students while guess and prior do so after 100, given a sequence length of 10.

There seems to be a slowly decreasing linear relationship between the typical sequence length and parameter fit error, with the prior parameter showing the greatest improvement in MAPE. These analyses show that there is not nearly as much benefit to fitting error by increasing the sequence length (i.e., giving students more problems) as there is by increasing the number of students.

Figure 1: Mean absolute percentage error (MAPE) of fit parameters as a function of number of students (left) and sequence length (right).



4.2 Synthetic Mastery Estimation Accuracy

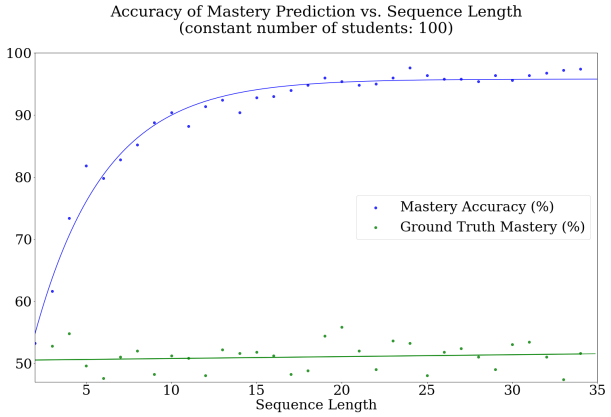
We look to evaluate the worst-case accuracy of the standard BKT model's mastery estimation, its most common task within a computer tutoring system, using a mastery threshold of $P(L_t) \geq 0.95$ on simulated problem solving sequences. We use the same predetermined ground truth BKT parameters and data generation methodology as in the previous subsection with the exception of the learn rate, which is set dynamically in this analysis.

It is known that the probability of mastery will converge to $1 - forgets$ in a finite number of time steps given a learn rate > 0 [27]. This means that cognitive mastery estimation accuracy will increase with respect to sequence length, as student mastery state becomes more homogeneous.

In order to model the worst-case mastery estimation of the model, we find the learn rate that will produce an average probability of mastery close to 0.5 across students at the final time step τ for all our chosen sequence lengths, thus preventing a trivial estimation of a majority mastery state. We find the learn rate via grid search with a granularity of 0.001 since this cannot be solved analytically [27].

The mastery estimation accuracy exponentially decays upward with respect to sequence length with a Pearson correlation $R_{\log(acc)} = 0.73$ as shown in Figure 2. The mastery estimation accuracy in our analysis can be observed to asymptote around a sequence length of 15. This suggests that the worst-case mastery estimation accuracy scenario can be mitigated, given our chosen predefined parameter values, with an average response sequence length per skill of 15 or greater.

Figure 2: Worst-case accuracy of mastery estimation as a function of sequence length for the standard BKT model.



5. EVALUATION OF PYBKT MODELS

To gauge the validity of the BKT models and extensions supported by pyBKT, we perform predictive model evaluations replicating those found in prior literature. Models were evaluated by performing five-fold cross-validation on the ASSISTments 2009-2010 Skill Builder dataset, the Cognitive Tutor 2006-2007 Bridge to Algebra dataset[6], and specialized datasets from Feng et al. [8] and Piech et al. [24] in order to validate more specific model extensions. While there are slight differences between our results and the results of other papers, we believe this is due to our random parameter initialization and small differences in fitting methods. Our complete model evaluations, data, and results are located in a pyBKT examples repository[7].

5.1 Standard BKT and BKT+Forget

In general, the predictive accuracy of the models generated by pyBKT are in line with what others have observed from BKT. For instance, in Khajah et al. [11], they found that by fitting the basic BKT model on the train/test split provided by Piech et al. [24] from the 2009-2010 ASSISTments dataset for each skill, they obtained an AUC of 0.73, whereas pyBKT predicts with an AUC of 0.76. Similarly, when Khajah et al. [11] added the forgets parameter into their model, they achieved an AUC of 0.83, exactly the same AUC we achieve using pyBKT.

5.2 KT-IDEM

When using the KT-IDEM model on the ASSISTments 2009-2010 Skill Builder dataset, pyBKT achieves an average AUC increase of 0.01932, which is very close to the 0.021 average increase reported in Pardos and Heffernan [20]. While the exact subset of data was not exactly specified in that paper, we used the ten skills with the most responses, using different template ids as the guess/slip classes as prescribed in [20]. Since the ASSISTments data has a very high average response to template ratio ($\sim$1,000), the KT-IDEM model performs very well compared to the standard BKT model using RMSE as the metric of comparison, being lower or equal in nine of the ten skills selected.

5.3 KT-PPS

The Prior Per Student model was applied to the ASSISTments' Groups of Learning Opportunities dataset [8] consisting of 42 problem sets. In Pardos and Heffernan [19], it was found that the KT-PPS model performed better than the standard BKT model on 30 out of the 42 problems sets, as evaluated on the predictions of the last response of each student's response sequence. This was achieved using a variant of KT-PPS that models a high and low prior and assigns students to the high prior if they answer correctly on the first problem of the problem set, and to the low prior otherwise. The high prior was set to an ad-hoc value of 0.90 and the low prior to 0.15 in that work.

The pyBKT replication of this model is done without true multiple prior modeling. Instead, when the multiprior option is set to True, $P(L_0)$ is set to 0 and a dummy time step is created at the beginning of the sequence. Three learn rates are created, the first corresponding to the high prior, the second to the low prior, and the third corresponding to the standard $P(T)$ applied between all subsequent time steps. The initial values of these virtual priors were set to the ad-hoc values from [19]; however, since pyBKT does not support parameter fixing as of this writing, these parameters were learnable. With these settings, pyBKT's KT-PPS performs better than standard BKT on 27 out of 42 of the problem sets. The small difference in prediction accuracy of this model may be attributable to the difference in the algorithm regarding fixed parameters, but the similarity in performance is promising.

[7] `https://github.com/CAHLR/pyBKT-examples`

5.4 Item Order and Item Learning Effect

Results from the Item Order Effect [18] and Item Learning Effect [17] papers were not focused on response prediction improvement. In fact, no prediction accuracy results were provided. Instead, the purpose of the models was to compare the learn rates of classes to flag effective and ineffective items and orders. The examples repo of pyBKT depicts such differences. Nevertheless, a modest 0.01 RMSE improvement for both model variants was obtained compared to the standard BKT model.

6. CONCLUSIONS

We demonstrated pyBKT as a seamlessly installable, efficient, and portable Python library with model extensions such as KT-IDEM, KT-PPS, BKT+Forgets, Item Order Effect and Item Learning Effect. The Model class abstraction in pyBKT provides an expressive way to interact with the BKT model extensions with ease, with one-line methods to create, initialize, fit, predict, evaluate, and cross-validate any combination of BKT model extensions. We measured the runtime of pyBKT to be nearly 3x-4x faster than its predecessor, xBKT, and nearly 30,000x faster than BNT, a standard BKT implementation. Through the analyses presented, we established 50 as a reasonable number of students to achieve convergence to canonical parameter values with any average student sequence length and 15 as a reasonable sequence length to mitigate worst-case mastery estimation accuracy. Lastly, through real-world dataset analyses, we showed the validity of the model implementation through its agreement with past results using established software.

Acknowledgments

We recognize Matthew J. Johnson, who co-developed xBKT, the predecessor to pyBKT, and Cristian Garay, who developed the initial Python and Boost adaptation of xBKT.

On the Limitations of Human-Computer Agreement in Automated Essay Scoring

Afrizal Doewes, Mykola Pechenizkiy
Eindhoven University of Technology
{a.doewes, m.pechenizkiy}@tue.nl

ABSTRACT

Scoring essays is generally an exhausting and time-consuming task for teachers. Automated Essay Scoring (AES) facilitates the scoring process to be faster and more consistent. The most logical way to assess the performance of an automated scorer is by measuring the score agreement with the human raters. However, we provide empirical evidence that a well-performing essay scorer from the quantitative evaluation point of view are still too risky to be deployed. We propose several input scenarios to evaluate the reliability and the validity of the system, such as off-topic essays, gibberish, and paraphrased answers. We demonstrate that automated scoring models with high human-computer agreement fail to perform well on two out of three test scenarios. We also discuss the strategies to improve the performance of the system.

Keywords

Automated Essay Scoring, Testing Scenarios, Reliability and Validity

1. INTRODUCTION

Automated Essay Scoring (AES) system is a computer software designed as a tool to facilitate the evaluation of student essays. Theoretically, AES systems work faster, reduce cost in term of evaluator's time, and eliminate concerns about rater consistency. The most logical way to assess the performance of an automated scorer is by measuring the score agreement with the human raters. The score agreement rate must exceed a specific threshold value to be considered as having a good performance. Consequently, most studies have focused on increasing the level of agreement between human and computer scoring. However, the process of establishing reliability should not stop with the calculation of inter-coder reliability, because automated scoring poses some distinctive validity challenges such as the potential to misrepresent the construct of interest, vulnerability to cheating, impact on examinee behavior, and users' interpretation on score and use of scores [1]. Bennet and Bejar [2] have argued that reliability scores are limited in their reliance on human ratings for evaluating the performance of automated scoring primarily because human graders are fallible. Humans raters may experience fatigue and have problems with scoring consistency across time. Reliability calculations alone are therefore not adequate as the current trend for establishing validity [3]. A well-performing essay scorer from the quantitative evaluation perspective is too risky to be deployed before evaluating the system's reliability and validity.

The initial attempt to discuss validity issues regarding automated scoring in a larger context of a validity argument for the assessment was made by Clauser et al. [4]. They presented several outlines of the potential validity threats that automated scoring would introduce to the overall interpretation and use. Enright and Quinlan [5] discussed how the evidence for a scoring process that uses both human and e-rater scoring is relevant to validity argument. They described an e-rater model which was proposed to score one of the two writing tasks on the TOEFL-iBT writing section. Automated scorer was investigated as a tool to complement to human judgement on essays written by English language learners.

Several criticisms for Automated Essay Scoring (AES) system were highlighted in [6]. They argued that there were limited studies on how effective automated writing evaluation was used in writing classes as a pedagogical tool. In their study, the students gave negative reactions towards the automated assessment. One of the problems was that the scoring system favored lengthiness; higher scores were awarded to longer essays. It also overemphasized the use of transition words, which increased the score of an essay immediately. Moreover, it ignored coherence and content development as an essay could achieve a high score by having four or five paragraphs with relevant keywords, although it had major coherence problems and illogical ideas. Another concern is described in [7]. Specifically, knowing how the system evaluates an essay may be a reason why students can fool the system into assigning a higher score than what is warranted. They concluded that the system was not ready yet as the only scorer, especially for high-stakes testing, without the help of expert human raters.

Most researchers agree that human - automated score agreement still serves as the standard baseline for measuring the quality of machine score prediction. However, there is an inherent limitation with this measurement because the agreement rate is usually derived only from the data used for training and testing the machine learning model. The aim of this paper is to highlight some limitations of standard performance metrics used to evaluate automated essay scoring model, using several input scenarios to evaluate the reliability and the validity of the system, such as off-topic essays, gibberish, and paraphrased answers. We show empirical evidence that a well-performing automated essay scorer, with high agreement rate between human-machine, is not necessarily ready for deployment for operational use, since it fails to perform well on two out of three test scenarios. In addition, we also discuss some strategies to improve the performance of the system. This paper begins with the explanation of the quantitative performance acceptance criteria for an automated scoring model from [1]. Then, we present the experiment settings, including the training algorithm and the essay features, for creating the model. Afterwards, we discuss the experiment results, model performance analysis, reliability and validity evaluation and the strategies for improvement, and finally, we conclude our work.

2. SCORE AGREEMENT EVALUATION

According to Williamson et al. in [1], the following are some of the acceptance criteria used for evaluation of automated scoring with respect to human scores when automated scoring is intended to be used in conjunction with human scoring:

1. Agreement of scores between human raters and computer

Agreement between human scores and automated scores has been a long-established measure of the performance of automated scoring. This is to measure whether the agreement satisfies a predefined threshold. The quadratic weighted kappa (QWK) between automated and human scoring must be at least .70 (rounded normally). It is important to note that the performance of automated scorer will rely on the quality of the human scoring. Therefore, the interrater agreement among human raters must first be reliable.

2. Degradation from human-human score agreement

The human-automated scoring agreement cannot be more than .10 lower than the human-human agreement. This standard prevents the case in which automated essay scoring may reach the .70 threshold but still be notably deficient in comparison with human scoring. In addition, it does not rule out the cases in which the automated–human agreement has been slightly less than the .70 threshold, but very close to a borderline performance for human scoring. For example, a human-computer QWK of .69 and human-human QWK of .71. Such model is approved for operational use based on being highly similar to human scoring. Moreover, Williamson et al. stated that it is relatively usual to observe automated-human agreements that are higher than the human-human agreements for tasks that predominantly target linguistic writing quality (e.g. GRE Issue and TOEFL Independent tasks).

3. Standardized mean score difference between human and automated scores.

Another measure for association of automated scores with human scores is that the standardized mean score difference (standardized on the distribution of human scores) between the human and computer cannot exceed .15. The standardized difference of the mean is formalized as follows:

$$\overline{Z} = \frac{[\overline{X}_{AS} - \overline{X}_H]}{\sqrt{\frac{SD_{AS}^2 - SD_H^2}{2}}} \quad (1)$$

where $\overline{X}_{AS}$ is the mean of the automated score, $\overline{X}_H$ is the mean of the human score, SD_{AS}^2 is the variance of the automated score, and SD_H^2 is the variance of the human score.

3. EXPERIMENTS

3.1 DATASET

We used the Automated Student Assessment Prize (ASAP) dataset[1], hosted by the Kaggle platform, as our experiment data. ASAP is the most widely used dataset to evaluate the performance of AES systems [8]. All the essays provided are already human graded. ASAP dataset consists of eight prompts, with varying score ranges for each prompt. Table 1 highlights the topics of each prompt in ASAP dataset.

Table 1 Prompts in ASAP Dataset

ASAP Dataset	Topics
Prompt 1	The effects computers have on people
Prompt 2	Censorship in the libraries
Prompt 3	Respond to an extract about how the features of a setting affected a cyclist
Prompt 4	Explain why an extract from *Winter Hibiscus* by Minfong Ho was concluded in the way the author did.
Prompt 5	Describe the mood created by the author in an extract from *Narciso Rodriguez* by Narciso Rodriguez
Prompt 6	The difficulties faced by the builders of the Empire State Building in allowing dirigibles to dock there
Prompt 7	Write a story about patience
Prompt 8	The benefits of laughter

3.2 FEATURES EXTRACTION

Each essay is transformed into a 780 dimension of features vector. We extract the essay features into two categories: 12 interpretable features, and 768 dimension of Sentence-BERT vector representation. Table 2 contains the essay features we used to train the scoring model.

Table 2 Essay Features

Type	Description
Interpretable essay features (12 features)	Answer Length (Character counts) Word count Average word length Count of "good" POS n-grams Number of overlapping tokens with the prompt Number of overlapping tokens (including synonyms) with the prompt Number of punctuations Spelling errors Unique words count Prompt – answer similarity score (SBERT representation) Prompt – answer similarity score (BOW representation) Language Errors
Sentence-BERT features (768 dim)	The encoding of the essay using Sentence-BERT pretrained model

3.2.1 Interpretable Essay Features

Six out of the twelve interpretable essay features are extracted from EASE (Enhanced AI Scoring Engine) library[2], written by one of the winners in ASAP Kaggle competition. This features set have been proven to be robust [9]. EASE generates 414-length features. However, we exclude most of the features generated by EASE library that are mostly Bag-of-Words vectors. The other six features extracted from the text are the number of punctuations, the number of spelling errors, unique words count, similarity scores between

[1] https://www.kaggle.com/c/asap-aes

[2] https://github.com/edx/ease

answer and prompt using S-BERT and BOW (Bag-of-Words) vector representations, and the number of language errors.

The grammar feature is measured by the number of good n-grams in the essay. EASE library extracts the essay text into its POS-tags and compares them with a list of valid POS-tag combinations in English. Good POS n-grams are defined as the ones that separate high- from low-scoring essays, determined using the Fisher test [10]. Moreover, we count the number of language errors in an answer using Language Tool Python library[3]. Mechanics in a language include aspects such as the usage of punctuation and the number of spelling errors found in the answer.

The average word length and long words count are used by Mahana et al. to estimate language fluency and dexterity [11]. Larkey also used the number of long words to indicate the complexity of term usage [12]. Unique words count feature is useful to estimate the richness of vocabulary in the answer.

The relevance factor of an answer combines two features from EASE library, which are related to the degree of tokens overlap between the prompt and the answer, including their synonyms. Two additional features are the cosine similarity measurement between the answer and the prompt, both using the Sentence-BERT and the BOW representation.

3.2.2 Sentence-BERT representation

Sentence-BERT, introduced by Reimers and Gurevych (2019), is a modification of pretrained BERT network using Siamese and triplet network [13]. It converts a text into a 768-dimension feature vectors and produces semantically meaningful sentence embedding. The embedding result can then be compared using cosine-similarity.

3.3 MODEL TRAINING

We train the regression models using Gradient Boosting algorithms, with 80% training data and 20% testing data (using 5-fold cross-validation). We use Quadratic Weighted Kappa (QWK) [14] score as the evaluation metric, which measures the agreement between system predicted scores and human-annotated scores. QWK is the standard evaluation metric to measure the performance of an AES system [1]. Although ASAP dataset has 8 prompts, we trained 9 models in total. The reason is that prompt 2 was scored in two different domains (Writing Application and Language Conventions). Therefore, we must create two separate predictions for this essay prompt. To train all nine models, we used different hyperparameters for each model.

4. RESULTS

4.1 Model Performance Evaluation

In this subsection, we evaluated the model performance based on the quantitative evaluation criteria as discussed in Section 2. Furthermore, we also analyzed the distribution of overall holistic scores assigned by human raters and computer.

4.1.1 Score Agreement Evaluation

We conducted the quantitative evaluation of our models based on the acceptance criteria by Williamson et al. in [1], and the results are shown in Table 3. The table describes the performance measurements for the scoring model of each prompt. The first column is the QWK score, which measures the human-computer agreement. The human-human agreement score in the second column is used to calculate the degradation value. The last column contains the standardized mean score difference between human and automated scores.

Table 3 Model Performance Evaluation for ASAP Dataset

Dataset	QWK Score	Human Agreement	Degradation	$\overline{Z}$
1	0.7826	0.72095	-0.06165	0.0056
2_dom1	0.6731	0.81413	0.14103	0.0007
2_dom2	0.6715	0.80175	0.13025	0.0394
3	0.6887	0.76923	0.08053	0.0272
4	0.7736	0.85113	0.07753	0.0094
5	0.8065	0.7527	-0.0538	0.0229
6	0.7985	0.77649	-0.02201	0.0102
7	0.7771	0.72148	-0.05562	0.0023
8	0.6668	0.62911	-0.03769	0.0147

Based on the above results, we concluded that five models (prompt 1, 4, 5, 6, and 7) satisfy the quantitative evaluation criteria defined as a standard in [1]. Next, we continued our analysis and the reliability and validity tests on only these well-performing models and ignored the other underperforming models (prompt 2_dom1, 2_dom2, 3, and 8).

4.1.2 Distribution of overall holistic scores

We investigated the distribution of the overall holistic scores assigned by human raters and the automated scorer. It is important to understand the distribution of the scores, especially in relation to the decision of an exam. For this purpose, we presented the decision into three categories: passing, borderline, and failing. Table 4 shows the rubric score and resolved score range in ASAP dataset, in which our model passed the quantitative performance evaluation in the previous subsection. The resolved score is the final score after combining the rubric scores from two human raters. Each prompt has a different score resolution. In some prompts, if there was a difference between scorer 1 and scorer 2, the final score was always the higher of the two. In another prompt, the final score was the sum of scores from rater 1 and rater 2 if their scores are adjacent. If non-adjacent, an expert scorer will determine the final score.

Table 4 ASAP Rubric and Resolved Score Range

Dataset	Rubric score	Resolved Score	Borderline Score
Prompt 1	1 - 6	2 - 12	6-8
Prompt 4	0 - 3	0 - 3	1
Prompt 5	0 - 4	0 - 4	2
Prompt 6	0 - 4	0 - 4	2
Prompt 7	0 - 12	0 - 24	12

To categorize the exam results, we created a borderline score from the resolved score. It is not necessarily the exact middle score because some datasets do not have it. We considered scores below the borderline as failing and scores above the borderline as passing.

[3] https://github.com/jxmorris12/language_tool_python

Table 5 Frequency Comparison for Passing, Borderline, and Failing (in %)

	ASAP 1			ASAP 4			ASAP 5			ASAP 6			ASAP 7		
	HR1	**HR2**	**AES**	**HR1**	**HR2**	**AES**	**HR1**	**HR2**	**AES**	**HR1**	**HR2**	**AES**	**HR1**	**HR2**	**AES**
Passing	35.2	35.5	50.1	39.6	40	45.2	37.8	39.2	45.9	59.4	59.1	65	74	72.8	82
Borderline	62.7	62.5	48.8	42.7	41.9	42.3	38.5	36	38.7	25.7	25.9	25.6	8.9	9.8	4.9
Failing	2.1	2	1.1	17.7	18.1	12.5	23.7	24.8	15.4	14.9	15	9.4	17.1	17.4	13.1
Total	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**	**100**

As can be seen from Table 5, the use of automated scorer will put the students at an advantage, compared to when the exam only employs human raters. In all datasets, we have the same overview. The AES models assigned scores with much higher passing rates than both human raters. And as far as the failure rates are concerned, the scores from AES indicate very low failing rates, compared to human raters. This finding supports the result in [15], with a different dataset for the experiment.

4.2 Evaluating and Improving the Model

We examined the performance of the model using three scenarios: gibberish answer, paraphrased answer, and off-topic answer. We discuss the evaluation results and strategies to improve the system in the following sections.

4.2.1 Off-topic essay

One way to validate the use of an automated essay scoring system is by checking its performance against off-topic answers. For this study, we use ASAP dataset which has eight sub datasets (prompts). To simulate the experiment, for each model, we used the answers in the other seven prompts as the off-topic essays. We randomly sampled 50 essays from each dataset, resulting in a total of 350 off-topic essays. Using 5-fold cross-validation, we measured the accuracy of the model in predicting the score of the off-topic essays, which we assume should get 0 (zero), due to the complete irrelevance with the corresponding prompt.

Table 6 Accuracy of off-topic detection

Dataset	Training Data	Accuracy (%)	QWK Score
Prompt 1 (2 – 12)	Original	0%	0.7826
	Original + 350 off-topic	55.4%	0.7031
Prompt 4 (0 – 3)	Original	4.3%	0.7736
	Original + 350 off-topic	91.4%	0.7697
Prompt 5 (0 - 4)	Original	0.6%	0.8065
	Original + 350 off-topic	88%	0.7951
Prompt 6 (0 – 4)	Original	5.80%	0.799
	Original + 350 off-topic	97%	0.787
Prompt 7 (0 - 24)	Original	0%	0.7771
	Original + 350 off-topic	45.7%	0.7225

We also investigated the change of value of the QWK scores after retraining the model. The motivation is, we want to avoid that the retraining process degrades the performance of the original model. The new model should still perform well in predicting the original essay set.

Table 6 describes the experiment results of the retraining process, the improvement in accuracies, and the change in QWK scores. The models trained with only the original dataset performed with very low accuracies. The highest result is by prompt 6, with 5.8% of the off-topic essays are correctly given 0 scores. Prompt 1 and prompt 7 are the worst with no correct prediction at all. It means all off-topic essays are graded with scores greater than 0.

We can observe the effect of including the off-topic essays in the training data. The model performance for prompt (4, 5, and 6) drastically increase. For prompt 6, the accuracy on predicting the unseen data of the off-topic essays (test set) reached 97%, with only a slight decrease on the QWK score. There are moderate improvements for prompt 1 and especially prompt 7. We assume this is due to a larger score range, which for prompt 7 is 0 – 24. If we are being less strict about the score 0 (zero) policy for off-topic essays, for example by categorizing score between 0 – 3 as failed score, we obtain a much better accuracy, which is 81.7%. Meanwhile, for prompt 1, the lowest resolved score is 2. However, we trained the model to give off-topic essays 0 score prediction. If we create a score range 0 – 2 as failed category, the accuracy increases to 93%. Because we have many score predictions for the off-topic answers ranging from 0 to 2 by prompt 1.

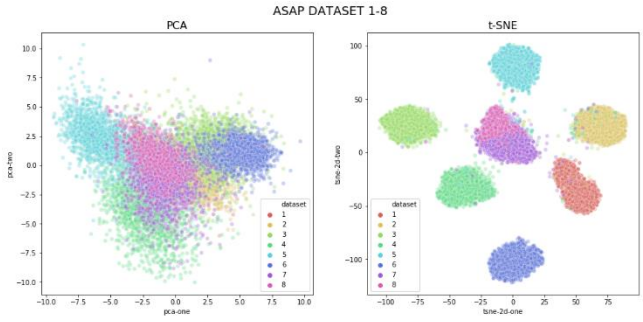

Figure 1 SBERT representation for 8 prompts in ASAP dataset

We conclude that the solution for detecting off-topic essays is relatively simple. Without using additional features for detecting off-topic essays, we found out that the SBERT features are very helpful to be used as features for training a scoring model. Using PCA and t-SNE, we plotted the SBERT vector representation of the essays in all eight of ASAP dataset prompts. Figure 1 shows that using t-SNE, all prompts are almost perfectly separated, although we can see both dataset 7 and dataset 8 are close to each other in the middle of the plot. We assume that it is caused by their similar prompt topics. If we check Table 1 for the description of topics in ASAP dataset, in prompt 7 the students are asked to write a story about patience, while prompt 8 discusses about the benefits of laughter. Both topics are arguably more closely related to each other than when we compare them with the topics of prompt 1 – prompt 6.

4.2.2 *Gibberish*

For the next input scenario, we want to avoid that the system receives invalid answers such as gibberish, and undeservedly returns scores other than zero. Ideally, any gibberish answer must get the score zero. However, using our model, we tested several gibberish as the answers, and the scores are not zero. We provide some examples of the inputs as shown in Table 7. In this table, we show the examples of wrong predictions by the scoring model that was trained using ASAP dataset prompt 6. Nevertheless, we can also observe similar problems in the other models.

Table 7 Examples of Wrong Predictions by Prompt 6

Answer	Score (0-4)
asdafafdf adjhgladghad	1
Eyoqtuwrpituauoyeqo ngbambgagadhkq3124 31794613 hbfka df	1
orkesbroh	1

To analyze the reason, we conducted local model interpretation, which means that we are interested in understanding which variable, or combination of variables, determines the specific prediction. We use SHAP (SHapley Additive exPlanations) values to help in determining the most predictive variables in a single prediction [16]. In AES, the system output is a real number. Each variable contribution will either increase or decrease the output value. One implementation of SHAP libraries is TreeExplainer, a faster library for obtaining SHAP values for tree ensemble methods [17].

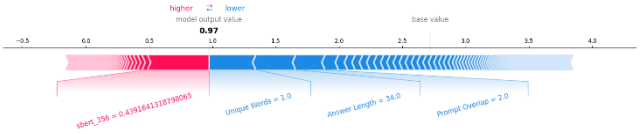

Figure 2 Local interpretation for a single prediction

From Figure 2, it seems that some of the most important interpretable features (number of unique words, answer length, and prompt overlap) have the correct effects to the prediction, they play a role in decreasing the score. However, there is one feature from the SBERT vector representation that helps the score of gibberish answers to increase, i.e. sbert_356. Most of the wrong gibberish predictions have a similar explanation to the one shown in Figure 2. SBERT vector is not interpretable, therefore we cannot explain and analyze the reason of this peculiar model behavior. We propose two solutions to this problem as follows:

1. Retrain model using gibberish data, with label score zero.

We created 200 gibberish essays and transformed them into a 780-dimension vector representation of text, and then include them in the training and testing data. Table 8 shows the performance comparison of three model training scenarios. We can observe a large improvement on the accuracy of the model to detect gibberish answers, and to punish them with the scores zero. For example, by prompt 1, the accuracy increases from 0% to 92.8% by adding only 100 gibberish data to the model training. By adding 100 more data, the accuracy only improves by a little less than 2%. After changing the training data by adding gibberish for the training process, we want to make sure that the main performance metrics (QWK score) on the original data is not being sacrificed. The results show that in all prompts, the addition of gibberish data to the training phase did not harm the performance of the models. The QWK scores decreased by a very small margin, and they still have the human-computer agreement score above the required threshold. Even in prompt 7, the final QWK score increased with the addition of gibberish to the training set.

Table 8 Accuracy of Gibberish Detection

Dataset	Training Data	Accuracy (%)	QWK Score
Prompt 1	Original	0	0.7826
	Original + 100 gibberish	92.8	0.7768
	Original + 200 gibberish	94.4	0.7683
Prompt 4	Original	18.6	0.7736
	Original + 100 gibberish	97.8	0.779
	Original + 200 gibberish	98.6	0.7749
Prompt 5	Original	3.5	0.8065
	Original + 100 gibberish	98	0.7986
	Original + 200 gibberish	98.6	0.8049
Prompt 6	Original	18.2	0.799
	Original + 100 gibberish	96	0.794
	Original + 200 gibberish	97.9	0.782
Prompt 7	Original	0	0.7771
	Original + 100 gibberish	68	0.7798
	Original + 200 gibberish	73.4	0.781

2. Use rule-based mechanism.

This is arguably a simpler solution, without the need to involve any additional model retraining process and could be a more generalizable solution. The system is configured to automatically give score zero for possible gibberish answer, this can be done automatically for example with a valid English word detection library. If none of the token in the answer is valid English vocabulary, we can consider the answer as gibberish. The main drawback is possibly the added processing time for the program to validate each word in the answer, depending on how large the vocabulary is.

4.2.3 *Paraphrased Answer*

To further evaluate the performance of the system, we investigated the reliability of the system by testing whether the model consistently gives the same score for the same answer. For this experiment, we generated paraphrased answers of all answers in the dataset. And we examine whether the model would predict the same score for each paraphrased answer. We utilized an online paraphrasing tool[4] to generate the paraphrased version of the answer.

We use Quadratic Weighted Kappa (QWK) to compute the agreement between the original test set prediction and the

[4] https://spinbot.com/

paraphrased test set prediction. Based on the scores in Table 9, it is evident that the agreements for all datasets are high. Therefore, we conclude that the models perform consistently in predicting the scores of paraphrased answers.

Table 9 Agreement of Prediction between Original and Paraphrased Answers

Dataset	QWK
Prompt 1	0.8109
Prompt 4	0.8674
Prompt 5	0.8645
Prompt 6	0.846
Prompt 7	0.9411

The highest agreement score is achieved by the model of prompt 7, which shows a near perfect agreement with QWK score of 0.9411. Although not as high as the result of prompt 7, the QWK scores in prompt 1, 4, 5, and 6 are considered as very high agreement.

5. CONCLUSION

The purpose of this research is to highlight the limitations of the current performance measurement standard for automated essay scoring. A quantitatively well-performing model with high human – automated score agreement rate, is not necessarily ready for deployment in the real-world usage. We demonstrated that such models still possess some performance concerns against varying input scenarios. We showed empirical evidence that those models have some difficulties, proven by very low accuracies, in detecting off-topic essays and gibberish. We also proposed and proved several strategies that can successfully improve the performance of the system. In another scenario, for consistency testing, the models already performed quite well for predicting paraphrased answers, judged from high agreement results with the predictions on the original answer. While we are aware that there remain more validity questions to be studied, this research can serve as additional techniques towards a better holistic evaluation framework for AES.

Predicting Student Performance Using Teacher Observation Reports

ABSTRACT

Studying for entrance examinations can be a distressing period for numerous students. Consequently, many students decide to attend cram schools to assist them in preparing for these exams. For such schools and for all educational institutes, it is necessary to obtain the best tools to provide the highest quality of learning and guidance. Performance prediction is one tool that can serve as a resource for insights that are valuable to all educational stakeholders. With accurate predictions of their grades, students can be further guided and fostered in order to achieve their optimal learning goals. In this regard, we target middle school students to be able to guide them on their educational journey as early as possible. We propose a method to predict the students' performance in entrance examinations using the comments that cram school teachers made throughout the lessons. Teachers in cram schools observe their student's behavior closely and give reports on the efforts taken in their subject material. We show that the teachers' comments are qualified to construct a tool that is capable of predicting students' grades efficiently. This is a new method because previous studies focus on predicting grades mainly using student data such as their reflection comments or earlier scores. Experimental results show that using readily available feedback from teachers can remarkably contribute to the accuracy of student performance prediction.

Keywords

text mining, student grade prediction, teacher observation reports, machine learning

1. INTRODUCTION

"If you could reinvent higher education for the twenty-first century, what would it look like?". A question like this one invites many observations about the advantages and issues that the current state of higher education has in the world. As a matter of fact, this question has been addressed specifically by the founders of the Minerva Schools at KGI [1] in the United States. At such innovative universities and schools, active learning and student engagement with the material are highly encouraged [2, 3, 4, 5, 6]. Additionally, the student/teacher ratio is expected to be lower than in traditional schools for higher teacher effectiveness [7]. Students are assessed and observed closely by their teachers and they can receive written feedback from their teachers daily. These reports clarify any confusion, reinforce strong points and give more specific advice and guidance [8, 9]. Besides, since teachers frequently engage with students, research has proven that these teachers, especially those with professional development, can accurately judge and forecast their students' computational skills [10].

In this paper, we propose a novel method for predicting students' performance or final grades. We show that we can use reports carefully written by teachers that closely observe the students, to construct a grade prediction model. If these predictions can be made accurately, it would be an invaluable resource to help the teachers better regulate their students' learning. Future performance prediction is considered a powerful means that can provide all educational stakeholders with insights that are beneficial to them. Many grade prediction models have been proposed by researchers in the last decade [11, 12, 13], but no model has used teacher reports as far as we know. The teacher reports we use are provided by a cram school in Japan. Cram schools are specialized in providing extra and more attentive education for students who want to achieve certain goals, particularly studying for high school or university entrance exams [14]. To capture the meanings of the teacher reports, we obtain vector representations by applying the term-frequency inverse document-frequency (TF-IDF) method and extracting BERT embeddings. Our model uses these vectorized reports as the explanatory variables for a Gradient Boosting regressor. The regressor then predicts the students' scores. Our experiment results show that when adding teachers' reports to the regular student exam scores, we can predict their letter grade with an accuracy up to 62%. To sum up, our contributions can be outlined as follows:

- We propose a new performance prediction method using teacher observation reports represented using TF-IDF and BERT.
- We conducted 2 main different models of prediction and compared the experiment results to show that using teacher reports has the potential to contribute to an increase in accuracy of grade prediction models.

All in all, to the best of our knowledge, this is the first study to use NLP to mine teacher observation comments

Menna Fateen and Tsunenori Mine "Predicting Student Performance Using Teacher Observation Reports". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 481-486. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

to predict student grades. Our research and experimental results demonstrate the potential that these unstructured teacher observation comments have in predicting students' total scores and final letter grades.

2. RELATED WORK

The utilization of data mining and machine learning or deep learning tools to construct predictive models are increasingly being adopted in many different fields [15, 16]. Needless to say, the educational field has not been an exception. Topics in educational data mining vary widely from course recommendation systems [17] to automatic assessment [18]. More specifically, an extensive amount of studies have been dedicated to prediction modeling whether it be predicting student grades or performance such as next-term grade prediction [19] or student dropout. These prediction models are essential since they underlie applications to important educational AI-based decision-making systems [20]. With accurate predictions, the performance of students can be monitored using these systems, and students that have difficulties in their studies can easily be detected and given further guidance early on.

Over the past years, several methods have been developed to predict student's performance using Natural Language Processing (NLP) techniques. It has been proven that mining unstructured text using NLP has the capacity to contribute to accurately predicting students' success over the information obtained from usual fixed-response items [21]. Luo et. al [13] proposed a method to predict student grades based on their free-style reflection comments collected after each lesson. The comments were collected according to the PCN method [22] that categorizes the students' comments. To represent the students' reflection comments, Word2Vec embeddings were adopted followed by an artificial neural network. Their experiments show a correct rate of 80%. Teacher or advisor notes have been used by Jayaraman, not to predict student grades, but to detect students that are at risk of dropping out of college [23]. In their study, they use sentiment analysis to extract the positive and negative sentiment from the advisors' notes and use those as features to train a model. The model achieves 73% accuracy at identifying at-risk students.

3. DATA DESCRIPTION

The dataset obtained and used for our model was provided by a cram school in Fukuoka, Japan. To ensure confidentiality, no student names or other identifying data were presented. Reports were obtained monthly and sent as CSV files. Since our model is focused on predicting the performance of students in their entrance examinations, we focused on those students in their final year of middle school. The final dataset after preprocessing composed of 11,960 reports over the period from May to October for 159 students.

3.1 Monthly Reports

In addition to the student ID and the class date, each report also consisted of the subject code, the teacher's comments, understanding, attitude and homework scores. More data in the reports were also provided but were unstructured and considered redundant for the prediction model. The features that were extracted from the reports and used in the study are discussed in more detail in Section 4.1. However our main explanatory variable used in the study is the teachers' observation comments written in Japanese. The average length of these comments is 96 characters. In addition, by analyzing comments, it was observed that teachers tend to encourage and energize their students by using words such as "better" and "work on". Moreover, the words used in the comments depend on the context or class subject to some degree. For example, the expression "calculation problem" is likely to be used in math lessons.

Table 1: Number of Reports in Each Subject

	Japanese	Math	Science	Social	English
Number of Reports	1157 (9.7%)	3547 (29.6%)	2428 (20.3%)	1669 (14%)	3159 (26.4%)

In the cram school, students take different lessons for each subject. These lessons fall under the 5 main subjects: Japanese, Mathematics, Science, Social Studies and English. Since the main objective of our model is to predict a student's total score, reports in all 5 subjects are required. Therefore, testing the model was only possible for those students who attended classes for all subjects. The number of reports that fall under each subject are shown in Table 1. The values in the table show that the most taken lessons and therefore the most reports provided were in the subject of Mathematics followed directly by English. The number of total reports for each student varied depending on the classes attended. The average number of total reports recorded for each student was 82 reports with a maximum of 206 and a minimum of 24 reports.

3.2 Test Scores

Students attending the cram school were naturally registered in many different schools. The results of their regularly taken examinations at school were recorded and provided. These scores were what we considered student data and would be traditionally used as the main feature to predict their performance in the entrance exam. To teach the model to perform these predictions, we adopted the supervised learning method. In supervised learning, training data needs to be labeled with the required outputs for each input. This enables the model to train its learning function by altering it based on the correct result so that the function can then be applied to new inputs. In our study, we used the students' results in their cram school simulation exams as the labels for the model since their actual performance in the entrance exam was unattainable.

The simulation scores for the 159 students were recorded for all subjects and also provided as the total score. To visualize the distribution of the students' scores, histograms were plotted as shown in Figure 1. The shape of the graph for the subject scores distribution and total score distribution is approximately bell-shaped and seems symmetric about the mean, so it is assumed that the scores follow the normal distribution. The standard deviation, σ, for all scores are displayed in Table 2 to show how dispersed the values are.

4. METHODOLOGY

4.1 Feature Selection

Figure 1: Distribution of Simulation Test Scores

Table 2: Standard deviation of subject scores

	Japanese	Math	Science	Social	English	Total
σ	11.85	16.62	20.33	16.93	18.47	70.01

For our experimental settings, we adopt 3 main feature sets for the sake of comparison. The first feature set, FS_1, consists of using teachers' report contents as the main explanatory variables. A teacher's report in one lesson evaluating the student consists of 1-Comments 2- Understanding Score 3- Attitude Score and 4-Homework Score. We use all of these attributes except for the homework score. This is mainly because more than 36% of the reports did not include homework scores since not all lessons necessarily require homework. After each lesson, the teacher writes some comments based on their observations, assesses the student on their understanding giving them a score of either (0-30-60-80-100) and an attitude score of either (1-2-3-4). The second feature set, FS_2, consists of student-related data only, specifically their gender and the score of their regularly scheduled exam at school. Since we predict each subject score separately, the regular score corresponds to the subject score. As for the students' gender, the Pearson correlation coefficient between it and the score is 0.12 while the correlation coefficient between the regular score and the simulation score is 0.80 which suggests that the important factor in FS_2 is essentially the student regular score and not the gender. Finally, we investigate using both teachers' reports and the regular student scores to verify whether adding teachers' reports contributes to the accuracy of the prediction model or not. The third feature set, FS_3, is essentially a concatenation of FS_1 and FS_2. A sample of FS_1 is shown in Table 3.

4.2 Natural Language Processing

There are numerous ways to represent text data for a machine learning model to convey the original meanings of the text and prevent information loss. In our experiments, we chose to represent the teachers' comments using two techniques. We used the traditional TFIDF vectorization method and compared it with BERT embeddings.

4.2.1 TF-IDF

The first essential step in transforming text into a numerical representation is preprocessing the text. This step begins with tokenization or splitting the sentences into words. Tokenization in languages such as English can be done by splitting the sentence strings at each space. However, for Japanese, this step is merged with the next, which is morphological analysis, since there are no spaces in Japanese sentences. We use the fugashi [24] parser for this step, which is essentially a wrapper for Mecab[1], a Japanese tokenizer and morphological analysis tool. Our parser extracts from each report the following parts of speech: nouns, verbs, auxiliary verbs, adjectives and adverbs. We use the corresponding terms to these extracted parts of speech to build a bag-of-words vector with weights given by the TF-IDF method implemented by sklearn [25]. Since the teachers' comments are given in Japanese, we provide the mentioned parser to the tokenizer parameter. We also give a list of predefined Japanese stop words to the vectorizer.

4.2.2 BERT

BERT or Bidirectional Encoder Representations from Transformers is a new method of pre-training language representations presented by Google [26]. BERT obtains state-of-the-art results on many NLP tasks. It is a Transformer Encoder stack that pre-trains language representations. A pre-trained BERT model is basically a general purpose language understanding model trained on a large corpus which can then be used for downstream tasks. The BERT model we used for the comments was pretrained by Inui Laboratory, Tohoku University[2]. The corpus they used for pretraining was Japanese Wikipedia and the model was trained with the same configuration as the original BERT. In the experiments shown in this paper, we used the BERT [CLS] token embeddings as our BERT embeddings.

4.3 Evaluation Metrics

To evaluate our experiments, we use the Mean Absolute Error (MAE) metric. The MAE is calculated using the following formula :

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |\text{score}_{pred,i} - \text{score}_{true,i}| \qquad (1)$$

where $\text{score}_{true,i}$ is the actual score that student i obtained. The predicted score ($\text{score}_{pred,i}$) is calculated differently for subject scores and total score. For a specific subject $s \in$ S, where S = {Japanese, Math, Science, Social Studies, English}, a student i can attend a variable number t of lessons. Therefore, to predict the subject score ($\text{SubjectScore}_{pred,i,s}$) of student i we use each of their reports as independent inputs to the model and obtain an ordered list $X_{i,s,t}$ of pre-

80	4	We are trying applied problems of resolution into factors. You look like making many mistakes carelessly, but know formulas very well.
100	4	He took notes while watching the commentary and focused on the problem. If you keep going at this rate, you will be able to meet the target, the 5th time. So, let's do our best!

dicted scores for student$_i$. The estimated score for the subject is then decided using:

$$\begin{aligned}\text{SubjectScore}_{pred,i,s} &= Med(X_{i,s,t}) \\ &= \begin{cases} X_i[\frac{t}{2}], & \text{if t is even} \\ \frac{1}{2}(X_i[\frac{t-1}{2}] + X_i[\frac{t+1}{2}]), & \text{if t is odd} \end{cases}\end{aligned} \tag{2}$$

To measure the central tendency, we used the median rather than the mean as it is robust to skewness and outliers. Nevertheless, if the estimations follow a normal distribution, the median would be close to the mean. The total predicted score ($\text{TotalScore}_{pred,i}$) can then be estimated by:

$$\text{TotalScore}_{pred,i} = \sum_{s \in S} \text{SubjectScore}_{pred,i,s} \tag{3}$$

Finally, since students receive letter grades for their total score, we map the estimated total score to its closest corresponding letter grade according to the percentages shown in Table 4 [27]. We then compute the percentage of grades that are x ticks away from their actual grades. A tick, as specified by [28], is defined as the difference between two successive letter grades. We name this metric percentage by tick accuracy or PTA. PTA_0 stands for the Percentage by 0 Tick Accuracy which means the model successfully predicted the letter grade with no error while PTA_1 is the percentage of incorrectly predicted grades but are 1 tick away from the true letter grade (e.g. A vs B). A similar metric was used in previous studies regarding grade prediction models [11, 28].

Table 4: Letter grades and their corresponding percentages

Grade	S	A	B	C	D	F
%	90-100	80-89	70-79	60-69	50-59	0-49

5. EXPERIMENTS

5.1 Model Overview

In our experiments, we adopt gradient boosting, a composite machine learning algorithm. We employed its sklearn implementation, `GradientBoostingRegressor` [25] to predict the continuous value of the students' scores in each subject. Since there is no prior research on the effect of using teacher observation reports in predicting students' grades, we use the following method as the baseline in our experiment. At first, subject codes were unavailable for each teacher observation record. Therefore, we constructed a model that used all of each student's reports, regardless of the subject, to directly predict and estimate the total score according to Equation 2. We call this model, the 'Direct' model. Subject codes then became accessible and we were able to map each report to its corresponding subject. Leveraging that, we created a separate regression model for each subject's reports and estimated the total score as shown in Equation 3. This model is called the 'Subjects' model.

5.2 Experimental Results

All experiments in the study were evaluated using group 10-fold cross-validation. The advantage of group k-fold cross validation method is that all data are used for both training and testing, and each instance is used for testing once. This is especially useful in situations where data is limited. Since the dataset comprises reports for 159 students, we used 143 students' reports for each fold as the training set and 16 as the testing set. The number of reports or instances for each subject model, therefore, varied depending on how many lessons each student had attended. The average MAE, which is calculated as in Equation 1, of all ten folds was computed and used as the main evaluation metric. We ran the baseline Direct model with the 3 feature sets described in Section 4.1. Teachers' comments were represented using BERT embeddings. The performance results are shown Using all 3 feature sets, the Subjects model consistently outperforms the Direct baseline model. Specifically, predicting the total score using the Subjects model with FS_3, which uses both teachers' reports and student data, resulted in a decrease in MAE of 5.62. Using teachers' reports alone (FS_1) resulted in a comparatively higher MAE in both models. However, adding teachers' reports to student data (FS_3) showed a smaller value in MAE than using student data only (FS_2) which suggests that teachers' reports as features can contribute to the accuracy of the grade prediction model.

Table 6 shows the MAE, PTA_0 and PTA_1 of each subject's score prediction model. We ran the subject model with all 3 feature sets. For FS_1 and FS_3, we compared the performance of the two text representations, TF-IDF vectors and BERT embeddings. Values in bold indicate the leading scores for each metric in all subjects. In terms of MAE, using FS_3 consistently outperforms the other feature sets. It can also be seen that BERT embeddings tend to have better overall

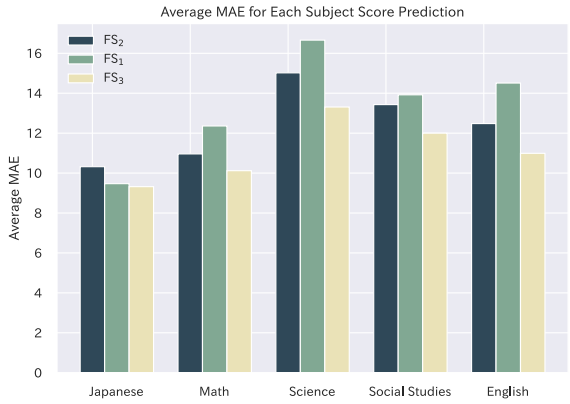

Figure 2: Average MAE of subject scores across all FS

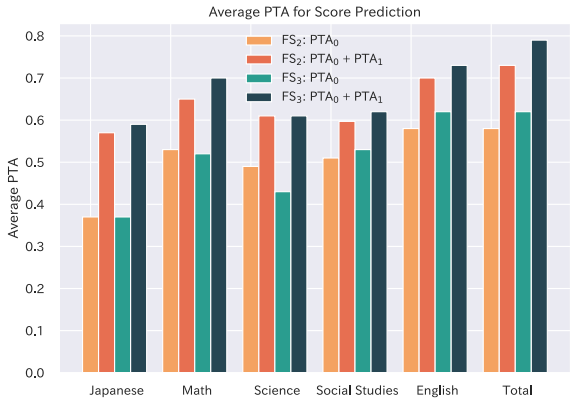

Figure 3: A comparison of PTA metric evaluated when using FS_2 and FS_3 across all subject scores and total score

performance than the TF-IDF vectors. Moreover, running the Subjects model with FS_1 using BERT resulted in lower MAE than when using TF-IDF. Finally, when predicting the total score, using FS_3 with BERT held the top scores across all evaluation metrics.

Figure 2 depicts the performance of each subject seperately in terms of MAE across the three feature sets. It can be observed that FS_3 continuously achieves lower MAE than FS_2 and FS_1. In addition, as shown in Figure 3, FS_3 also consistently achieves higher overall PTA. When predicting the total score, FS_3 shows an increase of 6.2% in $PTA_0 + PTA_1$. These results provide evidence and suggest that teachers' reports can in fact add value and contribute to grade prediction models.

6. DISCUSSION

The results presented in the previous section can be summarized into the following main points.

- The highest performance of the grade prediction model can be achieved by using a concatentation of the two feature sets, FS_1 and FS_2.
- When predicting the total score with teachers' reports, using BERT embeddings outperforms TF-IDF.

The success of BERT can be attributed to the fact that the BERT model has been pretrained on huge corpora of Japanese text data. TFIDF vectors, on the other hand, only use the data on hand to produce the representations. However, an important advantage of TFIDF is that the numerical vector representations are computed much faster than extracting BERT embeddings. To further increase the accuracy of the prediction model considering FS_3 and FS_1, we aim to pre-train BERT on each of the 5 subject reports. It has been proven that pretraining BERT on specific domains can lead to a significant increase in performance [29].

7. CONCLUSION

At educational institutes where students are closely observed by their teachers, large amounts of unstructured data exist in the form of reports and comments. In this paper, we attempted to employ and take advantage of these comments to help identify students that may need extra guidance or attention. Our model used teacher observation comments to predict students' total scores. We applied both TF-IDF and BERT embeddings to the observation comments and used the vectors as inputs to a gradient boosting regressor. Three main feature sets were employed in our model, teacher-related features, student-related features, and a concatenation of both. The performance of our model on each set was then demonstrated. Our experimental results showed that the readily available teachers' reports have the potential to create a grade prediction model. Using teachers' reports can increase the accuracy of a grade prediction model that uses only students' previous exam scores by 6.2%. However, there remains room for improvement in our experiments. We believe that with more teachers' comments, the accuracy of our model could increase. We also plan to enhance the text representations by pretraining BERT on the teachers' comments in advance. Additionally, we intend to experiment with another model architecture that would focus on classifying the students' performance first. We hope that with

such well-defined grade prediction models, we can help guide young students and provide a more focused and personalized education to them.

Recommending Knowledge Concepts on MOOC Platforms with Meta-path-based Representation Learning

Guangyuan Piao

ABSTRACT

Massive Open Online Courses (MOOCs) which enable large-scale open online learning for massive users have been playing an important role in modern education for both students as well as professionals. To keep users' interest in MOOCs, recommender systems have been studied and deployed to recommend courses or videos that a user might be interested in. However, recommending courses and videos which usually cover a wide range of knowledge concepts does not consider user interests or learning needs regarding some specific concepts. This paper focuses on the task of recommending knowledge concepts of interest to users, which is challenging due to the sparsity of user-concept interactions given a large number of concepts. In this paper, we propose an approach by modeling information on MOOC platforms (e.g., teacher, video, course, and school) as a Heterogeneous Information Network (HIN) to learn user and concept representations using Graph Convolutional Networks based on user-user and concept-concept relationships via meta-paths in the HIN. We incorporate those learned user and concept representations into an extended matrix factorization framework to predict the preference of concepts for each user. Our experiments on a real-world MOOC dataset show that the proposed approach outperforms several baselines and state-of-the-art methods for predicting and recommending concepts of interest to users.

User Modeling, MOOC, Learning Analytics, Knowledge Concept, Recommender Systems

1. INTRODUCTION

MOOCs (Massive Open Online Courses), which are free online courses available to anyone to enroll around the world, have gained a lot of popularity in the past decade. By the end of 2018, popular MOOC platforms such as edX[1], and Coursera[2] have provided 11,400 courses with 101 million users/learners on those platforms[3]. Previous studies have shown that MOOCs do have a real impact [24, 8]. For example, Chen et al. [8] showed that 72% of survey respondents reported career benefits and 61% reported educational benefits. Despite of the popularity, one main challenge of MOOCs is the overall completion rate of those courses is normally lower than 10% [19, 30]. Therefore, understanding and predicting user behaviors and learning needs are important to keep users learning on MOOC platforms.

To this end, previous studies have focused on understanding dropout or procrastination behavior [28, 12, 38, 14] and recommending content such as courses and learning paths that a user might be interested in [16, 26, 4]. A MOOC can be seen as a sequence of videos where each video is associated with some knowledge concepts. For example, a video in a computer science MOOC can cover several concepts such as "software" and "hardware". More recently, Gong et al. [13] argued that course or video recommendations overlook user interests regarding specific knowledge concepts. For example, data mining courses taught by different teachers can be quite different in a microscopic view, and a user who is interested in some specific concepts such as "association rules" might be interested in various video clips or learning materials from different teachers covering those concepts from different perspectives. Therefore, understanding a user's learning needs from a microscopic view and predicting knowledge concepts that the user might be interested in are important.

In this work, we focus on predicting and recommending knowledge concepts that might be interesting to users on MOOC platforms. Based on the interaction history between users and concepts (i.e., a user has interacted with a concept if the user has learned that concept), traditional recommendation approaches such as collaborative filtering (CF) — which recommends similar items (concepts) based on a user's interaction history or interesting items from similar users — can be applied. However, the sparsity of user-item (user–concept) relationships can limit the performance of CF-based methods. In addition to users and concepts, MOOC platform data normally contain other entities such as courses, videos, and teachers as well as the relationships among those entities.

To cope with the sparsity problem, we model those enti-

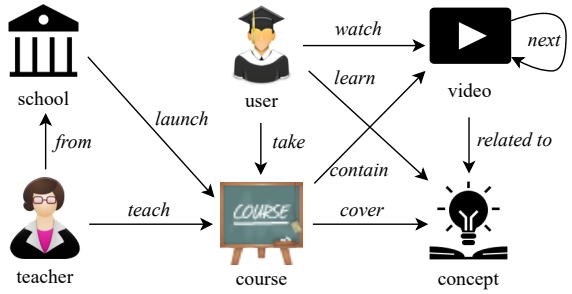

Figure 1: Different types of entities and relationships between two entities in MOOCs. A user u is interested in a concept if u has learned or is going to learn it in the future.

ties and their relationships as a heterogeneous information network (HIN) [33] consisting of the entities and relationships inspired by [13], which can be used for learning user (concept) representations/embeddings by exploring indirect user-user (concept-concept) relationships with Graph Convolutional Networks (GCNs). Figure 1 illustrates such a HIN which we discuss in detail in Section 3. For example, one can derive a homogeneous user graph based on an indirect path in the HIN, e.g., a graph with users and edges between two users if they have taken the same course. Given such a homogeneous graph, traditional GCNs can be applied to the graph to learn the representations/embeddings of users and concepts with respect to the chosen path.

Based on different indirect paths chosen, we can derive various user (concept) representations, and those representations of users (concepts) regarding different paths can be aggregated, e.g., using the mean of those representations. Instead of the straightforward mean aggregation, we propose and investigate different attention mechanisms to derive aggregated user (concept) representations based on different paths. The intuition behind using an attention mechanism is that different paths might have different importance for each user. Afterwards, those learned user and concept representations can be used for predicting the preference scores of concepts for recommendations. Our contributions in this work are as follows: (1) We propose an end-to-end framework[4] for predicting and recommending knowledge concepts of a user's interest in Section 4; (2) We investigate two attention mechanisms for aggregating information from different meta-paths (the definition can be found in Section 3) to derive user and concept representations. We then incorporate those representations into our extended matrix factorization framework for predicting the preference score of a concept with respect to a user; (3) Finally, we evaluate our approach with several baselines and state-of-the-art approaches in terms of well-established evaluation metrics, and show the effectiveness of our proposed approach in Section 6.

2. RELATED WORK

Recommender Systems and User Modeling on MOOC Platforms. There has been growing interest in recommender systems on MOOC platforms since 2013 with respect to different aspects such as course, video, and learning paths [16, 26, 3, 43, 9, 23]. For instance, the authors in [3] proposed YouEDU, which is a pipeline for classifying MOOC forum posts and recommending instructional video clips that might be helpful for resolving confusion detected in those posts. In [21], the authors showed that peer recommendations can improve users' engagement significantly in the context of a Project Management MOOC. Dai et al. [9] proposed analyzing course content for recommending personalized learning paths on MOOC platforms. Khalid et al. [18] provides a comprehensive survey on recent advances regarding different recommender systems in the context of MOOCs. More recently, researchers have started modeling user interests in the context of MOOCs while user modeling has been widely studied in other domains such as social media [42]. For example, Li et al. [22] investigated the impact of acquiring user interests via surveys or questionnaires on course recommendations. In [2], the authors proposed LeCoRe which exploits user interest modeling for recommending courses as well as similar users for promoting peer learning in enterprise environment. Gong et al. [13] argued that course recommendations overlook user interests regarding specific knowledge concepts, and studying users' online learning interests from a microscopic view and recommending knowledge concepts can capture user interests better and provide the flexibility of choosing learning resources of their interest. In this work, we also focus on the microscopic view for knowledge concept recommendations.

Recommendation Approaches with HIN. The basic idea of early recommendation approaches with HIN is to leverage path-based semantic relatedness between users and items over HINs, e.g., leveraging meta-path-based similarities for recommendation [40, 32, 41]. For example, Shi et al. [32] proposed predicting item ratings based on those from similar users measured via different meta-paths. With the advances of graph representation learning, the authors in [31] proposed using pre-trained user and item embeddings based on meta-path information with random walk, and incorporated those pre-trained embeddings as features into an extended matrix factorization framework. The most similar work to ours is Gong et al. [13], which is one of the first works for recommending knowledge concepts on MOOC platforms in a heterogeneous view. The authors showed that their proposed approach outperforms other CF-based baselines as well as metapath2vec [11], which uses learned node representations of a given HIN for knowledge concept recommendations by measuring the similarities between two nodes. Our work differs from [13] in several aspects. First, we formulate interacted concepts for each user as implicit feedback while [13] treated the number of clicks as ratings and formulated the problem as rating prediction for recommending top–k unknown concepts with higher ratings. Secondly, we investigate different attention mechanisms including the one incorporating the latent features of users (items) from matrix factorization. Thirdly, the prediction layer (Eq. 6) for estimating the preference score of a concept is different from [13] which uses the user (item) representations as features for the final prediction.

3. PRELIMINARIES

In this work, we consider the task of predicting and recommending concepts that a user might be interested in based

[4]GitHub repo:`https://github.com/parklize/kgc-rec`

on their learning history, which includes a set of learned concepts and their contextual information such as courses, videos, etc. With n users $\mathcal{U} = \{u_1, \cdots, u_n\}$, and m concepts $\mathcal{C} = \{c_1, \cdots, c_m\}$, we define an implicit feedback matrix $\mathbf{R} \in \mathbb{R}^{n \times m}$ with each entry $r_{u,c} = 1$ if u has learned c and $r_{u,c} = 0$ otherwise. The task can be framed in the context of HIN which is denoted as $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ consisting of a object set $\mathcal{V}$ and a link set $\mathcal{E}$. A HIN is also associated with an object type mapping function $\phi : \mathcal{V} \rightarrow \mathcal{O}$ and a link type mapping function $\psi : \mathcal{E} \rightarrow \mathcal{R}$. $\mathcal{O}$ and $\mathcal{R}$ denote the sets of predefined object and link types, where $|\mathcal{O}|+|\mathcal{R}| > 2$ [33]. The MOOC data in our study can be represented as a HIN. The HIN consists of six types of entities such as *user*, *concept*, *video*, *course*, *school*, and *teacher*. In addition, there is a set of links describing the relationships among those entities. On top of the definition of HIN, the concept of network schema is used to describe the meta structure of a network [31].

The **network schema** [35] is denoted as $\mathcal{S} = (\mathcal{O}, \mathcal{R})$. It is a meta template for an information network $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ with the object type mapping $\phi : \mathcal{V} \rightarrow \mathcal{O}$ and the link type mapping $\psi : \mathcal{E} \rightarrow \mathcal{R}$, which is a directed graph defined over object types $\mathcal{O}$, with edges as links from $\mathcal{R}$. Fig. 1 shows the network schema of our MOOC dataset with the six different entity types and the semantic links between them. Given the network schema, we can extract semantic meta-paths between a pair of entities. A meta-path can be formally defined as follows:

A **meta-path** [34] MP is defined on a network schema $\mathcal{S} = (\mathcal{O}, \mathcal{R})$ and is denoted as a path in the form of $O_1 \xrightarrow{R_1} O_2 \xrightarrow{R_2} \cdots \xrightarrow{R_l} O_{l+1}$, which describes a composite relation $R = R_1 \circ R_2 \circ \cdots \circ R_l$ between object O_1 and O_{l+1}, where $\circ$ denotes the composition operator on relations.

4. PROPOSED APPROACH

In this section, we introduce our proposed approach `MOOCIR` (MOOC Interest Recommender) based on meta-paths in the MOOC HIN. In high level, our approach extends the matrix factorization (MF) $\hat{y}_{u,c} = \mathbf{x}_u^T \mathbf{z}_c$, where $\hat{y}_{u,c}$ denotes the predicted preference score of concept c with respect to user u, and $\mathbf{x}_u$ and $\mathbf{z}_c$ refer to *latent features* of u and c, respectively. We extend the MF with user (concept) representations/embeddings that are learned by applying GCNs to meta-path-based graphs. Fig. 2 shows an overview of our approach, which consists of four main components. In the following, we describe each component in detail.

Table 1: Meta-paths selected for extracting user-user and concept-concept relationships.

Type	Meta-path
User	$user \rightarrow concept \xrightarrow{-1} user$
	$user \rightarrow course \xrightarrow{-1} user$
	$user \rightarrow video \xrightarrow{-1} user$
	$user \rightarrow course \rightarrow teacher \xrightarrow{-1} course \xrightarrow{-1} user$
Concept	$concept \rightarrow user \xrightarrow{-1} concept$
	$concept \rightarrow course \xrightarrow{-1} concept$

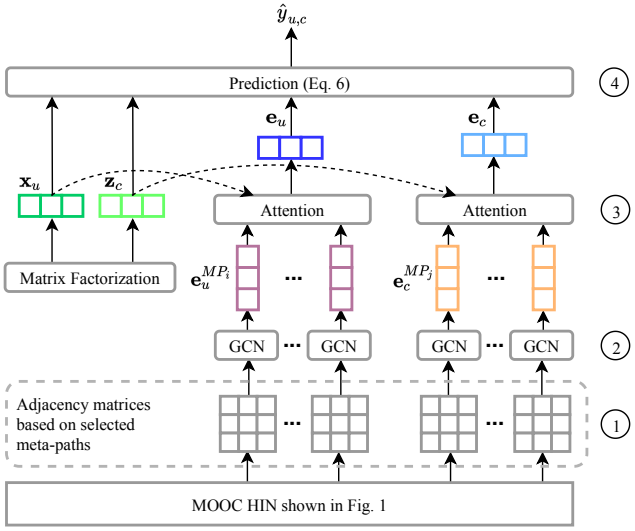

Figure 2: Overview of our proposed approach `MOOCIR`.

Meta-path selection. As discussed in Section 3, meta-paths provide the capability to derive entity-entity relationships through those paths. Similar to previous studies [13, 31], we consider user-user and concept-concept relationships via different meta-paths. To fairly compare with [31] in our experiments, we use the same set of meta-paths used in [31] for our study. Table 1 summarizes six meta-paths used for our work where four paths for users and two for concepts. For each meta-path, a homogeneous graph with respect to users (concepts) can be extracted, which is depicted as its corresponding adjacency matrix in Fig. 2. As one might expect, each entry in the adjacency matrix $\mathbf{A}$ regarding a meta-path is equal to one if two users (concepts) can be connected via that meta-path, and zero otherwise. Afterwards, we can learn user (concepts) representations for each meta-path using GCNs.

Graph Convolution Networks (GCNs). GCNs learn node representations of a graph by inspecting neighboring nodes. In this work, we adopt the following layer-wise propagation rule to learn user (concept) representations/embeddings with respect to a meta-path.

$$\mathbf{h}^{(l+1)} = g(\mathbf{P}\mathbf{h}^l\mathbf{W}^l) \tag{1}$$

where $g(\cdot)$ is an activation function which we use $ReLu$ [25] here. $\mathbf{P} = \mathbf{D}^{-1}\widetilde{\mathbf{A}}$ where $\mathbf{D}$ is the diagonal node degree matrix of $\mathbf{A}$ to normalize the matrix $\widetilde{\mathbf{A}}$, and $\widetilde{\mathbf{A}} = \mathbf{A} + \mathbf{I}$ is an adjacency matrix with self-loops in a graph based on a specific meta-path. $\mathbf{W}^l$ refers to a trainable weight matrix at layer l for all nodes. $\mathbf{h}^0$ can be fed with features of each node if there is a set of features for each node or can be initialized and learned afterwards as well. The output representation of the last layer can be used as user (concept) representations. For example, when $l = 2$, the representation of a user u for a meta-path MP_i will be $\mathbf{e}_u^{MP_i} = \mathbf{h}^3_{u_{MP_i}}$ where $\mathbf{h}^3_{u_{MP_i}}$ is the output of the last layer of GCNs for the meta-path MP_i with respect to u. In our study, we use a single layer GCN where $\mathbf{h}^0$ is initialized randomly and learned during the training process, but one can easily extend it with more

layers or using existing features for $\mathbf{h}^0$.

Attention. Attention mechanism [36] is motivated by how we pay visual attention to different regions of an image or relevant words in one sentence, and has been used widely to advance various fields such as natural language processing and recommender systems [37, 13]. In our context, different meta-paths can have different importance with respect to each user, and incorporating the importance of each meta-path differently for each user can be beneficial when aggregating user representations from different meta-paths, i.e., $\{\mathbf{e}_u^{MP_1} \dots \mathbf{e}_u^{MP_{|MP|}}\} \rightarrow \mathbf{e}_u$. In our work, we apply the attention mechanism from [6] for our context as follows:

$$\alpha_u^{MP_i} = \frac{exp(\mathbf{V}_u^T \sigma(\mathbf{W}_u \mathbf{e}_u^{MP_i}))}{\sum_{j \in |MP|} exp(\mathbf{V}_u^T \sigma(\mathbf{W}_u \mathbf{e}_u^{MP_j}))} \tag{2}$$

where the output $\alpha_u^{MP_i}$ indicates the weight (or importance) for $\mathbf{e}_u^{MP_i}$, and $\mathbf{V}_u^T$ and $\mathbf{W}_u$ are trainable matrices for users. The attention mechanism can be formulated in the same manner for concepts. Next, the user representations coming from different meta-paths can be aggregated as follows:

$$\mathbf{e}_u = \sum_{j \in |MP|} \alpha_u^{MP_j} \mathbf{e}_u^{MP_j} \tag{3}$$

The above-mentioned attention mechanism takes into account different meta-paths but does not consider any context in the extended MF, which can be the latent features of users and concepts for MF. Therefore, we also investigate the following attention mechanism which considers the latent features of user $\mathbf{x}_u$, which has not been explored in previous studies. In this case, a meta-path based embedding $\mathbf{e}_u^{MP_i}$ and $\mathbf{x}_u$ are concatenated together when calculating the attention scores as follows.

$$\beta_u^{MP_i} = \frac{exp(\mathbf{V}_u^T \sigma(\mathbf{W}_u [\mathbf{e}_u^{MP_i}; f(\mathbf{x_u})]))}{\sum_{j \in |MP|} exp(\mathbf{V}_u^T \sigma(\mathbf{W}_u [\mathbf{e}_u^{MP_j}; f(\mathbf{x_u})]))} \tag{4}$$

where $f(\mathbf{x_u})$ applies non-linearity with a single layer feed-forward neural networks to $\mathbf{x_u}$ instead of using it directly, which is inspired by [31] where the authors showed that non-linear fusion is required when combining latent features from matrix factorization and entity embeddings from GCNs. Afterwards, the final user representation can be obtained in the same manner as Eq. 3.

$$\mathbf{e}_u = \sum_{j \in |MP|} \beta_u^{MP_j} \mathbf{e}_u^{MP_j} \tag{5}$$

The attention mechanism can be formulated in the same manner for concepts.

Prediction. Given those learned user and concept representations/embeddings $\mathbf{e}_u$ and $\mathbf{e}_c$. The preference score of a concept c for a user u can be calculated as follows by extending the matrix factorization framework:

$$\hat{y}_{u,c} = \mathbf{x}_u^T \mathbf{z}_c + \gamma \cdot \mathbf{e}_u^T \mathbf{M} \mathbf{e}_c + b_c \tag{6}$$

where $\hat{y}_{u,c}$ is the preference score, $\mathbf{x}_u$ and $\mathbf{z}_c$ are the latent features for the matrix factorization, and b_c is a bias term. In addition, $\mathbf{M}$ is a trainable matrix to let $\mathbf{e}_u$ in the same space with $\mathbf{e}_c$, and γ is a trainable parameter for the trade-off between the prediction scores from matrix factorization and the user and concept embeddings.

4.1 Training Details

Loss function. We use the Bayesian Personalized Ranking (BPR) [29] which has been widely used for recommender systems with implicit feedback [7, 5, 27]. The intuition behind BPR is that a learned concept for a user should be ranked higher (with a higher score) compared to a random one in the list of concepts with which the user has not interacted, which can be formulated as follows:

$$\mathcal{L} = \sum_{(u,i,j) \in D_s} -ln(\sigma(\hat{y}_{uij})) + \lambda \left\| \Theta \right\|^2 \tag{7}$$

where (u, i, j) refers to a triplet including a user u, an interacted concept i and an unknown concept j for the user. $\hat{y}_{uij} = \hat{y}_{ui} - \hat{y}_{uj}$ measures the preference difference between the interacted concept and the unknown one, σ denotes the *sigmoid* function: $s(x) = \frac{1}{1+e^{-x}}$, λ is the regularization parameter for the $\mathcal{L}_2$ norm, and Θ denotes the set of parameters to be learned. The training set D_s can be constructed by paring an unknown concept randomly with an interacted concept in the training set of a user.

To learn the parameters of our proposed approach for minimizing the loss in Eq. 7, we use a mini-batch gradient decent with 1,024 as the batch size, and use the Adam update rule [20] to train the model using the training set. In addition, the learning rate is set as 0.01, the regularization parameter λ is set as $1e-8$, and the dimension of latent features for MF and that of user (concept) embeddings are set as 30 and 100 respectively as in [13].

To overcome the overfitting problem, we further construct a validation set by using the last interacted concept for each user, and randomly pair each known concept with 99 unknown concepts. We run 500 epochs where the convergence is observed, and monitor the performance of evaluation metrics (see Section 5) on the validation set. At the end, we choose the best-performing model on the validation set in terms of *MRR* (Mean Reciprocal Rank), which is one of the evaluation metrics measuring how well a ground truth concept is ranked in the corresponding set of 100 concepts. Any other evaluation metric can be used for choosing the best-performing model as well based on the preference for a specific metric.

5. EXPERIMENTAL SETUP

MOOC Dataset. We use the MOOCCube dataset [39] from the XuetangX platform for our experiments. The MOOCCube dataset is one of the largest and comprehensive MOOC datasets, and provides rich information about MOOCs and user activities on the platform from 2017 to 2019 [39]. Each course or video has a set of covered knowledge concepts in the dataset. In this work, we use user activities from 2017-01-01 to 2019-10-31 for training and those from 2019-11-01 to 2019-12-31 for testing. We limit users who have learned concepts in both training and testing periods and have at least one new concept (which did not appear in the training

Table 2: Statistics of the MOOCCube dataset for experiments.

Entities	Statistics	Relations	Statistics
users	2,005	user-concept	930,553
concepts	21,037	user-course	13,696
courses	600	course-video	42,117
videos	22,403	teacher-course	1,875
schools	137	video-concept	295,475
teachers	138	course-concept	150,811

period) in the testing period. Overall, the dataset consists of 2,005 users 21,037 concepts, 600 courses, 22,403 videos, 137 schools, 138 teachers, and the relationships among those entities. In total there are 930,553 interactions between users and concepts with 858,072 interactions in the training set and the rest (72,481) in the test set. The overall statistics of the dataset are presented in Table 2.

Evaluation Metrics. We evaluate the top–k predictions of concepts for users with the following widely used evaluation metrics where k is set to 5, 10, and 20. We calculate all metrics for each set of 100 concepts (with one interacted and 99 unknown) in the test set. For each interacted concept with respect to a user u, we generate the corresponding recommendation list $R_u = \{r_u^1, r_u^2, \ldots, r_u^k\}$ where r_u^i indicates concept ranked at the i–th position in R_u based on the predicted scores of those concepts.

Hit Ratio of top–k concepts ($HR@k$) measures the fraction of relevant concepts in the test set that are in the top–k concepts of the recommendations: $HR@k = \frac{1}{N}\sum_u I(|R_u \cap T_u|)$ where N is the total number of sets for testing, $I(x)$ is an indicator function which equals one if $x > 0$ and equals zero otherwise. *Normalized Discounted Cumulative Gain* ($nDCG@k$) takes into account rank positions of the relevant concepts, and can be computed as follows:$nDCG@k = \frac{1}{Z}DCG@k = \frac{1}{Z}\sum_{j=1}^{k}\frac{2^{I(|r_u^j \cap T_u|)}-1}{\log_2(j+1)}$ where Z denotes the score obtained by an ideal top–k ranking which serves as a normalization factor. *Mean Reciprocal Rank* (MRR) is the average of the reciprocal ranks of positive concepts: $MRR = \frac{1}{N}\sum_1^N \frac{1}{rank_i}$ where $rank_i$ refers to the rank position of the one interacted concept in the corresponding set of 100 concepts with the rest of unknown ones.

We use the paired *t-test* for testing the significance where the significance level of α is set to 0.05 unless otherwise noted.

5.1 Compared Methods

To better understand and investigate the contribution of each component and the performance with the two attention mechanisms introduced in Section 4, we first compare several variants of our approach. $\texttt{MOOCIR}_{\text{a1}}$ denotes our approach with the attention mechanism only considering different meta-paths using Eq. 3. $\texttt{MOOCIR}_{\text{a2}}$ refers to our approach with the attention mechanism incorporating the latent features of users (concepts) using Eq. 4. $\texttt{MOOCIR}_{\text{a-}}$ is a variant of our approach without any attention, i.e., different meta-paths are treated *equally* and the representations learned from those paths are averaged. $\texttt{MOOCIR}_{\text{mf-}}$ refers to a variant without the matrix factorization part for prediction in Eq. 6, which only uses meta-path-based user and concept representations for predicting the preference score of a concept.

Next, we compare `MOOCIR` with the following baselines and state-of-the-art methods to evaluate the performance of recommending knowledge concepts for users. `TopPop` is a straightforward baseline method which ranks concepts based on their popularity. Here, the popularity of a concept can be measured based on the number of users that have learned the concept. `MFBPR` [29] is a matrix factorization approach which optimizes a pairwise ranking loss for the recommendation task as our approach but without meta-path-based representation learning. That is, the second component in Eq. 6 based on user (concept) representations is removed. `FISM` [17] is an item-to-item collaborative filtering approach which provides recommendations based on the average embeddings of all interacted concepts and the embeddings of the target concept. `NAIS` [15] is also an item-to-item collaborative filtering approach, but with an attention mechanism, which is capable of distinguishing which historical items in a user profile are more important for a prediction. We use the author's implementation for both `NAIS` and `FISM`[5]. `metapath2vec` [11]. `metapath2vec` is a meta-path-based representation learning model which leverages meta-path-based random walks to construct the heterogeneous neighborhood of a node and then leverages a heterogeneous skip-gram model to learn node embeddings. We use the StellarGraph [10] implementation of `metapath2vec` for our experiment in which the parameters of `metapath2vec` are set the same as in [11] except the number of random walks is set as 500 instead of 1000[6]. `ACKRec` [13] also models the MOOC dataset as a HIN and extracts user (concept) representations from the same set of meta-paths in Table 1. However, `ACKRec` treats the problem as rating prediction task where the rating of a concept for a user is the number of interactions between the user and the concept. Also, it exploits user and concept representations as features while extending the matrix factorization framework. We use the author's implementation[7] for our experiments. `MFBPR` and those `MOOCIR` variants are implemented using Tensorflow [1]. All experiments are run on an Intel(R) Core(TM) i5-8365U processor laptop with 16GB RAM, and `MOOCIR` variants take less than two days for training.

6. RESULTS

Table 3 summarizes the results using the variants of `MOOCIR`. As we can see from the table, $\texttt{MOOCIR}_{\text{mf-}}$ — which uses user and concept representations learned based on meta-paths with the HIN but without the matrix factorization component — provides worse performance compared to the other variants. The results indicate that extending the matrix factorization is necessary for `MOOCIR`.

Next, we compare $\texttt{MOOCIR}_{\text{a-}}$ and the variants with attention mechanisms (i.e., $\texttt{MOOCIR}_{\text{a1}}$ and $\texttt{MOOCIR}_{\text{a2}}$). We observe that both $\texttt{MOOCIR}_{\text{a1}}$ and $\texttt{MOOCIR}_{\text{a2}}$ outperform $\texttt{MOOCIR}_{\text{a-}}$ in terms of all evaluation metrics, which shows that using at-

[5] `https://github.com/AaronHeee/Neural-Attentive-Item-Similarity-Model`

[6] We noticed that using 1000 random walks took more than 10 days for training and did not improve the performance compared to using 500.

	HR			*nDCG*			*MRR*
	k=5	10	20	k=5	10	20	
MOOCIR$_{mf^-}$	0.676	0.812	0.906	0.499	0.543	0.567	0.468
MOOCIR$_{a^-}$	0.701	0.832	0.920	0.513	0.556	0.578	0.477
MOOCIR$_{a1}$	**0.704**	0.836	**0.922**	**0.520**	**0.562**	**0.584**	**0.484**
MOOCIR$_{a2}$	0.703	**0.838**	**0.922**	0.517	0.561	0.583	0.482

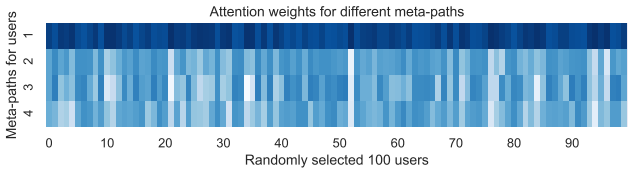

Figure 3: Attention weights of different meta-paths for 100 randomly chosen users learned using MOOCIR$_{a1}$ where we observe different weights of meta-paths for each user. In this heatmap, a darker cell indicates a higher attention weight.

tention can indeed improve the performance and different meta-paths have different importance for deriving user (concept) representations. This can be verified further by investigating learned attention weights for different meta-paths in MOOCIR as well. For example, Fig. 3 shows a heatmap regarding the learned attention weights for 100 randomly selected users using MOOCIR. In the figure, x-axis refers to the 100 users and y-axis indicates the attention weights for the four different meta-paths for users described in Table 1 in Section 4. From the figure, we can notice that the first meta-path (i.e., $user \rightarrow concept \xrightarrow{-1} user$) overall has a higher weight compared to others. In addition, we observe that the attention weights vary across users, which indicates the importance of each meta-path varies for different users.

Finally, by comparing the two different attention mechanisms, we observe that the one incorporating the latent features of users and concepts (Eq. 4) does not improve the performance compared to the simpler one (Eq. 3), which is different from our assumption. Instead, we observe that MOOCIR$_{a2}$ performs significantly worse than MOOCIR$_{a1}$ in terms of *HR@10* and *HR@20* for the users who have interacted with a limited number of concepts. Table 4 shows the performance for three groups of users with less than 150, 350, and 550 concepts, respectively. As we can see form the figure, MOOCIR$_{a1}$ outperforms MOOCIR$_{a2}$ significantly for the first group of 353 users. The results suggest that fusing information from the latent features of users (concepts) into the attention mechanism is a non-trivial task, and other approaches should be investigated in the future.

Table 4: Results of *HR@10* and *HR@20* for MOOCIR$_{a1}$ and MOOCIR$_{a2}$ for three groups of users (G150, G350, G550) with less than 150, 350, 550 concepts in the training set.

	HR@10			*HR@20*		
	G150	G350	G550	G150	G350	G550
MOOCIR$_{a1}$	0.806	0.830	0.851	0.894	0.911	0.927
MOOCIR$_{a2}$	0.801	0.829	0.852	0.886	0.908	0.925

Table 5: Performance of MOOCIR$_{a1}$ and compared methods in term of different evaluation metrics with the best-performing scores in bold.

	HR			*nDCG*			*MRR*
	k=5	10	20	k=5	10	20	
TopPop	0.486	0.629	0.767	0.343	0.390	0.425	0.332
MFBPR	0.668	0.811	0.907	0.481	0.527	0.552	0.448
FISM	0.584	0.701	0.800	0.438	0.476	0.501	0.418
NAIS	0.568	0.691	0.811	0.420	0.461	0.491	0.403
metapath2vec	0.642	0.773	0.873	0.468	0.511	0.537	0.440
ACKRec	0.659	0.764	0.842	0.503	0.538	0.557	0.475
MOOCIR$_{a1}$	**0.704**	**0.836**	**0.922**	**0.520**	**0.562**	**0.584**	**0.484**

Overall, MOOCIR$_{a1}$ provides the best performance among all variants. In the following, we discuss the performance of MOOCIR$_{a1}$ compared with other baselines and state-of-the-art methods.

Table 5 shows the performance of MOOCIR$_{a1}$ and compared methods. We first observe that all the other methods outperform TopPop which is a baseline method recommending popular concepts. For example, MOOCIR$_{a1}$ and ACKRec improves *MRR* over TopPop 45.8% and 43.1%, respectively. Among all the compared methods in Table 5, MOOCIR$_{a1}$ provides the best performance followed by ACKRec, MFBPR, and metapath2vec. ACKRec performs best in terms of *nDCG* and *MRR*, and MFBPR performs best in terms or *HR* among compared methods. In detail, a significant improvement of MOOCIR$_{a1}$ over ACKRec in *MRR* (+1.9%), *nDCG@5* (+3.1%), *nDCG@10* (+4.5%), *+nDCG@20* (4.8%) can be noticed ($\alpha < 0.01$). Compared to MFBPR, MOOCIR$_{a1}$ improves the *HR* scores 6.7%, 9.2%, and 9.4% when k =5, 10, 20, respectively ($\alpha < 0.01$). The two item-item CF methods (FISM and NAIS) do not perform well compared to MFBPR and ACKRec. One possible explanation might be due to the sparsity of the dataset, which makes that deriving item-item similarities based on interacted users for each item is challenging and limits the performance.

Those results indicate that the proposed approach MOOCIR$_{a1}$ can achieve competitive performance in terms of those evaluation metrics for top–k concept recommendations compared to the baselines and state-of-the-art methods.

7. CONCLUSIONS AND FUTURE WORK

In this paper, we presented MOOCIR for predicting and recommending concepts that might be of users' interest on MOOC platforms. The comparison of MOOCIR variants in Section 6 shows that extending the matrix factorization with user and concept representations learned from different meta-paths and using attention for deriving those representations play crucial roles in achieving better performance. In addition, the results compared to other baselines and state-of-the-art methods indicate that MOOCIR$_{a1}$ can improve the performance of predicting and recommending concepts significantly. The comparison between the two introduced attention mechanisms (Eq. 3 and 4) suggests that a more comprehensive approach is required while fusing the latent features of users and concepts into the attention mechanism, which will be investigated in the near future.

Automatic Assessment of the Design Quality of Python Programs with Personalized Feedback

ABSTRACT

The assessment of program functionality can generally be accomplished with straight-forward unit tests. However, assessing the design quality of a program is a much more difficult and nuanced problem. Design quality is an important consideration since it affects the readability and maintainability of programs. Assessing design quality and giving personalized feedback is very time consuming task for instructors and teaching assistants. This limits the scale of giving personalized feedback to small class settings. Further, design quality is nuanced and is difficult to concisely express as a set of rules. For these reasons, we propose a neural network model to both automatically assess the design of a program and provide personalized feedback to guide students on how to make corrections. The model's effectiveness is evaluated on a corpus of student programs written in Python. The model has an accuracy rate from 83.67% to 94.27%, depending on the dataset, when predicting design scores as compared to historical instructor assessment. Finally, we present a study where students tried to improve the design of their programs based on the personalized feedback produced by the model. Students who participated in the study improved their program design scores by 19.58%.

Keywords

Assessment, neural networks, intelligent tutoring

1. INTRODUCTION

Recently there has a been a lot of work in the development of tools for education in programming and computer science. Specifically there are many systems for intelligent tutoring which are designed to help students learn how to solve a programming challenge. The tutoring involved is primarily focused in suggesting functional improvements, that is, how to finish the program so that it works correctly.

Intelligent tutors such as [4] uses reinforcement learning to predict a useful hint in the form of an edit to a student's program that will get them one step closer to the goal of a functioning program. It uses histories of edits made by students, starting with a blank slate and ultimately terminating with a functional program to train the model. The system is based on *Continuous Hint Factory* [9] which uses a regression function to predict a vector that represents the best hint then translates that vector into a human-readable edit. Similarly [11] used a neural network to embed programs and predict the program output. Using that model of the program output, an algorithm was developed to provide feedback to the student on how to correct their program. Also, [16] use a recurrent neural network to predict student success at a task given a history of student submissions of their program for evaluations.

All these systems model student programs from *Hour of Code* [2]. *Hour of Code* is a massively open online course platform that teaches people how to code with a visual programming language. The language is simple and does not contain control constructs such as *loops*.

Moreover, the combination of language and problem setting are simple enough that there is a single or very few functional solutions for each problem [4]. This level of simplicity precludes the consideration of program design. However for general purpose programming languages such as Python, there are many ways of creating functionally equivalent programs. It is important for the sake of maintainability, modularity, clarity, and re-usability that students learn how to design programs well.

When it comes to the quality of design, there are varying standards. Further, some standards are more objective or easier to precisely identify that others. For example, the use of global variables are both widely recognized as poor design and are easy to identify. For some programming languages, "linters" exist to apply rules to check for common design flaws. For Python, Pylint [12] is a code analysis tool to detect common violations of good software design. It detects design problems such as the use of global variables, functions that are too long or take too many arguments, and functions that use too many variables. Pylint is design to enforce the official standards of the Python programming community codified in PEP 8 [15].

There are aspects of good design that are difficult to identify. For example, simple logic is a good design idea, but is quite nebulous. The complexity of a program's logic is con-

Walker Orr and Nathaniel Russell "Automatic Assessment of the Design Quality of Python Programs with Personalized Feedback". 2021. textual, it entirely depends on the problem the program is solving. Also, modularity is universally judged as a quality of good design, however it is not always clear to what extent a program should be made modular. How many functions or classes are too many? Again, it depends on the context of the problem for which the program is designed.

In a professional setting, code reviews are often practiced to promote quality design that goes beyond the straightforward rules of "linters." Code reviews are a manual process which require a lot of human effort. A recently developed system call DeepCodeReviewer [5] automates the code review process with a deep learning model. By using proprietary data on historical code reviews taken from a Microsoft software version control system, DeepCodeReviewer was trained to successfully annotate segments of C# code with useful comments on the code's quality.

However, to our knowledge, there is no system to perform in-depth code analysis for the purposes of evaluating and assessing design for general purpose languages in an educational context. The process of assessing the design of a program is time consuming for instructors and teaching assistants and it is an important component of complete intelligent tutoring system. Such a system needs to be adjusted or calibrated for the context of particular problems or assignments since there are important aspects of software design are context dependent. Moreover the system needs to match the particular standards of an instructor. Hence we propose a system that models design quality with a neural network trained on previously assessed programs.

1.1 Our Approach and Contribution

We propose a design quality assessment system based on a feed-forward neural network that utilizes an abstract syntax tree (AST) to represent programs. The neural network is a regression model that is trained on assessed student programs to predict a score between zero and one. Each feature the model uses is designed to be meaningful to human interpretation and is based on statistics collected from the program's AST. We intentionally do not use deep learning as it would make the representation of the program difficult to understand. Personalized feedback is generated based on each feature of an individual program. By swapping a feature's value for an individual program with the average feature value of good programs, it is possible to determine which changes need to be made to the program to improve is design. The primary contributions of this work are the following:

- The first to explicitly predict the design quality of programs in an educational setting to the best of our knowledge.
- High efficacy with an accuracy from 83.67% to 94.27% with only small amounts of training data required.
- The first intelligent tutoring system for design quality for Python.
- Personalized feedback without the explicit training or annotation.

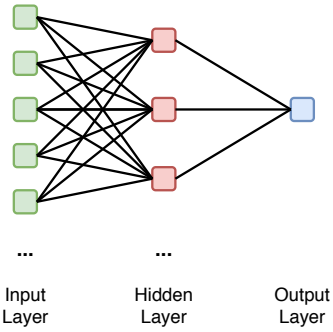

Figure 1: The model of program design quality, a feed-forward neural network. The "Input Layer" is the feature vector created from the AST. The "Hidden Layer" corresponds to calculation of x' specified in Equation 1. Finally, the "Output Layer" produces a single value, the design score as found in Equation 2.

2. METHOD

The task is to predict a design quality score for a student program written in Python. The score y is a real number between zero and one. The program is represented by a feature vector $\vec{x}$ produced by the output of a series of feature functions computed from the program's AST.

For an AST T, a series of feature functions $f_i((T)$ output is concatenated in to a feature vector $\vec{x}$ that represents key aspects of the program's design. The model $g(\vec{x}; \Theta)$ is a feed-forward neural network with a single hidden layer. It is a regression model that predicts the score y based on the feature vector $\vec{x}$ and parameters Θ.

2.1 Features

Despite recent advances in deep learning, we chose to represent the student program with feature functions computed on its AST. Deep learning is highly effective at learning useful feature representations of everything from images to time series to natural language texts. However, deep learning also requires large amounts of data and in this setting the quantity of manual annotated student programs is limited.

Additionally, AST are a natural and effective means of representing and understanding programs and can be created with free, available tools. An AST is an exact representation of the source code of program based on the programming language's grammatical structure. Producing an AST representation of a programming language is an essential first step in compilers and interpreters. The AST of a program contains all the content of its source but also is augmented with the syntactic relationships between every element. A parser and tokenizer to produce an AST for the Python programming language is provided by its own standard library. This makes the AST the natural representation to use, since it is free, convenient, exact, interpretable, and does not required any additional data. In contrast, deep learning would require a large amount of data to effectively reproduce the same representation.

Prior to representation as an AST, a program must first be broken into a series of tokens via the process of lexicaliza-

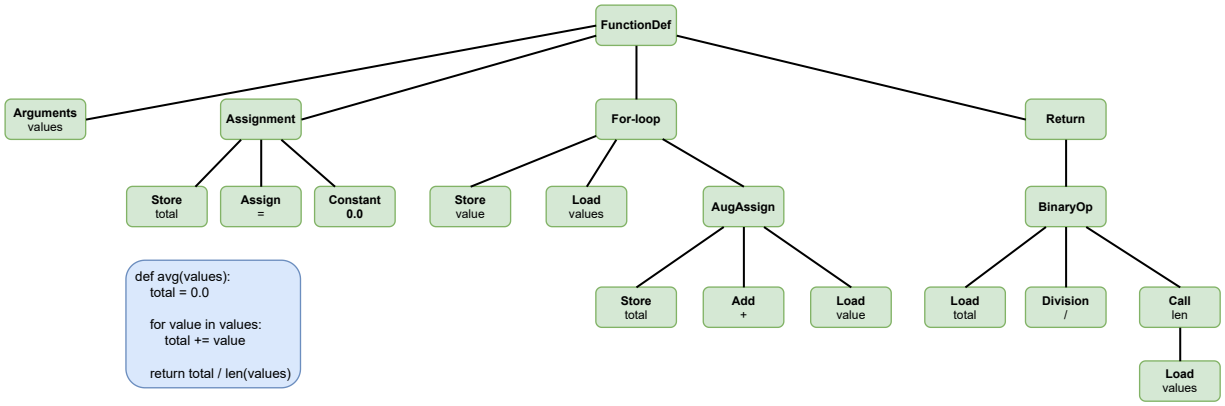

Figure 2: An abstract syntax tree for a segment of Python code that computes the average of the values in a list. The AST has been condensed for the sake of brevity and the restrictions of space. The related code segment is shown in blue.

tion. Lexicalization is the process of reading a program, character-by-character and dividing into work-like tokens. These tokens are also assigned a type such as a function call or variable reference. The grammatical rules of the language are applied to the lexicalized program to create the AST. In an AST, the leaf nodes of the tree are the program's tokens while the interior nodes correspond to syntactic elements and constructions. For example, an interior node could represent the body of a function or the assignment of a value to a variable. An example of an AST is found in Figure 2.

Given that an AST is a complete representation of a program, it is a natural basis for assessing the quality of a program's design. Deep learning may be able to automatically learning the same key syntactic relationships with enough data, however this information is simply available via AST. Further, features computed from the AST will be human interpretable unlike a representation produced by deep learning.

The features we created are all based on statistics collected from a program's AST. Some consist of simply counting the number of nodes of a given type, for example, the number of user defined functions. Other feature functions are based of subsections of the AST, such as the number of nodes per line or per function. Finally, some features are ratios or percentages such as the average percent of lines in a number in a function that are empty. All of the features are relatively simple and fast to compute, yet generally capture the design and quality of a program. Each of the feature functions $f_i(T)$ we defined can be found in Appendix A.

2.2 Model

The model is a feed-forward neural network [13] with a single hidden layer and single neuron in the output layer. The model's structure is illustrated in Figure 1. The values of the input layer are the feature vector $\vec{x}$. Each neuron in the hidden layer x'_j defined with the following equation:

$$x'_j = \text{ReLU}\left(\sum_{i=1}^{d} w_{i,j} x_i\right) \tag{1}$$

where d is the dimension of $\vec{x}$ and $w_{i,j} \in \Theta$ are the parameters, "weights" of the neuron. We use the ReLU [8] as the activation function for the hidden layer neurons. The final prediction of the design score is made by the output layer's single neuron:

$$y = \sigma\left(\sum_{j=1}^{d'} w_j x'_j\right) \tag{2}$$

where d' is the number of hidden layer neurons and $w_j \in \Theta$ are weights of this neuron. The function sigmoid is used because its domain spans from $(-\infty, \infty)$ but its range is $[0, 1]$ which ultimately guarantees the model always outputs a valid score. The model is trained with mean squared error as the loss function:

$$\text{MSE} = \frac{1}{n}\sum_{k=1}^{n}(y^*_k - y_k)^2 \tag{3}$$

where y^*_k is the ground-truth design score for the k^{th} instance i.e. program and n is the number of instances in the training data. The model is trained with the ADAM algorithm [7] and each parameter in the model was regularized according to their L2 norm [6]. For all our experiments, a hidden layer of size 32 was used. The model was trained for 250 epochs and the model from the best round according to a development set was selected for our experiments.

2.3 Ensemble

Due to the fact that fitting neural networks to data is a local optimization problem, the effect of initial values of the parameters Θ of the model remain after training. The process of training a neural network will produce a different model given the same data. This variation in the results of a trained model is particularly pronounced when the training data set is relatively small. To address this variation and mitigate its impact an ensemble of models can trained, each with different initial parameter values. Each model is independently trained and a single prediction is made by a simple of the average of individual predictions i.e.

$$y = \frac{1}{m}\sum_{l=1}^{m} y_l \tag{4}$$

where m is the number of models and y_l is the prediction of the l^{th} model. For our experiments, an ensemble of 10 models was used.

2.4 Personalized Feedback

The goal of intelligent tutors is to provide personalized feedback and suggestions on how to improve a program. The most straight-forward means of providing feedback would be to simply predict which possible improvements apply to a given program. However, training a model to directly predict relevant feedback would require a dataset of program with corresponding feedback and such a dataset can be hard to find or is expense to construct.

In order to avoid the need for a dataset with explicit feedback annotation, we use our model, trained on predicting design score, to evaluate how changes in program features would lead to a higher assessed score. Using the training data, we compute an average feature vector $\underline{\vec{x}}$ of all the "good" programs i.e. those with a design score greater than 0.75. To generate feedback for a program, its feature vector $\vec{x}$ is compared to the average $\underline{\vec{x}}$. For each feature, a new vector $\vec{x}'$ is created by replacing the feature value x_i with value with the average's value $\underline{x}_i$. This process is setting up a hypothesis, what if the program was closer to the average "good" program with regards to a particular feature? To answer this, the trained model $g(\vec{x};\vec{\theta})$ is used to predict a design score for the new vector i.e. $y_i' = g(\vec{x}';\vec{\theta})$. By comparing the original score of the program y with the new score y_i', the hypothesis can be tested. If the new score y_i' is greater than the original predicted score y, then the alteration of x_i to be closer to $\underline{x}_i$ is an improvement. Feedback based on this alteration is recommended to the student as personalized feedback. Since each feature in $\vec{x}$ is understandable to a human, feedback is given in the form of the suggestion to increase or decrease particular features. The suggestion for alteration is based on the comparison of x_i versus $\underline{x}_i$, if $x_i > \underline{x}_i$, the feedback of decrease x_i is given. In the other case, where $x_i < \underline{x}_i$ the feedback is to increase x_i. Based on the feature and the feedback of increase or decrease, a user-friendly sentence is selected from a table of predefined responses. For example, if x_i is the number of user defined functions and $x_i = 3$, $\underline{x} = 5$, and $y_i' > y$ then the feedback of "increase the number of user defined functions" is created.

3. EXPERIMENTS

The system was evaluated in two different experimental settings. The first evaluation is direct test of the model's accuracy on known design scores. For this, several different datasets and settings were compared against several baselines. The second evaluation is a small study of how student's responded to the system's feedback. Students were given feedback on the quality of their programs based on the model. They were given the chance to correct their programs after receiving feedback and have it manually reassessed.

3.1 Dataset

The dataset was collected over three years from an introduction to computer science course which teaches Python 3. It consists of four separate programming assignments which involve a wide range of programming skills. The simplest is "Travel," an assignment that involves the distance a vehicle travelled after going a constant speed for a specified duration. There are 118 student programs for "Travel." The next assignment, "Budget" is a budgeting program that lets a user specify a budget and expenses and determines if they are over or under their budget. 168 student programs were collected for "Budget". The third assignment in the dataset consists of creating a program to play "Rock-Paper-Scissors" against the computer. For this assignment, there are 111 student programs. The last assignment is programming the classic casino game "Craps" which involves rolling multiple dice and placing different types of bets and wagers. This assignment has 120 collected student programs.

All the assignments require the student to write the program from scratch in Python 3. The programs are to have a command-line, text-based interface and user validation. Students are required to use if-statements, loops, user defined functions. The "Craps" program also requires the student to do exception handling, and file I/O. A requirement of the program was to maintain a record of their winnings across sessions of playing the game, hence the results were required to be stored to a file. Also, the standards of design quality go up as the course progresses and since "Craps" is the last assignment, it has the highest standards. Each student program has an associated design score that was normalized to value between zero and one.

3.2 Baseline Methods

The model is compared against a variety of baseline regression methods. The simplest is linear regression, which simply learns a weight per each feature. Next is a regression decision tree which is trained with the CART algorithm [1]. It has the advantage over linear regression in that it can learn non-linear relationships. Non-linearity means a model can learn "sweet-spots" rather than simply having a "more is better" understanding of some features. For example, having some modularity in the form of user defined functions is good, however, too many is cumbersome. The "correct" number of user defined functions likely should fall into a relatively small range. Model selection on the maximum depth of the tree with a development set was used to determine that 10 was the best setting.

However, both of these models have the issue that they are not constrained to produce a score between zero and one, their prediction can be any real number. Hence another baseline method was used, created to be an intermediary step between linear regression and the neural network model. It is a linear model with a sigmoid transformation which guarantees the output be between zero and one. This model is effectively the final layer of the neural network model, i.e. the neural network without the hidden layer. The model is specified by the equation:

$$y = \sigma\left(\sum_{i=1}^{d} w_{i,j} x_i\right) \tag{5}$$

This model is also trained with ADAM [7]. All the baseline models and the neural network are trained with MSE as the loss function.

Method	Travel		Budget		RPS		Craps		Combined	
	MSE	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE	Accuracy	MSE	Accuracy

Table 1: Design Score Prediction Results

3.3 Results

The model was compared versus each baseline in five different settings: the "Travel", "Budget", "Rock-Paper-Scissors", and "Craps" programs, and a combined dataset which includes all the programs. The results of the experiments can be found in Table 1. Each model is evaluated according to two different metrics: MSE and average accuracy. Average accuracy is defined as $\frac{1}{n}\sum_{k=1}^{n}\left(1-|y_k-y_k^*|\right)$.

Overall, the decision tree and the sigmoid-transformed were clearly the two worst models. This was surprising since decision trees are generally thought to be strictly more powerful than linear models. However, decision trees look for highly discriminative features to partition the data into more consistent groups. The under-performance of the decision tree possibly indicates that none of the features were especially indicative of a good or bad design on their own. Instead, the quality of a program is better described by a collection of subtle features, which gives credence to the belief that design quality is nuanced.

The reason sigmoid-transformed linear model under-performed linear regression was likely due to it being trained with ADAM. ADAM does not guarantee convergence to a global optimum like the analytical solution to linear regression. Apparently the restriction on predictions to be within the specified range of zero to one was not important.

Linear regression did surprisingly well, beating both the neural network and network ensemble in the "Craps" and combined datasets, though barely. In those cases, the difference between the ensemble and linear regression was less than a percent. This is likely due to the stability of linear regression's predictions. Though linear regression does not have the power and flexibility of neural networks this can also be a benefit by limiting how wrong their predictions are. Neural networks and even ensembles can make overconfident predictions on outliers or other unusual cases. The "Craps" dataset contained the most complex programs and it is likely a handful of predictions significantly brought down the average.

The network ensemble outperformed the single neural network in every case, which is to be expected. The margin of improvement of the ensemble versus the single neural network in accuracy on the four individual program datasets ranged from 1% to 4%. The network ensemble did the best overall by being the best in most cases or coming in a close second in all the other cases. The importance of using an ensemble is evident on the "Craps" dataset where the individual neural network under-performed significantly. On the other datasets, the neural network outperformed linear regression by a small margin, but on "Craps" the neural network model under-performed the linear regression model by 5%. Again, this is most likely due the instability and variability of neural network predictions i.e. small differences in features can lead to a large difference in the prediction. In the "Craps" dataset, the improvement of the ensemble over the single neural network model illustrates the relative stability of the ensemble's predictions. In every case, the ensemble is superior to the single neural network and had the best overall performance by producing the most accurate results on three of the datasets and effectively tying for the best on the other two.

One noticeable pattern was that all the models performed better on the "Travel" and "Budget" datasets than on the "RPS", "Craps", and combined datasets. Universally, the most difficult dataset was "Craps" which likely lowers the accuracy on the combined dataset. Due to the shifting standards and expectations of student assignments, a model per assignment appears to worthwhile. This is a bit counter-intuitive since there are many common standards and expectations across assignments.

Overall, the network ensemble produced reliable, accurate results when trained per dataset. The accuracy of the ensemble is arguably close to being useful in practical application. Further, comparing the scores of an instructor versus another instructor or even against themselves, the rate of agreement must be less than 100% and with an accuracy of the network ensemble ranging from 83.67% to 94.27%, the model's accuracy is possibly close to a realistic ceiling.

3.4 Feedback Study

In order the evaluate the effectiveness of the personalized feedback, we conducted a small study on the effect of the feedback on the design score of student programs. For the "Rock-Paper-Scissors" program the network ensemble was used to generate personalized feedback for the student programs instead of the usual instructor feedback. The network ensemble was the same as used in the design score experiments, it was trained with prior years worth of student programs. Having received the personalized feedback, students opted into correcting their program for extra credit on their assignment. The feedback was in form of a series of comments, where each comment was "increase" or "decrease" the name of a feature as described in Section 2.4.

The class is an introduction to computer science course with multiple sections and two different instructors. Students from both instructors participated in the study. Out of 73 students enrolled across the sections of the course, 15 stu-

dents chose to opt-in.

The revised programs were assessed again manually for design quality and the scores were compared against the originals. The design score of the programs started at an average of 68.33% and after the feedback and correction the average rose to 87.92%, a 19.58% absolute improvement. Using a paired t-test, the improvement was judged to be significant with a p-value of 0.001.

The results of the study suggest the feedback was generally useful in guiding students to improve the design quality of their programs. The improvement was noticeable to the instructors anecdotally as well. For example, the usage of global variables and "magic numbers" decreased significantly. Though the study does have some caveats including its small sample size and opt-in participation. It could be that those students willing to opt-in are those most willing or able improve with a second chance.

4. CONCLUSIONS & FUTURE WORK

Overall, we proposed a neural network model ensemble for predict the design quality score of a student program and experimentally demonstrated its effectiveness. Further, our system provided personalized feedback based on the difference between a program's feature values and the average features' value of "good" programs. A small study provides evidence that the feedback was of practical use to students. Students were able to improve their programs significantly based on the feedback they received.

There is also evidence that training models per assignment is most effective. However, the model needs to be evaluated on more programming assignments. Further, there is a possibility of utilizing transfer learning [10] to help the model learn what is in common across the assignments.

The feedback given was shown to be effective, but more nuanced feedback could be useful. Specifically, feedback targeted to individual lines or segments of code would possibly help students improve their program's more effectively. However, this may require additional supervision i.e. annotation for explicit training. Active learning [14] or multi-instance learning [3] may be alternatives to gathering additional annotation.

Exploring the Importance of Factors Contributing to Dropouts in Higher Education Over Time

ABSTRACT

The aim of this work is to provide data-driven insights regarding the factors behind dropouts in Higher Education and their impact over time. To this end, we analyzed students' data collected by a Higher Education Institute over the last 11 years and we explored how socio-economic and academic changes may have impacted student dropouts and how these changes may have been reflected or captured by students' data. To analyze the data, we engineered features that may predict student dropouts on three dimensions: academic background, students' performance and students' effort. Then we carried out a correlation analysis to investigate the potential relationship between these features and dropouts, we performed a multivariate analysis of variance (MANOVA) to investigate whether the engineered features change significantly among student cohorts with different admission year and, finally, we carried out a regression analysis to confirm that the engineered features' impact on predicting dropouts changes over the years. The results suggest that the importance of features regarding the academic background of students (such as the students' prior experience with the academic institution), and the effort students make (for example, the number of days students spend on academic leave) may change over time. On the contrary, performance-based features (such as credit points and grades) do interact with time suggesting that performance measures are stable predictors of dropouts over time. On the basis of the findings, we argue that the performance of prediction models for assessing students at risk of dropping out of their studies can be affected by the age of data and we outline the possibility of including a forgetting factor for non-recent data in order to leverage their impact on prediction performance.

dropouts, feature engineering, predictive modeling, higher education

1. INTRODUCTION

Student retention is pivotal for success of an educational institute. To understand the reasons behind dropouts, individual cases of students had to be analyzed on one by one basis. The advent of information technology, the use of digital technologies by educational institutes and the collection of rich data regarding students' background, performance and effort offer the possibility of using advanced analytical approaches, such as machine-learning in order to identify trends and patterns that may indicate students at risk of dropping out from their studies [13].

To ensure quality education, Higher Education Institutes (HEIs) typically offer analytical solutions - such as, learning dashboards - to inform stakeholders (for example, program directors, academic specialists and instructors) with respect to student dropouts [2]. To do so, machine-learning models are typically employed to analyze data collected by Study Information Systems (SISs) and Learning Management Systems (LMSs) and to predict whether a student faces a risk to drop out from their studies [1, 4]. This is a well-established practice but little research has been carried out with respect to the temporal aspects of data, such as the age of data used to train predictive models for assessing dropouts. One may argue that – in terms of predictive performance – the more training data, the better. However, our hypothesis is that the factors affecting dropouts in Higher Education (HE) change significantly over time due to socio-economic conditions [16] and to such an extent that data age may affect the computational model's predictive accuracy.

The goal of this research is to analyze the data collected over 11 years, 2010 to 2020 from the SIS of a national European HEI. The objective is to engineer and identify the important log-based features behind dropouts, how these features may change over years, and to explore their impact on predicting dropouts. The contribution of this work is twofold:

- to provide insights regarding log-based features that may relate to student dropouts in HE;
- to explore the relationship between the aforementioned features and time regarding their impact on dropout prediction.

In the following section we provide a short overview of related research, then we present our methodological approach and we follow up with the results of our analysis. We conclude with a contextualized discussion on our findings, the

practical implications of this work and limitations as well as potential future directions.

2. RELATED WORK

As dropouts in Higher Education, we identify the cases of students who do not successfully complete their studies for reasons that indicate lack of motivation and willingness to pursue an academic degree. Dropouts in HE is a prominent issue with negative impacts for students, and institutions that also affects national and international policies[1].

The reasons behind students dropouts can vary between personal (for example, students feeling isolated or homesick [8]), academic (such as students' lack of background knowledge or study skills [9]) and socio-economical (for example, financial difficulties and cultural adaptation [16, 12]). At the same time, factors that relate to the academic institution rather than the students themselves (such as the quality of studies and resources that the institution offers [3]) can also affect student dropouts. Tinto's theoretical model of students' dropouts from college [15] identified two dimensions as crucial in terms of academic success: student's characteristics (such as family background and goals) and student's experience with the academic system (such as student's performance and relationship with mentors and colleagues). Crosling et al. [7] attributed student dropouts to the services the academic institutes offer to students, such as information regarding the admission process, quality of the teaching, and assessment and [11] investigated the relationship between the socio-economic status of a country and students dropouts. Other work [10] argued that student dropout is often related to a combination of reasons that include individual and curriculum-level factors, for example, inefficient study skills and inefficient academic or social environment.

In this work, we examine the case of an Estonian HEI. Estonia, being a relatively new member of European Union, is going through social, structural and economic changes in many sectors, including higher education. We argue that these socio-economic changes that arguably affect student dropouts, may also affect the performance of predictive algorithms that model student dropouts if temporal aspects of students' data (such as, the age of data as depicted for example by students' admission year) are not taken into account.

3. METHODOLOGY

This research was carried out in an Estonian Higher Education Institute (HEI). Recently, the HEI launched an initiative aiming to support students in successfully completing their studies. To do so, the HEI designed a learning analytics (LA) dashboard that provided information to academic stakeholders (in this case, program directors and academic specialists) regarding potential reasons that may contribute to dropouts in their programs and suggestions concerning appropriate feedback and support that they could offer to students-at-risk. To provide this information, the LA dashboard used students' data collected by the SIS of the HEI – with the students' informed consent – throughout the students' academic career [5].

To identify students at risk from dropping out from their studies, the LA dashboard used a predictive model (described in [5] that assessed dropout risk on three dimensions: academic background of the student, student's performance, and effort. The separation of the dimensions would help the institute to link dropout factors directly to students' cohorts. Each dimension was defined based on pre-selected engineered features from the SIS database. In this work, we used data collected for students on the bachelor level from 2010 to 2020) to explore whether the predictive features used by the model change over time, to what extent, and what is the impact of this change on dropout prediction.

3.1 Method of Study

Our hypothesis was that the performance of dropout predictive models that were trained with students data collected over various admission years, will not be consistent over time; the reason for that being that the predictive features change significantly over time. For the purpose of our research, we followed a three-step approach:

- we performed a correlation analysis to explore indications of potential relationships between log-based, engineered student features and dropouts per admission year;
- we carried out a MANOVA to establish that the log-based features retrieved from the correlation analysis vary significantly over student cohorts of different admission years;
- we performed a regression analysis with interaction terms to investigate the effect of the log-based features – retrieved from correlation analysis and MANOVA – on dropout prediction for student cohorts admitted on different years.

As a proof of concept, we trained a regression model as a binary classifier to predict student dropouts using the engineered features that we acquired from the aforementioned process. Then, we tested the performance of the classifier on unseen data. An overview of the method of study is presented in Figure 1.

3.2 Description of data

In this work, we used data of bachelor-level students that the HEI collected using the Study Information System (SIS) over a period of 11 years (from 2010 to 2020). The data was originally organized in 4 tables containing information regarding students' academic background, demographics, study place, and study info data.

In the SIS database, each student and each study place (or else, curriculum enrollment) have different unique identifiers ("person ID" and "study place ID", respectively). This consequently means that the relationship between students and curriculum enrollments is 1 to N - that is, one student may be enrolled in multiple curricula at the same time. In order to create one working dataset, we merged the four database

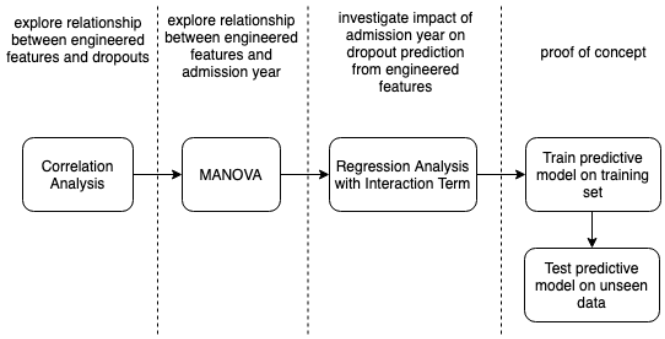

Figure 1: A graphical representation of the method of study, including the three-step analytical approach and the proof-of-concept example.

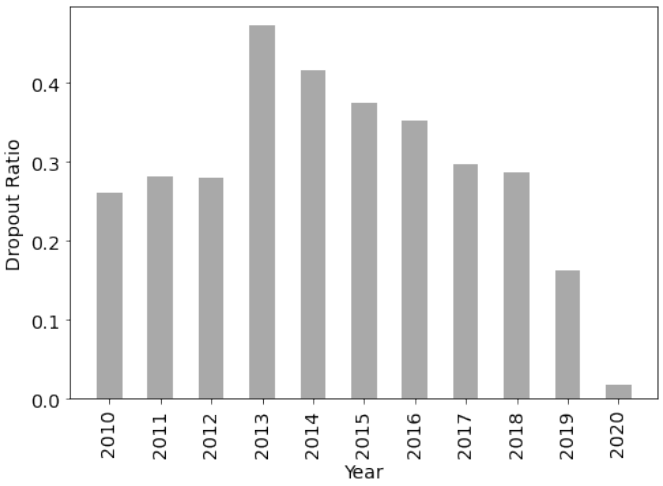

Figure 2: The dropout ratio, that is the ratio of the students who dropped out over the whole bachelor-level student population per admission year, from 2010 to 2020

tables using a combination of the unique keys "person ID" and "study place ID". Using this dataset, we engineered a set of features that can potentially describe student's academic profile on three dimensions – that is, student's academic background, student's academic performance, and student's academic effort – and may provide insights regarding students who may be at risk of dropping out from their studies. Following the recommendation of the ethics committee of the HEI, we excluded information that could be linked to students identity and demographic background to avoid potential discrimination, gender or racial bias.

As dropouts, we identified students who terminated their studies due to reasons (as recorded by the SIS of the HEI) that may indicate lack of motivation, or unwillingness to pursue an academic degree. Students can dropout at any point during the academic year, but the HEI records students' "exmatriculation" in the beginning of every semester. In total, the dataset consisted of 9623 students who are enrolled in the bachelor programs offered by the HEI. Out of these students, 3428 students dropped out at some point during their studies before they acquire an academic degree. Figure 2 shows the distribution of the dropout ratio – that is, the number of students who dropped out over the whole bachelor-level student population per admission year, over 11 years. For Year 2020 we only obtained data for the first academic semester (February to June).

3.3 Features Engineering

For each dimension of a student's academic career, we engineered a set of features from data recorded from the SIS of the HEI. In brief:

- Academic Background: The SIS records information regarding students' earlier academic background when students enroll to a study program offered by the HEI. We engineered features related to students earlier academic degrees, the admission score, admission special conditions (for example, good results in Olympiads, high scores in the academic aptitude test) and the number of previous enrollments to study programs offered by the same HEI.
- Performance: Here, we engineered features related to students' performance as depicted by grades and awarded credits throughout the study program. Performance-related features include credits earned, grades, and cumulative positive and negative study results (that is, numbers of passed and failed courses).
- Effort: Here, we considered features that can represent a student's overall effort during their studies. Some of these features are, the number of days a student spends on academic leave, the number of credits the student cancelled throughout the semester, the number of the registered courses during a semester and information about student's allowances and achievement stipends.

The complete set of features per dimension along with a short description for each is presented in the appendix (Table 4).

4. RESULTS

The results are presented per each step of the analytical process: the correlation analysis, the MANOVA and the regression analysis. For simplicity, we only report statistically significant findings at the $p < 0.05$ level. Then, we report our exploratory findings from the prediction example as proof-of-concept.

4.1 Correlation Analysis

We carried out a correlation analysis (Spearman's rank-order correlation) to explore the potential relationship between the engineered features and student dropouts. We only report statistically significant correlations at the $p < 0.05$ significance level with medium and strong correlation coefficients ($\rho \geq |0.3|$) (Table 1). The correlation analysis suggests that features representing student performance and effort, such as the number of credits a student earns or the number of courses they register, may relate negatively with the probability of dropping out from their studies (that is, the more courses they register, the less likely to dropout). One interesting finding was that the student's economic support was negatively correlated with student dropouts from 2010 to

Table 1: Spearman's Rank Correlation for the engineered features and student dropouts per admission year. Here we present correlations where $\rho \geq |0.3|$ and $p < 0.05$. The features for the dimension of Academic Background did not appear to correlate strongly with dropouts over the admission years.

2013 but no correlation appears for the past few years (with the exception of 2018). This may suggest that presently students are in a better financial situation and can therefore afford studying until they complete their degrees. Alternatively, it may indicate a change in the state's or the university's policy regarding tuition fees.

The correlation analysis did not reveal any strong and significant relationship between dropouts and features of the student's academic background. However, correlations only suggest the potential existence of relationships. Therefore additional analysis is necessary to establish whether the importance of the engineered features on dropouts may change over time.

4.2 Multivariate Analysis of Variance

Next, we performed a one-way MANOVA to investigate whether the engineered features vary significantly for student cohorts admitted over different academic years. The engineered features were the dependent variables and the admission year was the independent variable for each of the dimensions. The results of the MANOVA are presented in Table 2. For the academic background dimension, all the features appear to be significantly different among the independent groups ($p < 0.05$) which may indicate that the academic background features are year-dependent. For both the performance and effort dimensions, the majority of features vary significantly among student cohorts of different admission years with $p < 0.05$.

Based on the MANOVA results we assume that the engineered features appear to be significantly different for student cohorts based on the admission year. This may consequently signify that the impact of the log-based features on dropout can be time-dependent.

4.3 Regression Analysis

To further explore whether the performance of a predictive model depends on temporal aspects of training data, we carried out a (logistic) regression analysis with the variable "*dropout*" as the dependent variable, the predictive features as the independent variables and admission year as the interaction term. Table 2 presents the features that interacted with admission year. Regarding students' academic background, we found that the students' previous experience with the HEI is dependent on admission year while the normalized admission score is significant in terms of regression analysis but marginal ($p = 0.07$) in terms of interaction with admission year. Time-dependency of previous experience with the HEI may reflect structural or policy changes of the academic institution that affect students' experience. Regarding the admission special conditions, we did not find any interaction with admission year or dropout (also evident from the correlation analysis). Furthermore, the results suggested that the students' previous study level – in case of master's level studies – may be important for dropout prediction and interact with admission year. A potential explanation could be that there is a confounding effect between the feature indicating previous studies in the same institution and the feature indicating previous study level.

Concerning students' performance, the results suggest that features such as the credits a student earns or the grades they are awarded can be used to indicate dropout risk. However, performance-based features do not appear to interact with admission year. In other words, their impact on predicting student dropout does not depend on the year a student was admitted in the academic institution. Regarding the importance of features that denote effort, such as the time a student spends on an academic leave, and the number of registered credits, they seem to have a different effect on student dropouts depending on the year of admission. This means that the features' weight on dropout predic-

tion changes when coupled with the interaction term. This may indicate that the impact of these features on student dropouts is not consistent over time. We did not find any indications that effort-related features such as the credits a student cancels over the semester or the duration of studies (study period in years) depend on admission year.

4.4 Proof of Concept

To further explore the impact of time on modeling student dropouts using log-based student features, we split the data in two sets: a training and a test set. For the training set, we included all records of students admitted from 2010 to 2020, except those who were admitted on 2011 and on 2018 (both points representing instances close to the chronological beginning and the ending of our data collection). We used the training set to train a regression model, and we used the trained model as a binary classifier to predict student dropouts on the test set of unseen data. For both the training and testing, there are notable differences when examining the confusion matrices for the binary classifiers (Table 3). The binary classifier for performance and effort performed differently for student cohorts that were admitted on 2011 and on 2018 performed in terms of accuracy, precision and recall while the results were similar for the academic dimension. The model performed better on the 2011 dataset while in terms of recall the model performed better on the 2018 dataset. Recall is important here as the objective is to determine the students who are likely to dropout (positive class) and reduce the false negative outcomes (that is, students who were predicted as not at risk of dropping out but actually dropped out). Higher precision in 2011 test set indicates the models' dropout prediction inability as the model seem to retain less relevance with older data, (like, academic year 2011), resulting in lower false positives and increasing the overall precision value. On the contrary, higher recall in 2018 dataset indicates the model's better fit with recent data, thus contributing in lower false negatives. However, we acknowledge that 2018 is fairly recent and some students enrolled in that year might not have dropped out yet, leading to inaccurate results. As for accuracy, there are 36.05% (3273 out of 9078) instances are dropout (positive label) in the training dataset resulting in an imbalanced label distribution. The proof of concept analysis supports the hypothesis of the paper that age of the data affects the models' performance, therefore models' trained on newer data is important to increase the performance. We argue that this finding may suggest that the age of the data is pivotal to training predictive models. For the academic dimension, the overall performance was poor for both student cohorts.

5. CONCLUSION

In this paper, we explored the impact of log-based, engineered features that can be extracted from recorded student data on predicting student dropouts in Higher Education. In particular, we focused on investigating potential interactions between the engineered features and time – as represented by students' admission year – that may affect the performance of student dropout predictive models. We argued that the age of the data we use to train machine-learning models for predicting dropouts will impact the models' performance since socio-economic and cultural conditions, that arguably affect student retention, can change over time. For the purpose of this research, we engineered three sets of student features from data collected in the SIS of the HEI: one set describing the academic background of students, one set describing the performance of students and one describing the effort students put in their studies. To explore relationship between dropouts and features, and relationship between features and admission year we combined correlation analysis, MANOVA and regression analysis with admission year as the interaction term.

The results suggested that the admission year can play a critical role on the importance of the selected features for predicting dropouts. The importance of the features may change based on the socio-economic status of the state [11] which is subject to changes for multiple reasons, such as political functions, joining an economic trade or alliance, or even cultural changes and emergency situations, such as the COVID pandemic. For example, in our case, this is demonstrated by the importance of financial support provided by the state on dropout rates over the years that seems to be decreasing. One can argue that student dropouts in Higher Education is a complex topic that extends beyond the academic institution and the students themselves but it reflects socio-economic, cultural and political aspects of the society or the state. Thus, we would expect that the predictive power of engineered student features relating to societal or financial aspects – such as, the academic decisions students' make in terms of investing effort and financial support – are susceptible to change over time. On the other hand, performance-related features (such as grades and positive or negative exam results) do not appear to interact with admission year but instead their effect remains steady over student cohorts, confirming prior work [14]. Features that aim to represent the students' academic background may relate to some extent to student dropouts – as the regression analysis suggested – but their predictive power is limited and their dependency on admission year requires further investigation. To demonstrate the impact of time of predictive performance, we presented an example where we trained a binary classifier using time-sensitive features and we tested its performance on unseen data from two student cohorts that were admitted in the same HEI with a 7-year difference.

As a practical implication of this work, we envision establishing time-sensitive, predictive models for addressing student dropouts. Towards that direction, one approach would be to limit the datasets used for model training with respect to the chronology of the data, resulting in fewer older data as new data are received. However, this could lead to insufficient amount of data for training purposes. Another approach would be to incorporate "forgetting" factors in order to minimize the impact of old, non-relevant data. In this case, forgetting could be implemented by applying weights to the training set in such a way so that temporally distant or temporally irrelevant data receive lower weights (and thus, have less impact on the training) than recent entries. Similarly, for random forest or decision trees models one could regulate the threshold limits for early stopping in tree growth as a means to include the forgetting factor.

In this research, we carried out our analysis on data collected during the past decade from the same institution. This does not allow us to generalize our findings across various tem-

poral and spatial contexts. Additionally, in this work we only used basic information about students' background and study progress - excluding demographics. Further analysis on an extended dataset may reveal significant patterns on dropouts regarding cultural background or gender. However, it is important to ensure the safe and ethical use of sensitive and personal information of students and to establish that future use of the outcomes aims to support students and academic stakeholders in a fair and accountable context. In future work, we aim to design a predictive model for addressing dropouts in HE that will implement the forgetting factor based on data's recency. For triangulation, we will compare the forgetting factor's impact both for a regression model and for a random forest model and we will explore further the impact of the forgetting factor in terms of predictive accuracy, effectiveness and efficiency. Moreover, we will consider the possibility of analyzing gender segregated data to explore if the findings show gender bias [6].

ABSTRACT

Knowledge tracing (KT), the task of tracking the knowledge state of each student over time, has been assessed actively by artificial intelligence researchers. Recent reports have described that Deep-IRT, which combines Item Response Theory (IRT) with a deep learning model, provides superior performance. It can express the abilities of each student and the difficulty of each item such as IRT. However, its interpretability and applicability remain limited compared to those of IRT because the ability parameter depends on each item. Namely, the ability estimate for the same student and time might differ if the student attempts a different item. To overcome those difficulties, this study proposes a novel Deep-IRT model that models a student response to an item by two independent networks: a student network and an item network. Results of experiments demonstrate that the proposed method improves prediction accuracy and the interpretability of earlier KT methods

Keywords

Deep Learning, Item Response Theory, Knowledge Tracing

1. INTRODUCTION

Recently, along with the advancement of online education, Knowledge Tracing (KT) has attracted broad attention for helping students to learn effectively by presenting optimal problems and a teacher's support [5, 14, 16, 22, 23, 24, 37, 39, 43, 45, 46]. Important tasks of KT are tracing the student's evolving knowledge state and discovering concepts that the student has not mastered based on the student's prior learning history data. Furthermore, predicting a student's performance (correct or incorrect responses to an unknown item) accurately is important for adaptive learning. Many researchers have developed various methods to solve KT tasks. Methods for KT are divisible into probabilistic approaches and deep-learning approaches.

For example, Bayesian Knowledge Tracing (BKT), a traditional and well known probabilistic model for KT [1, 5, 8, 14, 16, 22, 23, 26, 45], employs a Hidden Markov Model to trace a process of student ability growth. It predicts the probability of a student responding to an item correctly. Item Response Theory (IRT) [3, 34, 35], which is used in the test theory area [10, 11, 12, 13, 28, 33, 36], has come to be used for KT [6, 40]. Actually, IRT predicts a student's correct answer probability to an item based on the student's latent ability parameter and item characteristic parameters.

Actually, a learning task is associated with multiple skills. Students must master the knowledge of multiple skills to solve a task. However, BKT and IRT have a restriction by which they express only uni-dimensional ability.

To overcome the limitations, Deep Knowledge Tracing (DKT) [24] was proposed as the first deep-learning-based method. DKT employs Long short - term memory (LSTM) [27] to predict a student's performance. LSTM relaxes the restrictions of skill separation and binary state assumptions. However, the hidden states include a summary of the past sequence of learning history data in LSTM. Therefore, DKT does not explicitly treat the student's ability of each skill.

To improve the DKT performance, various deep-learning-based methods have been proposed [2, 4, 17, 19, 29, 30, 31, 38, 42, 44]. Especially, the dynamic key-value memory network (DKVMN) was developed to exploit the relations among underlying skills and to trace the respective knowledge states [46]. To trace student ability, DKVMN uses a Memory-Augmented Neural Network and attention mechanisms. Furthermore, to improve the explanatory capabilities of the parameters, Deep-IRT was proposed by combining DKVMN with an IRT module [43]. In fact, Deep-IRT can estimate a student's ability and an item's difficulty just as standard IRT models can. However, the ability parameter of the Deep-IRT depends on each item characteristic because it implicitly assumes that items with the same skills are equivalent. The assumption does not hold when the item difficulties for the same skills differ greatly. Items for the same skills which are not equivalent hinder interpretation of a student's ability estimate.

Most recently, Gosh et al. (2020) proposed attentive knowledge tracing (AKT) [7], which incorporates a forgetting function of past data to attention mechanisms. Additionally, they indicated a problem by which earlier KT methods assumed that items with the same skills are equivalent. To re-

Emiko Tsutsumi, Ryo Kinoshita and Maomi Ueno "Deep-IRT with independent student and item networks". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 510-517. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

solve that difficulty, they employed both items and skills as inputs. The predictive accuracy of a student's performance was improved by AKT. However the interpretability of the parameters is limited because it cannot express a student's ability transition of each skill.

Earlier studies have tackled to develop deep-learning-based methods to give parameter interpretability similarly to IRT models, but those studies have not achieved it for student ability parameters, which are most important for student modeling. The problem is the difficulty of incorporating the ability parameters and item parameters independently into deep-learning-based methods so as not to degrade prediction accuracy. This study addresses that problem.

Recent studies of deep learning have shown that redundancy of parameters for training data reduces generalization error, contrary to Occam's razor. The studies also clarify the reasons [9, 20, 21]. Based on state-of-the-art reports, this study proposes a novel Deep-IRT that models a student's response to an item by two independent redundant networks: a student network and an item network. The proposed method learns student parameters and item parameters independently to avoid impairing the predictive accuracy. A student network employs memory network architecture to reflect dynamic changes of student abilities as DKVMN does. Therefore, the ability parameters of the proposed method do not depend on each item characteristic. They have higher interpretability than those of Deep-IRT. Moreover, the proposed method employs both items and skills as inputs in a different mode of Gosh et al. (2020) [7]. Although Tsutsumi et al. previously proposed a Deep-IRT for test theory, it cannot be applied to KT because a student's ability is constant throughout a learning process [32].

2. RELATED WORK

2.1 Item response theory

There are many item response theory (IRT) models [3, 18, 34, 35, 41]. This subsection briefly introduces two-parameter logistic model (2PLM): an extremely popular IRT model. In 2PLM, the probability of a correct answer given to item j by student i with ability parameter $\theta_i \in (-\infty, \infty)$ is assumed as

$$P_j(\theta_i) = \frac{1}{1 + exp(-1.7a_j(\theta_i - b_j))}, \tag{1}$$

where $a_j \in (0, \infty)$ is the j-th item's discrimination parameter expressing the discriminatory power for student's abilities, and $b_j \in (-\infty, \infty)$ is the j-th item's difficulty parameter representing the degree of difficulty.

2.2 Dynamic key-value memory network

The salient feature of DKVMN is that it assumes N underlying skills and relations between the input (items). Underlying skills are stored in key memory $\boldsymbol{M}^k \in \mathbb{R}^{N \times d_k}$. However, value memory $\boldsymbol{M}_t^v \in \mathbb{R}^{N \times d_t}$ holds abilities of underlying skills at time t. Here, d_k and d_t are tuning parameters. To express the j-th item, the input of DKVMN is a one-hot vector $\boldsymbol{q}_j \in \{0, 1\}^J$, where J represents the number of items for which the j-th element is 1 and for which the other elements are zeroes. DKVMN predicts the performance of item j at time t as explained below.

First, DKVMN calculates the attention, which indicates how strongly an item j is related to each skill as

$$\boldsymbol{\beta}_1^{(j)} = \boldsymbol{W}^{(\beta_1)}\boldsymbol{q}_j + \boldsymbol{\tau}^{(\beta_1)}, \tag{2}$$

$$w_{tl} = Softmax\left(\boldsymbol{M}_l^k \boldsymbol{\beta}_1^{(j)}\right), \tag{3}$$

where M_l^k represents a l th row vector and w_{tl} signifies the degree of strength of the relation between skill l and item j addressed by a student at time t. In addition, $\boldsymbol{W}^{(\cdot)}$ is the weight matrix and weight vector. $\boldsymbol{\tau}^{(\cdot)}$ is the bias vector and scalar. Next, student vector $\boldsymbol{\theta}_1^{(t)}$ is calculated using the weighted sum of value memory.

$$\boldsymbol{\theta}_1^{(t)} = \sum_{l=1}^{N} w_{tl} \left(\boldsymbol{M}_{tl}^v\right)^\top. \tag{4}$$

Finally, it concatenates $\boldsymbol{\theta}_1^{(t)}$ with $\boldsymbol{\beta}_1^{(j)}$ and predicts correct probability P_{tj} for an item j as

$$\boldsymbol{\theta}_2^{(t)} = \tanh\left(\boldsymbol{W}^{(\theta_2)}\left[\boldsymbol{\theta}_1^{(t)}, \boldsymbol{\beta}_1^{(j)}\right] + \boldsymbol{\tau}^{(\theta_2)}\right), \tag{5}$$

$$P_{tj} = \sigma\left(\boldsymbol{W}^{(u)}\theta_2^{(t)} + \boldsymbol{\tau}^{(u)}\right), \tag{6}$$

where $\boldsymbol{M}_{tl}^v$ represents the l th row vector of $\boldsymbol{M}_t^v$, $[\cdot]$ is a concatenation of vectors, and $\sigma(\cdot)$ represents the sigmoid function. Reportedly, DKVMN has the capability of accurately predicting performance. However, unfortunately, a lack of the interpretability of the parameter remains.

2.3 Deep-IRT

Deep-IRT is implemented by combining DKVMN with an IRT module [43] to improve the DKVMN interpretability. Deep-IRT exploits both the strong prediction ability of DKVMN and the interpretable parameters of IRT. Deep-IRT adds a hidden layer to DKVMN to gain the applicable ability and item difficulty. Specifically, when a student attempts item j at time t, an ability $\theta_3^{(t,j)}$ and item difficulty $\beta_2^{(j)}$ are calculated as shown below.

$$\theta_3^{(t,j)} = \tanh\left(\boldsymbol{W}^{(\theta_3)}\boldsymbol{\theta}_2^{(t)} + \tau^{(\theta_3)}\right), \tag{7}$$

$$\beta_2^{(j)} = \tanh\left(\boldsymbol{W}^{(\beta_2)}\boldsymbol{\beta}_1^{(j)} + \tau^{(\beta_2)}\right), \tag{8}$$

The prediction is based on the difference between $\theta_3^{(t,j)}$ and $\beta_2^{(j)}$ such as IRT.

$$P_{tj} = \sigma\left(3.0 * \theta_3^{(t,j)} - \beta_2^{(j)}\right). \tag{9}$$

Here, ability $\theta_3^{(t,j)}$ is calculated using $\boldsymbol{w}_t$ in equation (6), which depends on the item to solve because it implicitly assumes that items with the same skills are equivalent. In other words, the ability estimate for the same student and time might differ if the student attempts a different item. Furthermore, in equation (7), Deep-IRT uses item vector $\beta_1^{(j)}$ to calculate $\theta_2^{(t)}$. An important difficulty is that a student's ability, which depends on each item, hinders the interpretability of the parameters. Although Tsutsumi et al. [32] also proposed a Deep-IRT as a test theory, the purpose is different from this study because it can not be available for KT as mentioned before.

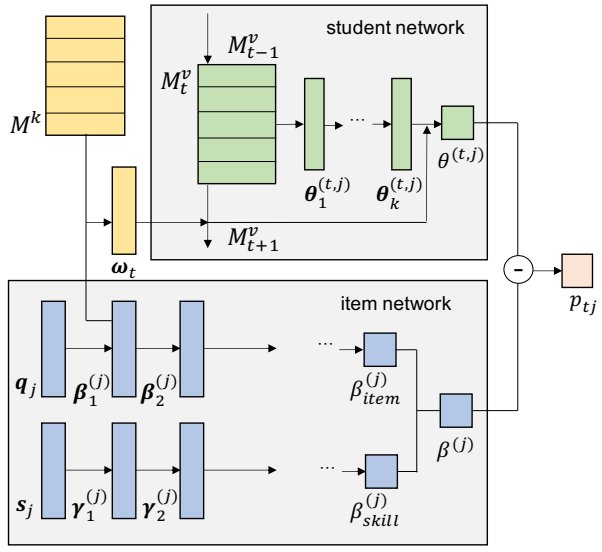

Figure 1: Network architecture for Deep-IRT with independent student and item networks. The yellow components represent the process of getting the attention weight. Also, the green components are associated with the student network and the process of updating the value memory. The blue components are associated with the item network.

3. DEEP-IRT WITH INDEPENDENT STUDENT AND ITEM NETWORKS

To resolve the difficulty described above, this study proposes a novel Deep-IRT method comprising two independent neural networks: the student network and Item deep network, as shown in Figure 1. The student network employs memory network architecture such as DKVMN to ascertain changes in student ability comprehensively. The item network includes inputs of two kinds: the item attempted by a student and the necessary skills to solve the item. Using outputs of both networks, the probability of a student answering an item correctly can be calculated.

The proposed method can estimate student parameters and item parameters independently such that prediction accuracy does not decline because the two independent networks are designed to be more redundant than with earlier methods , based on state-of-the-art reports [9, 20, 21]. The proposed method predicts P_{tj}, the probability of a correct answer assigned to item j at time t, using the item difficulties and the student abilities, as follows.

3.1 Item network

In the item network, two difficulty parameters of item j are estimated: the item characteristic difficulty parameter β^j_{item} and the skill difficulty β^j_{skill} to solve item j. The item characteristic difficulty parameter indicates the unique difficulties of the item, excepting the required skill difficulty. The proposed method expresses item difficulty as the sum of the two difficulty parameters of β^j_{item} and β^j_{skill}.

As with DKVMN, to express the j-th item, an input of the item network is a one-hot vector $\boldsymbol{q}_j \in \mathbb{R}^J$ as shown below.

$$q_{jm} = \begin{cases} 1 & (j = m) \\ 0 & (otherwise) \end{cases} \tag{10}$$

Here, J stands for the number of items. The item network comprises n layers. The item characteristic difficulty parameter of item j is calculated using a feed forward neural network as

$$\boldsymbol{\beta}^j_1 = \tanh\left(\boldsymbol{W}^{(q_1)}\boldsymbol{q}_j + \boldsymbol{\tau}^{(q_1)}\right), \tag{11}$$

$$\boldsymbol{\beta}^j_k = \tanh\left(\boldsymbol{W}^{(\beta_k)}\boldsymbol{\beta}^j_{k-1} + \boldsymbol{\tau}^{(\beta_k)}\right), \tag{12}$$

$$\beta^j_{item} = \boldsymbol{W}^{(\beta_{item})}\boldsymbol{\beta}^j_n + \tau^{(\beta_{item})}, \tag{13}$$

where $k = \{2, ..., n\}$. The last layer $\beta^{(j)}_{item}$ represents the j-th item characteristic difficulty parameter.

Similarly, to compute the difficulty of skills, the proposed method uses the input of necessary skills $\boldsymbol{s}_j \in \mathbb{R}^S$ as presented below.

$$s_{jm} = \begin{cases} 1 & (item\ j\ requires\ skill\ m) \\ 0 & (otherwise) \end{cases} \tag{14}$$

Here, S represents the number of skills:

$$\boldsymbol{\gamma}^j_1 = \tanh\left(W^{(\gamma_1)}\boldsymbol{s}_j + \tau^{(\gamma_1)}\right), \tag{15}$$

$$\boldsymbol{\gamma}^j_k = \tanh\left(W^{(\gamma_k)}\boldsymbol{\gamma}^j_{k-1} + \tau^{(\gamma_k)}\right), \tag{16}$$

$$\beta^j_{skill} = \boldsymbol{W}^{(\beta_{skill})}\boldsymbol{\gamma}^j_n + \tau^{(\beta_{skill})}, \tag{17}$$

where $k = \{2, ..., n\}$. The last layer β^j_{skill} denotes the difficulty parameter of the required skills to solve the j-th item.

3.2 Student network

In the student network, the proposed method calculates $\boldsymbol{\theta}^t_1$ based on the past response history as

$$\boldsymbol{\theta}^{(t,j)}_1 = \sum_{l=1}^{N} \boldsymbol{M}^v_{t,l}, \tag{18}$$

where $\boldsymbol{M}^v_t$ is a memory matrix holding a students' latent knowledge state, which are estimated similarly to DKVMN. Next, an interpretable student's ability vector θ^t_n is estimated as follows. Therein, n represents a number of hidden layers decided depending on the prediction accuracy of actual data.

$$\boldsymbol{\theta}^{(t,j)}_k = \tanh\left(W^{(\theta_k)}\boldsymbol{\theta}^{(t,j)}_{k-1} + \tau^{(\theta_k)}\right), \tag{19}$$

$$\theta^{(t,j)} = \boldsymbol{w}^\top_t \boldsymbol{\theta}^{(t,j)}_k, \tag{20}$$

where $k = \{2, ..., n\}$. As a difference between the proposed method and Deep-IRT, the proposed method does not multiply the attention in equation (18). In addition, $\boldsymbol{\theta}^{(t,j)}_k$ is not calculated using features of items such as equations (5) and (7). Therefore, the ability parameter vector $\theta^{(t,j)}$ does not depend on each item. Namely, it is independent from the difficulty parameter. The value of which denotes the ability for the corresponding latent skill because it is independent of any item. Therefore, $\boldsymbol{\theta}^{(t,j)}_k$ can be interpreted as a measurement model such as a multidimensional IRT [25].

3.3 Prediction of student response to an item

The proposed method predicts a student's response probability to an item using the difference between a student's ability $\theta^{(t,j)}$ to solve item j at time t and the sum of two difficulty parameters β^j_{item} and β^j_{skill}.

$$P_{tj} = \sigma\left(3.0 * \theta^{(t,j)} - (\beta^j_{item} + \beta^j_{skill})\right). \quad (21)$$

After the procedure, the value memory is updated using $\boldsymbol{c}_j$ based on the input $\boldsymbol{q}_j$ and actual performance such as DKVMN [46].

The loss function of the proposed method employs cross-entropy, which reflects classification errors. The cross-entropy of the predicted responses P_{tj} and the true responses u_{tj} is calculated as

$$\ell(u_t, P_{tj}) = -\sum_t \left(u_{tj} \log P_{tj} + (1 - u_{tj}) \log(1 - P_{tj})\right), \quad (22)$$

where u_{tj} is the true response to item j at time t. The student's response u_{tj} is recorded as 1 when the student answers the item correctly and 0 otherwise. All parameters are learned simultaneously using a well known optimization algorithm: adaptive moment estimation [15].

4. PREDICTIVE ACCURACY

4.1 Datasets

We conduct experiments to compare the performance of our approach against existing solutions. This section presents comparison of the prediction accuracies for student performance of the proposed method with those of earlier methods (DKT, DKVMN, Deep-IRT, AKT) using four benchmark datasets as ASSISTments2009[1], ASSISTments2015[2], Statics2011 [3], KDDcup[4]. ASSISTments2009 and KDDcup have item and skill tags, although most methods explained in the relevant literature adopt only the skill tag as an input. However, methods with skill inputs rely on the assumption that items with the same skill are equivalent [7]. That assumption does not hold when an item's difficulties in the same skill differ greatly. Therefore, as inputs to AKT and the proposed method, we employ not only skills but also items.ASSISTments2015 has only the skill tag. Therefore, we employ only the skill tag as an input.

Table 1 presents the number of students (No. Students), the number of skills (No. Skills), the number of items (No. Items), the rate of correct responses (Rate Correct), the average length of items which students addressed (Learning length), and the rate of items in which the number of student addressed is less than 10 (Sparsity). For all the datasets, we excepted students who addressed fewer than five items. Additionally, we set 200 items as the upper limit of the input length according to an earlier study [43]. When the input length of items becomes greater than 200, we use the first 200 response data for all methods.

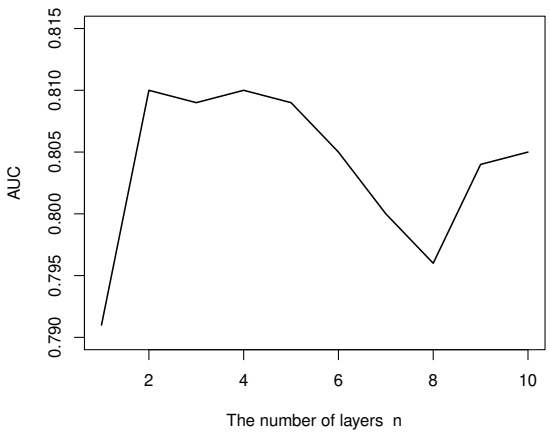

Figure 2: AUC and the Number of Layers

4.2 Hyperparameter selection and evaluation

We used ten-fold cross-validation to evaluate the prediction accuracies of the methods. The item parameters and the hyperparameters are learned using 70% of datasets. Given the estimated hyperparameters, a student's ability can be estimated at each time using the remaining 30% of each dataset. For all methods, the hidden layer size and memory dimension are chosen from $\{10, 20, 50, 100, 200\}$ using cross-validation. In addition, for the earlier methods, we used the hyperparameters reported from earlier studies [7, 43].

To ascertain the number of layers n for the proposed method, we conducted some experiments to gain experience using ASSISTments2009 while changing the layer number. The results are presented in Figure 2. As shown in the figure, AUC score reaches its highest level when $n = 2$ and $n = 4$. Based on this result, we employ $n = 2$ for the following experiments because the computation time of the proposal increases exponentially as the number of layers increases.

If the predicted correct answer probability for the next item is 0.5 or more, then the student's response to the next item is predicted as correct. Otherwise, the student's response is predicted as incorrect. For this study, we leverage three metrics for prediction accuracy: Accuracy (Acc) score, AUC score, and F1 score. The first, Acc, represents the concordance rate between the student predictive performance and the true performance. The second, AUC, represents the predictive accuracy of the correct answer probabilities. F1 indicates the average of the F1 score of incorrect answer prediction and the F1 score of correct answer prediction.

4.3 Results

The respective values of Acc, AUC, and F1 for those benchmark datasets are shown in Table 2. Results show that the proposed method with item and skill inputs provides the best performance for the metrics: averages of Acc and F1. Especially noteworthy is that the proposed method outperforms AKT, which is the most advanced method. Furthermore, the proposed method with item and skill inputs provides better performance than that with skill or item inputs. These results indicate that parameter estimation, not only with skill but also with item, improves the predictive accuracy.

Table 1: Summary of Benchmark Datasets

Dataset	No. students	No. skills	No. Items	Rate Correct	Learning Length	Sparsity
ASSIST2009	4,151	111	26,684	68.0%	70.8	55.2%
ASSIST2015	19,840	100	N/A	73.2%	34.2	12.6%
Statics2011	333	156	1,223	77.7%	180.9	2.6%
KDDcup	820	43	476	78.3%	11.9	57.8%

Table 2: Predictive Accuracy of Student Performance with Benchmark Datasets

		DKT	DKVMN	Deep-IRT	AKT	AKT (item&skill)	Proposed	Proposed (item&skill)

However, AKT with item and skill inputs shows the best average values of AUC. Actually, AKT with item and skill inputs also provides higher performance than that achieved with skill or item inputs, as shown in [7]. Gosh et al. (2020) reported that AKT is more effective for large datasets. Therefore, AKT provides the best performance for all the metrics of ASSISTments2015, which has an extremely large number of students.

Furthermore, surprisingly, the averages of ACC, AUC, and F1 obtained using the proposed method with skill input are better than Deep-IRT, although the proposed method separates student and item networks. This result implies that redundant deep student and item networks function effectively for performance prediction. These results are explainable from reports of state-of-the-art methods [9, 20, 21].

The performance results obtained using DKVMN are almost identical to those obtained using Deep-IRT because they have almost identical network structures. Results show that DKT provides the worst performance among the methods studied here.

5. PARAMETER INTERPRETABILITY

5.1 Interpretability of difficulty parameters

To evaluate the interpretability of the difficulty parameters of the proposed method, we compare the parameters of IRT with those of Deep-IRT using a simulation data. The dataset includes 2000 students' responses to 50 items and it is generated from 2PLM as shown in equation (1). The priors of the parameters have $\boldsymbol{\theta} \sim N(0,1), \boldsymbol{a} \sim LN(0,1), \boldsymbol{b} \sim N(0,1)$. We estimated the parameters of the proposal and Deep-IRT using the dataset. Table 3 shows the Pearson correlation between the true parameters of the true models and the estimated parameters, respectively, of the proposed method and Deep-IRT. Additionally, we show the prediction accuracies of the proposed method and Deep-IRT for the dataset. The proposal provides higher correlations with true parameters than Deep-IRT does, whereas the proposed method has higher accuracy than Deep-IRT has. The results demonstrate that the two independent networks of the proposed method function effectively for the interpretability of the estimated parameters and for the prediction accuracies.

Table 3: Pearson correlation

parameter	Deep-IRT	Proposed
difficulty	0.611	0.886
accuracy	0.694	0.695

5.2 Student ability transitions

This section shows student ability transitions using the proposed method. Visualizing the ability transition for each skill is helpful for both students and teachers because they can discover student strengths and weaknesses and can improve the learning method to fill in the learning gaps. Yeung [43] demonstrated a student ability transition for each skill using Deep-IRT. However, their results included some counter-intuitive ability estimates. For example, even when the student answered incorrectly, the corresponding student ability estimate increased. Moreover, Deep-IRT cannot identify a relation among multidimensional skills. There are cases in which a student's ability for low-level skills decreases even when the student responds correctly to items for high-level skills. These unstable behaviors of Deep-IRT might engender serious difficulties, which will consequently confuse students and teachers, as a student model.

Figure 3 depicts a student's ability transitions of the proposal for the ASSIST2009 dataset. The vertical axis shows

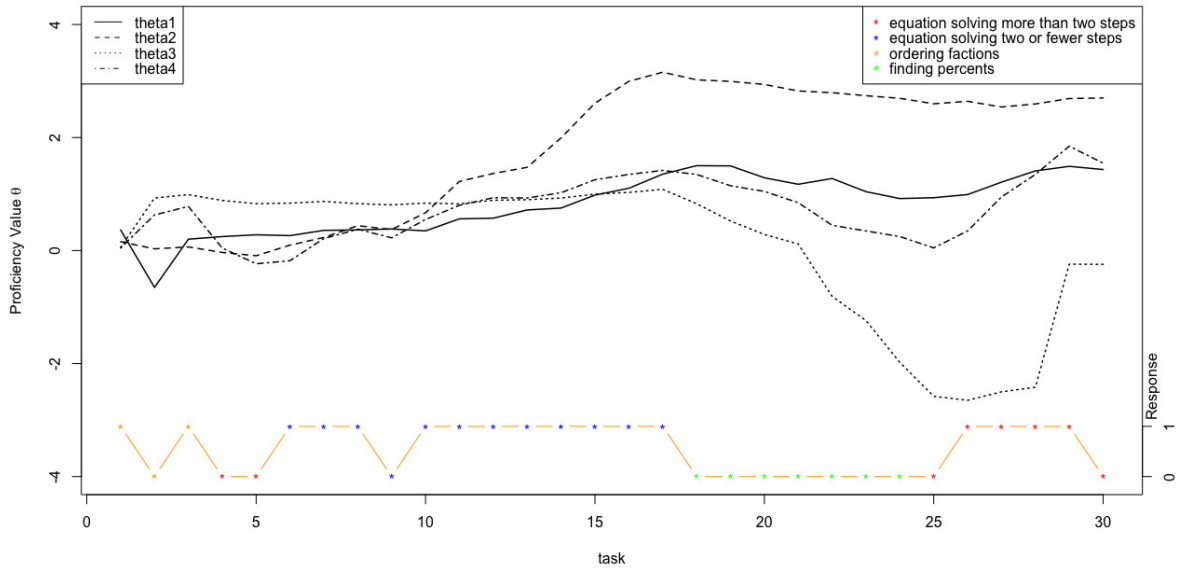

Figure 3: An example of a student ability transition from the ASSIST2009 dataset. The skill tags are classified respectively as equation solving two or fewer steps (blue), ordering fractions (orange), finding percents (green), and equation solving more than two steps (red). The student responses to items are shown at the bottom of the graph.

the student ability on the left side, with the student's response to an item on the right side. The horizontal axis shows the item number. The student's response is 1 when the student answers the item correctly; it is 0 otherwise. The student attempted skills of "equation solving more than two steps" (shown in red), "equation solving two or few steps" (shown in blue), "ordering factions" (shown in orange), and "finding percents" (shown in green). Figure 3 can be interpreted as explained below.

1. Theta 1 decreases when the student responds to item 2 "ordering factions" (orange) incorrectly and it increases when the student responds to item 3 correctly. Therefore, theta 1 indicates the ability of "ordering factions".
2. Items 6–17 correspond to the skill of "equation solving two or few steps"(blue). Theta 2 indicates the ability of "equation solving two or few steps" because theta 2 greatly increases while the student answers correctly.
3. For the skill of "finding percents" (green), the student answers all items incorrectly. Theta 3 indicates the ability of "finding percents" (green) because it greatly decreases in items 18–24.
4. Items 4, 5, and 25–30 correspond to the skill of "equation solving more than two steps" (red). Theta 4 decreases when the student answers to item 4 and 5 incorrectly, and increases when the student answers to items 26–29 correctly. Therefore, theta 4 represents the ability of "equation solving more than two steps" (red).

Figure 3 shows that the proposed method estimates the ability of each skill to reflect the student responses. Additionally, it estimates relations among the skills. Therefore, when a student responds to an item correctly/incorrectly, not only does the corresponding skill ability increase/decrease; those for other skills increase/decrease as well. Consequently, the results demonstrate that the proposed method improves both the interpretability and the prediction accuracies of Deep-IRT.

6. CONCLUSIONS

This study proposed a novel Deep-IRT that models a student's response to an item by two independent redundant networks: a student network and an item network. Because two independent redundant neural networks are used, the parameters of the proposed method can be highly interpreted with keeping hight prediction accuracy. Moreover, the proposed method employs both items and skills as inputs. Experiments demonstrated that the proposed method with item and skill inputs provided the best performance for the metrics: averages of Acc and F1. deep-learning-based methods. The result also showed AKT with item and skill inputs provided the best average values of AUC. Especially, AKT provided the best performances for large datasets as Gosh et al. (2020) reported [7]. In addition, results of experiments show that the parameters of the proposed method are more interpretable than those of Deep-IRT. This study employed slightly redundant deep networks compared to earlier methods. As future work, we intend to use the proposed method to investigate the performances of more redundant and deeper networks. In addition, we will try to optimize a forgetting function for past data to maximize the prediction accuracy for large data sets.

ABSTRACT

Promoting creativity is considered an important goal of education, but creativity is notoriously hard to define and measure. In this paper, we make the journey from defining a formal creativity and applying the measure in a practical domain. The measure relies on core theoretical concepts in creativity theory, namely fluency, flexibility, and originality, We adapt the creativity measure for Scratch projects. We designed a machine learning model for predicting the creativity of Scratch projects, trained and evaluated on ratings collected from expert human raters. Our results show that the automatic creativity ratings achieved by the model aligned with the rankings of the projects of the expert raters more than the experts agreed with each other. This is a first step in providing computational models for describing creativity that can be applied to educational technologies, and to scale up the benefit of creativity education in schools.

Keywords

Creativity, Creativity Tests, Visual Programming Environments

1. INTRODUCTION

Modern education generally tries to foster creativity in student problem solving [7, 11, 17]. There is wide agreement that creative solutions must not only solve the task but should additionally be *original*, i.e. distant from usual solutions to the task, *flexible*, i.e. employ very different concepts, and *fluent*, i.e. employ many concepts [10, 23]. However, creativity is notoriously hard to quantify in practice [7]. When being confronted with two student solutions for a given learning task, different teachers may well disagree which one is more creative [14].

Anastasia Kovalkov, Benjamin Paassen, Avi Segal, Kobi Gal and Niels Pinkwart "Modeling Creativity in Visual Programming: From Theory to Practice". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 518-524. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

In this paper, we make the journey from a definition of creativity which relate to prior concepts in the literature [23], to applying the definition to the Scratch programming environment, and using the measure to automatically quantifying the creativity score of projects in Scratch. We formalize originality of a product as the distance to usual solutions, flexibility as the distance between concepts in the student's solution, and fluency as the distance to an empty solution.

We apply the formalization to automatically measure the creativity on a set of projects from the popular visual programming language Scratch [13]. Using machine learning, we build a model that predicts the creativity ratings of Scratch projects using fluency, flexibility, and originality measures of our approach. We compare these automatic creativity ratings to those of five human experts, which were collected using a comprehensive user study. We find that the automatic ratings agree with the rankings of the experts more than the experts agreed with each other. We provide several examples that highlight the benefit of the model in light of the fact that human raters may disagree on the degree of creativity of Scratch projects.

The contribution of this work is in providing an automatic framework for defining and detecting creativity, that can scale up teacher's abilities to support creative thinking in students.

2. RELATED WORK

Prior works on measuring creativity have mostly been concerned with psychological tests, such as Williams' tests on creative thinking [25] or the Torrance test of creative thinking [10, 23]. However, such tests do not account for changes in creative ability, motivation, knowledge, and social context over time [2]. Accordingly, one should wish to measure creativity often and monitor the development across changing circumstances. This could be supported by automatic creativity assessment, towards which we work in this paper.

To measure creativity at one specific point in time, we follow Torrance's work and grade creativity on three scales, namely fluency, flexibility, and originality [10, 23]. Historically, these three scales grew out of Guilford's model of the structure of

intellect [6], which includes divergent production, i.e. the skill of generating a wide variety of ideas on the same topic. In particular, fluency refers to the sheer amount of ideas generated, flexibility to the number of distinct classes of ideas, and originality to the infrequency of the ideas compared to a general sample of the population. In addition to these three scales, Torrance's tests also include scales regarding the abstractness of generated ideas, the elaboration on ideas, and the resistance to premature closure during the generation process [10]. In this work, we stick to fluency, flexibility, and originality because they permit quite a direct formalization in mathematical and computeable terms. We further cover elaboration, to some extent, in our notion of fluency.

Multiple works focused on using technologies to infer creative thinking in numerous educational disciplines, such as math and programming [21, 12]. Previous research has shown that creativity is related to positive learning gains, and using technology to generate creativity is an active field of study [24]. Hershkovitz et al. [8, 9] examined the relationship between creativity and computational thinking within a block-based multi-level game environment for children's programming. Their findings show that creativity can contribute to the acquiring of computational thinking and can also be transferred across domains, stressing the importance of fostering creativity while promoting computational thinking.

Finally, the application domain of our work is Scratch, a block-based visual programming language targeted primarily at children. The environment allows users to create interactive stories, games, and animations [13]. Scratch blocks are designed to fit together in ways that make syntactic sense which generates the program logic. Users can use a wide variety of pre-defined basic code blocks, such as *When Key Pressed*, *Move* etc. Furthermore, programmers can use additional blocks such as *Pen Down* and *Language* from existing extensions such as 'Pen' and 'Translate', as well as define custom blocks. The environment allows the use of external data through importing images, music recordings, captured voices, and user-specific graphics [18]. By using Scratch, which is designed to enable creative expression in terms of code, graphical and audio aspects, we can expand the identification of creativity beyond the programming aspect [3, 5, 12].

3. COMPUTING CREATIVITY IN SCRATCH

In this section, we describe how we measure creativity of code and visual aspects of Scratch programs.

A Scratch project consists of the project's background called *stage* and the objects that appear on it called *sprites*[1]. Figure 1 presents a sample project, a game called 'Scratch in Scratch'. As its name implies, it simulates the Scratch environment. The player has to select a character and add block instances to a stack of blocks that control the character's behavior on the stage. The figure shows the white stage and different sprites (buttons, arrows and a cartoon character), as well as the graphics output area. Blocks are code elements that control the behavior of the stage and sprites [13]. When a sprite is selected, its blocks element are shown in the Code panel. Figure 1 (center) shows the blocks that are connected to the cartoon cat, whose sprite is selected (e.g., blocks *Hide* and *Show*).

Inspired by the creativity test of Torrance [23], we measure creativity on three scales: fluency, flexibility, and originality. Generally speaking, fluency refers to the amount of ideas involved in the Scratch project, flexibility to the diversity of ideas, and originality to the distance between a project and typical projects [10]. In the following, we describe how we compute these scales for code and visual aspects, respectively. For both aspects, our strategy is to first define a distance between building components (e.g. code blocks and images) and then compute fluency, flexibility, and originality based on that distance.

Code Creativity. We represent the Scratch code as a collection of syntax trees, one representing the stage, and one for each sprite. Each syntax tree, in turn, consists of code blocks. Figure 2 shows a graph of the blocks in Scratch, where blocks are connected to the semantic sub-category they belong to (like *move* or *events*) and sub-categories are connected to categories, namely basic blocks, extension blocks, and custom blocks. Let now δ be the shortest-path distance between blocks in this graph. More specifically, we define δ as zero for equal blocks (e.g., two *Move* blocks), as 1 if the blocks are different but within the same sub-category of blocks (e.g., *Move*, *Turn*), and as 2 if the blocks are different and from different sub-categories (e.g., *Move*, *When Key Pressed*). To explain, we add one unit of distance for the transition between the sub-categories and another for the blocks being different.

For different categories, the distance between the pre-defined blocks and the extension blocks is defined as 3, and the distance between the pre-defined blocks to the custom blocks is defined 4. To explain, we add one one unit of distance for the block's difference, the second unit of distance due to the different sub-categories, and the third for the category change. Since the Scratch environment provides by default the pre-defined blocks, while custom blocks require the user to build something new, we add an additional unit of distance.

Based on the distance, we define code fluency of a Scratch project as the sum $\sum_x \delta(x, 0)$, where x are the code blocks in the project and 0 is the gray zero node in Figure 2. The distance $\delta(x, 0)$ to basic blocks (e.g. *Move*) is defined as 3, the distance $\delta(x, 0)$ to extension blocks (e.g., *Pen-Up*, *Language*) is 4, and the distance $\delta(x, 0)$ to custom blocks is 5. In other words, we assign higher fluency for the production of non-existent components or the use of custom blocks that require additional user effort. For example, in the 'Scratch in Scratch!' program the *Show* block presented in Figure 1 is a basic block from the sub-category 'Looks'. The program gets 3 points for this block, and an overall fluency score of 10523[2].

To compute code flexibility, we remove all duplicated blocks,

[1] `https://www.scratch-wiki.info/`

[2] For mathematical reasons we square the distances, thus yielding large numbers.

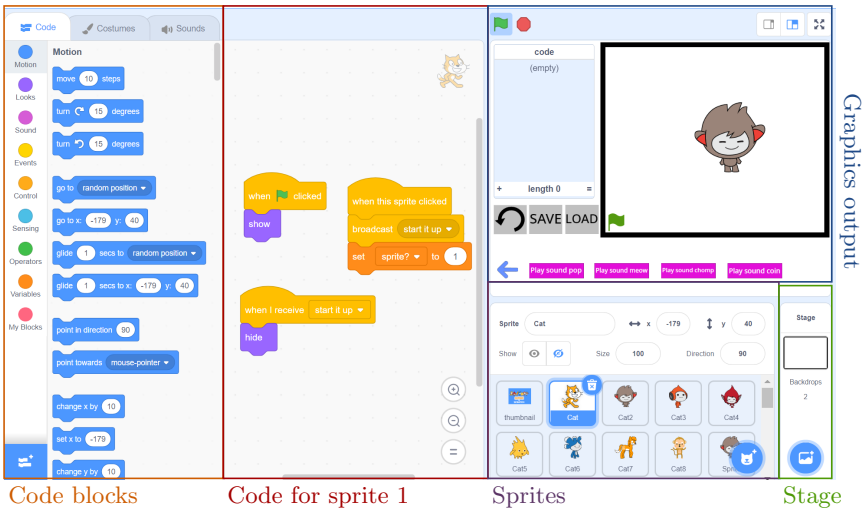

Figure 1: A screenshot of an example Scratch project. Left: A selection of possible code blocks. Center: The code blocks related to the currently selected sprite (the cat). Top right: The current graphical output. Bottom right: An overview of all sprites and the stage (i.e. the background).

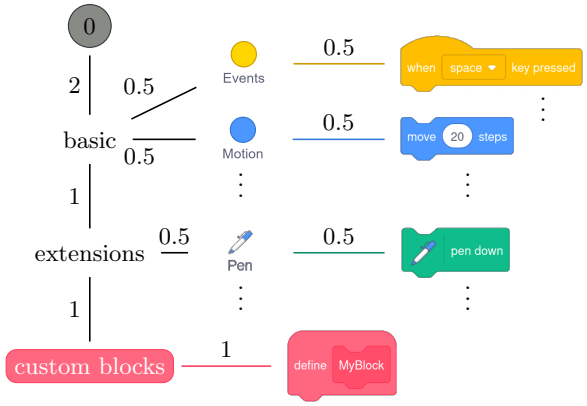

Figure 2: A graph of code blocks in scratch. We compute the distance between blocks by their shortest path distance in the graph, e.g. $\delta($  ,  $) = 0.5 + 0.5 + 1 + 0.5 + 0.5 = 3$.

then compute the sum of all pairwise distances $\sum_x \sum_y \delta(x, y)$ between code blocks in the project and divide by the number of unique code blocks. This measures how different the code blocks were, capturing the idea of flexibility as variability of concepts [10]. For example, the project 'Scratch in Scratch!' uses the blocks *Hide* and *Show* for each sprite. This increases fluency but not flexibility. Further, these two pre-defined blocks belong to the same sub-category 'Looks' and so $\delta(Hide, Show) = 1$. Overall, after normalizing by the number of the unique blocks in the program (58), it obtained a flexibility score of 395.37

We define code originality as the average distance of a Scratch project to a sample of typical projects in our data set, i.e. a project that is more distant from typical projects is considered more original. To compute the distance between projects, we follow the approach of Price et al. [22]. In particular, we use a three-step algorithm to construct an alignment between two Scratch projects. First, we compute the tree edit distance [26] between the stage syntax trees of both programs. Then, we compute all pairwise tree edit distances between sprites in both programs. Finally, we feed this result into the Hungarian algorithm [15] to obtain an alignment between the sprite trees. This is because sprites in a Scratch project do not have a clear ordering, making an unordered representation more natural.

While fluency and flexibility are based only on the program itself, the originality requires a reference sample of projects, i.e. we need a reference point with respect to which a project is original or not [23, 20]. To illustrate the effect of the reference set, we note that the originality of the 'Scratch in Scratch!' with respect to a reference set of 3 different project groups from the user study was 4488.84, 4168.89, and 2759, respectively.

Visual creativity. To represent visuals, we first collect all images (i.e. sprite and stage images) in our training data set and feed them into a ResNet50 neural network[3]. ResNet50 has been shown to generalize diverse image processing tasks and classifications [19, 16]. Accordingly, we hope that the representation of ResNet50 also helps to capture the semantic distance between images for our case. The output is a set of vectors, one for each image. To measure distance δ between images, we use the Cosine distance $\delta(x, y) = 1 - \frac{x^T \cdot y}{\|x\| \cdot \|y\|}$ because it is invariant against effects of scale/size, which would otherwise be a confounder in our data.

We compute visual fluency as the number of images in the Scratch projects, which is equivalent to the fluency definition of Torrance [23]. For example, in the project 'Scratch in

[3] `https://www.kaggle.com/keras/resnet50`

Scratch!' we have 47 images and that is its fluency score.

To measure visual flexibility, we use the same approach as for code flexibility, i.e. we compute the sum $\sum_x \sum_y \delta(x, y)$ of all pairwise distances over images in the project and then divide by the number of images. To illustrate, the program 'Scratch in Scratch' contains 2 similar button images 'Save' and 'Load' (see Figure 1). The Cosine distance between these images is relatively small $\delta('Save', 'Load') = 0.19$, based on the vectors created by the ResNet50 network. The flexibility score of the visual aspect of the project is 12.42.

We compute visual originality as the average distance of each image in a project to images in typical projects. To illustrate, the project 'Scratch in Scratch!' received an originality score of 0.57, 0.57 and 0.58 when using 3 different reference sets.

4. HUMAN CREATIVITY ASSESSMENT

In this section, we describe a user study to collect expert evaluations of creativity of Scratch projects. The experts were Scratch instructors without prior knowledge in creativity theory. Each expert was assigned a set of pre-selected Scratch projects and asked to separately evaluate the creativity of projects according to four different aspects: code, visual, audio and idea behind the project, which was identified in past work as an important factor in the creative process in Scratch [18].

We designed an online application to facilitate the rating process and to allow the experts to play and review each project as they see fit. The application was divided into three main screens. The Home Screen displays all of the projects that are assigned to an expert. When clicking on a project in the Home Screen, experts were able to see additional information about the project (e.g., the number of views and likes that the project received) and information about the user (e.g., country, date of registration in Scratch, and age if available) and also a link to the editor environment for the project's code and visuals and the embedded playable project.

For each project, experts were asked to answer questions that relate to the creativity of the four aspects of the Scratch project. Questions relating to visual aspects, such as whether the project contained images provided by scratch or originally created by the user. Experts were also asked to rate the novelty/quality and effort put into the visual aspects of the project. Questions relating to the project code, such as evaluating the code complexity, efficiency and novelty, and rating the effort put into the code. Questions about the project idea asked to include a short description of the idea and ratings for how much novelty and effort were required for developing the idea. If the project included sounds, experts were asked if these sounds were recorded by the user, imported or were provided by Scratch. Additionally, the experts rated the novelty of the sounds and the effort invested in the audio aspect.

Experts were also asked to provide a creativity score for each of the aspects (0-100), shown in Figure 3, as well as provide a weight (between 0 and 1, summing to 1) for each aspect according to its subjective importance in determining the creativity of a project. The creativity score of a given project for an expert is computed as the weighted summation of the creativity ratings for each aspect. The creativity score for each project is shown in the Home Screen, allowing experts to compare the scores and revise them at will.

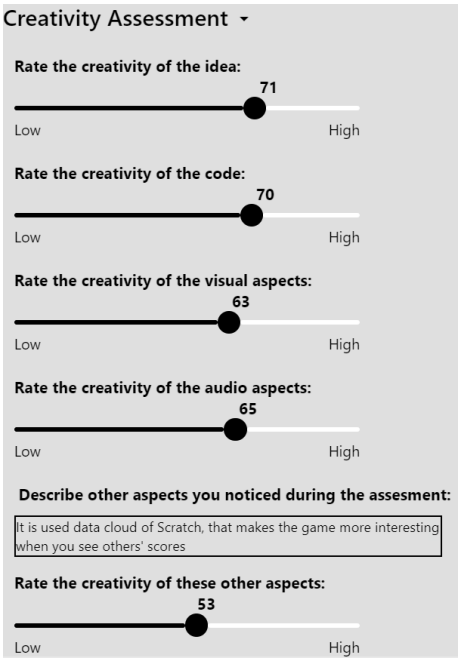

Figure 3: Overall creativity assessment.

Table 1: Experts grading statistics of code, visual and final creativity scores

Expert	Statistic	Code	Visual	Final score
1	Mean	69.55	75.85	67.59
	SD	24.04	24.97	21.31
2	Mean	66.75	67.70	66.89
	SD	13.11	14.28	13.80
3	Mean	70.75	77.65	65.30
	SD	10.18	10.50	11.89
4	Mean	72.90	83.40	76.11
	SD	24.00	20.11	17.78
5	Mean	64.60	68.55	63.52
	SD	15.27	13.15	13.17

4.1 User Study

We recruited 5 experts from 4 countries: Cuba, Vietnam, India and Israel. All experts had at least two years of Scratch training experience to students of different ages in schools and after-school activities. We selected 45 unique projects of different types (games and stories), created by different users (age ranged between 9 to 18, from 25 different countries, and with different experience, from 4 to 258 projects). We uniformly sampled projects to each of the experts from this set, so that there is a sufficient spread of creativity assessments across project, while still having some projects being rated by several experts. Four of the experts evaluated 20 projects, while one evaluated 10 projects.

Table 1 presents the statistics of the scores for code, visuals, and the final creativity scores provided by the experts. We note that the highest scores were provided by expert 4 and that this expert as well as expert 1 had the highest standard deviation across all aspects. Experts 2 and 5, on the other hand, gave relatively lower scores with a lower standard deviation.

4.2 Agreement between experts

Experts differed widely in the creativity scores they assigned to projects. For example, experts 1, 2, and 3 all evaluated the project 'Scratch in Scratch!'. Expert 1 gave this project a creativity score of 91 for the code aspect, while expert 2 gave it a score of 67, and expert 3 gave a score of 82.

We note that the low agreement between raters should not signify a mistake or lack of expertise. It reflects the fact that creativity assessment is largely subjective, and that experts can differ about which aspects are more or less important when measuring creativity, as we show in this section. To compensate for this, we measure agreement using the Kendall Rank Correlation Coefficient [1]. This measure ranges from -1 (complete disagreement between rankings) to 1 (perfect match) and is determined based on overlapping projects for each pair of experts.

Figure 4 displays for each pair of experts the number of overlapping projects (in parentheses) and the Kendall-τ score. Note that experts 2 and 4 had only one overlapping project, therefore the Kendall-τ score cannot be calculated for them. As shown in the figure, the highest agreement (Kendall-$\tau = 0.67$) is between expert 5 and 2. The other positive agreement scores are much lower and vary between 0.2 and 0.33. Moreover, we see four pairs of experts with negative Kendall-τ scores, with 2 of them including expert 4.

The experts with the highest agreement score (experts 2 and 5) also exhibited similar scores for code and visual aspects (See Table 1), suggesting that they interpret creativity for these aspects in similar ways. However, the same expert 5 commonly disagreed with expert 1 (Kendall-$\tau = -0.6$). Their scores and rankings of overlapping projects differed substantially, suggesting that they differ in their interpretation of creativity. For example for the code aspect, the same project was ranked 1st by expert 5 and 16th by expert 1.

We observe that most experts found the visual aspect more significant than the code aspect when evaluating creativity. For the majority of experts, the project idea was the most important aspect. By contrast, experts assigned low weights to audio aspects. We note that the project idea is very difficult to model computationally. This is an interesting avenue to explore in future work.

5. PREDICTING CREATIVITY SCORES

In this section we report on the design and evaluation of a computational model to predict the creativity scores of Scratch projects. We build an automatic tool to support teachers (and students) in Scratch that can be trained on examples taken from individual or multiple experts.

We use an XGBoost Regressor [4] to predict the expert creativity scores for each project. As input features we used the

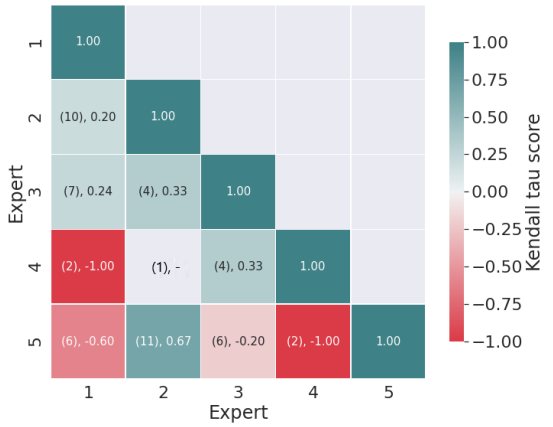

Figure 4: Kendall-τ Agreement between pairs of experts with overlapping projects on the final creativity score. (The number of overlapping projects is shown in parentheses.)

originality, flexibility, and fluency measures for both visual and code aspects, as described in Section 3. This provided us with 6 features for each instance (project). The reference sample for computing originality included all of the projects that the expert rated.

We created 2 types of XGBoost models: (1) a single rater model trained on projects for each expert separately and (2) a combined model trained on the projects from all experts together. Note that for the combined model, projects that were evaluated by more than one rater were treated as different instances. For each type of model, we created three different prediction models (a) predicting the code creativity score. (b) predicting the visual creativity score. (c) predicting the overall project score by the weighted combination score (visual and code). The features consisted of the originality, flexibility and fluency for the code aspect (model a), the visual aspect (model b), or both (model c).

The combined model and the single rater models were developed using the official implementation of XGBoost[4]. We selected the hyperparameters based on the structure of our data. We set the upper complexity limit of the model to six trees for the rater with 10 projects, 14 for the rest of the raters, and 29 trees for the combined raters and the maximum tree depth based on the number of features. The combined model was evaluated using 10-fold cross-validation. The single rater models were evaluated using 5 folds to ensure that the test set contained at least two projects.

Because of the high degree of variance between the raters, we do not seek to minimize error with respect to the predicted creativity score. Instead, we compare rankings. Ideally, we would compare the rankings of the projects in the test set with the true rankings for each expert. However, the size of the test set for some folds for some of the experts was small (4 projects for most experts). To increase the number of comparisons for Kendall-τ, we built a complete ranking

[4]`https://github.com/dmlc/xgboost`

Table 2: Kendall-τ score between XGBoost Regressor and experts scores - code creativity score, visual creativity score, and the weighed visual and code score

Experts	Kendall-τ		
Expert	Code	Visual	Weighed visual and code
1	0.52	0.52	0.42
2	0.51	0.42	0.42
3	0.53	0.58	0.36
4	0.46	0.52	0.57
5	0.52	0.42	0.50
Combined	0.43	0.44	0.42

over all projects for an expert, by combining the predicted scores of projects in the test-set with the scores of projects in the training set. However, we compute the Kendall-τ agreement only for project pairs with at least one project in the test set. We make a similar computation with respect to computing the Kendall-τ for the combined model.

Table 2 presents the Kendall-τ performance, computed as described above. As seen from the table, when predicting the creativity score for visual and code aspects, we achieve a Kendall-τ score of 0.51 and above for 3 out of 5 experts. When predicting the weighted creativity score, we achieve a Kendall-τ score of over 0.42 for 4 out of 5 experts. Overall, the agreement measure is higher than that of the inner-agreement between the experts themselves that is reported in Figure 4 (except for the pair 2 and 5).

The bottom row in Table 2 presents the results for the XGBoost model that is trained over the combined set for all experts. In all cases we achieve a Kendall-τ score above 0.42, which is higher than the inner-agreement scores for most pairs of experts. For visual aspects, the combined model is less successful than the individual models. In contrast, for the visual creativity, the combined model is better than the single rater model for two of the experts (experts 2 and 5); for weighted visual and code creativity score, the combined model is better or equal than the single rater model for 3 experts (experts 1, 2 and 3). This suggests that our models can define useful rules for aggregating creativity rankings by different experts despite the disagreement between them.

6. DISCUSSION AND CONCLUSION

In this paper we presented a formalization of creativity in terms of fluency, flexibility, and originality. We automatically computed creativity both for code and for visual aspects of Scratch projects and we intend to add the other possible modalities of that environment to our future work. Further, we set up a web application to rate the creativity in Scratch projects independently of our formalization. Finally, we recorded the ratings of five human experts on 45 Scratch projects via this application.

We observed that human raters tend to disagree on which projects are creative and which are not. Still, we were able to train regression forests, which achieved a higher ranking agreement with the human raters than they achieved with each other, and which only used the automatically generated ratings as input. We observed that the regression forest model could further improve its accuracy when being applied to individual experts instead of their shared data.

Our approach makes a step towards supporting teacher's abilities to detect and support creative outcomes in students' work. Ample future work is still to be done. Furthermore, we plan to analyze creativity ratings over time, thus tracking students' creative learning process. Future work will also need to address how an automatic assessment of creativity can support creativity at scale in technological environments, taking into account different subjective interpretations.

ABSTRACT

Peer assessment has been widely applied across diverse academic fields over the last few decades, and has demonstrated its effectiveness. However, the advantages of peer assessment can only be achieved with high-quality peer reviews. Previous studies have found that high-quality review comments usually comprise several features (e.g., contain suggestions, mention problems, use a positive tone). Thus, researchers have attempted to evaluate peer-review comments by detecting different features using various machine learning and deep learning models. However, there is no single study that investigates using a multi-task learning (MTL) model to detect multiple features simultaneously. This paper presents two MTL models for evaluating peer-review comments by leveraging the state-of-the-art pre-trained language representation models BERT and DistilBERT. Our results demonstrate that BERT-based models significantly outperform previous GloVe-based methods by around 6% in F1-score on tasks of detecting a single feature, and MTL further improves performance while reducing model size.

Peer assessment, peer feedback, automated peer-assessment evaluation, text analytics, educational data mining

1. INTRODUCTION

Peer assessment is a process by which students give feedback on other students' work based on a rubric provided by the instructor [20, 24]. This assessment strategy has been widely applied across diverse academic fields, such as computer science [28], medicine [27], and business [1]. Furthermore, massive open online courses (MOOCs) commonly use peer assessment to provide feedback to students and assign grades. There is abundant literature [7, 24, 25, 11] demonstrating the efficacy of peer assessment. For example, Doubling et al. [7] conducted a meta-analysis of 54 controlled experiments for evaluating the effect of peer assessment across subjects and domains. The results indicate that peer assessment is more effective than teacher assessment, and also remarkably robust across a wide range of contexts [7].

However, low-quality peer reviews are a persistent problem in peer assessment, and considerably weaken the learning effect [17, 22]. The advantages of peer assessment can only be achieved with high-quality peer reviews [14]. This suggests that peer reviews should not be simply transmitted to other students but rather should be vetted in some way. Course staff could check the quality of each review comment[1] and assess its credibility manually, but this is not efficient. Sometimes (e.g., for MOOCs), this is not remotely possible. Therefore, to ensure the quality of peer reviews and the efficiency of evaluating their quality, the peer-assessment platform should be capable of assessing peer reviews automatically. We call this Automated Peer-Review Evaluation.

Previous research has determined that high-quality review comments usually comprise several features [14, 2, 25]. Examples of such features are, "contains suggestions", "mentions problems", "uses a positive tone", "is helpful", "is localized" [14]. Thus, one feasible and promising way to evaluate peer reviews automatically is to adjudicate the quality of each review comment based on whether it comprises the predetermined features, by treating this task as a text classification problem. If a peer-review comment does not contain some of the features, the peer-assessment platform could suggest that the reviewer should revise the review comment to add missing features. Additionally, containing suggestions, mentioning problems, and using a positive tone, are among the most essential features. Thus, we use them for this study.

Previous work for automatically evaluating review comments has focused on tasks that detect a single feature. For example, Xiong and Litman [33] designed sophisticated features and used traditional machine-learning methods for identifying peer-review helpfulness. Zingle et al. [37] utilized different rule-based, machine-learning, and deep-learning methods for detecting suggestions in peer-review comments. However, to the best of our knowledge, no single study exists that investigates using a multi-task learning (MTL) model to detect multiple features simultaneously (as illustrated in Figure 1), albeit extensive research has been carried out on

[1]In some peer-assessment systems, reviews are "holistic". In others, including the systems we are studying, each review contains a set of review comments, each comment gives a response to a different criterion in the rubric.

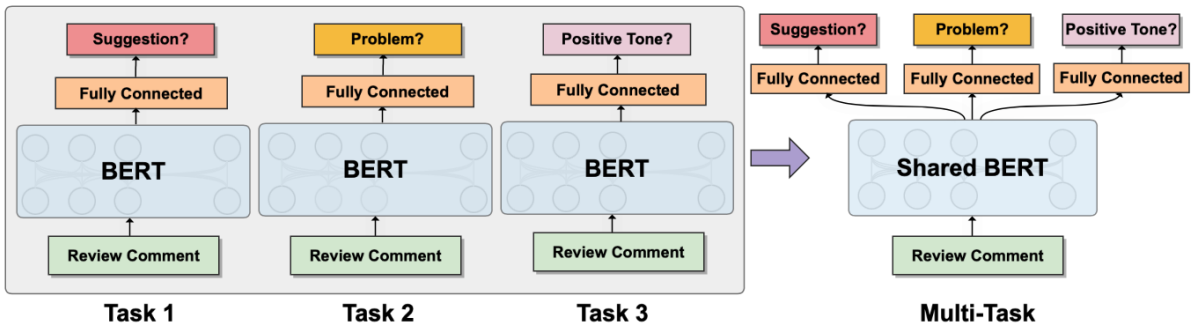

Figure 1: Illustration of the single-task and multi-task learning settings

the topic of automated peer-review evaluation (e.g., [34, 32, 33, 31, 30, 37, 13, 19, 8]).

There are at least two motivations for using multi-task learning (MTL) to detect features simultaneously. Firstly, the problem naturally leads itself well to MTL, due to multiple features usually needing to be employed for a comprehensive and precise evaluation of peer-review comments. If we treat this MTL problem as multiple independent single tasks, total model size and prediction time will increase by a factor of the number of features used for evaluating review comments. Secondly, MTL can increase data efficiency. This implies that learning tasks jointly can lead to performance improvement compared with learning them individually, especially when training samples are limited [5, 36]. More specifically, MTL can be viewed as a form of inductive transfer learning, which can help improve the performance of each jointly learned task by introducing an inductive bias [3].

Additionally, the pre-trained language model, BERT (Bidirectional Encoder Representations from Transformers) [6], has become a standard tool for reaching the state of the art in many natural language processing (NLP) tasks. BERT can significantly reduce the need for labeled data. Therefore, we propose multi-task learning (MTL) models for evaluating review comments by leveraging the state-of-the-art pre-trained language representation models BERT and DistilBERT. We first compare a BERT-based single-task learning (STL) model with the previous GloVe-based STL model. We then propose BERT and DistilBERT based MTL models for jointly learning different tasks simultaneously.

The rest of the paper is organized as follows: Section 2 presents related work. Section 3 describes the dataset used for this study. The proposed single-task and multi-task text classification models are elaborated in Section 4. Section 5 details the experimental setting and results. In Section 6, we conclude the paper, mention the limitations of our research, and discuss future work.

2. RELATED WORK

2.1 Automated Peer-Review Evaluation

The earliest study on automated peer-review evaluation was performed by Cho in 2008 [4]. They manually broke down every peer review comment into review units (self-contained messages in each review comment) and then coded them as praise, criticism, problem detection, solution suggestion. Cho [4] utilized traditional machine learning methods, including naive Bayes, support vector machines (SVM), and decision trees, to classify the review units.

Xiong et al. attempted to use features (e.g., counts of nouns, verbs) derived from regular expressions and dependency parse trees and rule-based methods to detect localization in the review units [32]. Then, they designed more sophisticated features by combining generic linguistic features mined from review comments and specialized features, and used SVM to identify peer-review helpfulness [33]. After that, Xiong et al. upgraded their models to comment-level (use whole review comment instead of review units as the input) [15, 16].

Then, researchers started to use deep neural networks on tasks of automated peer-review evaluation for improving accuracy. Zingle et al. compared rule-based machine-learning and deep neural-network methods for detecting suggestions in peer assessments, and the result showed that deep-learning methods outperformed other traditional methods [37]. Xiao et al. collected around 20,000 peer-review comments and leveraged different neural networks to detect problems in peer assessments [31].

2.2 Multi-Task Learning

Multi-task learning (MTL) is an important subfield of machine learning in which multiple tasks are learned simultaneously [35, 5, 3] to help improve the generalization performance of all the tasks. A task is defined as $\{p(x), p(y|x), L)\}$, where $p(x)$ is the input distribution, $p(y|x)$ is the distribution over the labels given the inputs, and L is the loss function. For the MTL setting in this paper, all tasks have the same input distribution $p(x)$ and loss function L, but different distributions over the labels given the inputs $p(y|x)$.

In the context of deep learning, all methods of MTL can be partitioned into two groups: hard-parameter sharing and soft-parameter sharing [3]. For hard-parameter sharing, the hidden layers are shared between all tasks while keeping several task-specific output layers. For soft-parameter sharing, each task has its independent model, but the distance between the different models' parameters is regularized. For this study, we use the hard-parameter sharing approach.

Table 1: Sample Rubric Criteria

Does the design incorporate all of the functionality required?
Have the authors converted all the cases discussed in the test plan into automated tests?
Does the design appear to be sound, following appropriate principles and using appropriate patterns?

only problem statement is explained and nothing about design. please add design and diagrams.	1	1	0

3. DATA

3.1 Data Source: Expertiza[2]

The data in this study is collected from an NSF-funded peer-assessment platform, Expertiza. In this flexible peer-assessment system, students can submit their work and peer-review the learning objects (such as articles, code, and websites) of other students [9]. This platform supports multi-round peer review. In the assignments that provided the review comments for this study, two rounds of peer review (and one round of meta-review) were used:

1. The *formative-feedback* phase: For the first round of review, students upload substantially complete projects. The system then assigns each student to review a set number of these submissions, based on a rubric provided. Sample rubric criteria are provided in Table 1.
2. The *summative-feedback* phase: After students have had an opportunity to revise their work based on feedback from their peers, final deliverables are submitted and peer-reviewed using a summative rubric. The rubric may include criteria such as "How well has the team has addressed the feedback given in the first review round?". Many criteria in the rubric ask reviewers to provide a numeric rating as well as a textual comment.
3. The *meta-review* phase: After the grading period is over, course staff typically assess and grade the reviews provided by students.

For this study, all textual responses to the rubric criteria from the formative-feedback phase and the summative-feedback phase of a graduate-level software-engineering course are extracted to constitute the dataset. Each response to a rubric criterion constitutes a peer-review comment. All responses from one student to a set of criteria in a single rubric are called a peer review or a review. In this study, we focus on evaluating each peer-review comment. After filtering out review comments that only contain symbols and special characters, the dataset consists of 12,053 review comments. In the future, we will update the platform, and this type of review comments will be rejected by the system directly.

3.2 Annotation Process

One annotator who is a fluent English speaker and familiar with the course context annotated the dataset. For quality control, 100 reviews were randomly sampled from the dataset and labeled by a second annotator who is also a fluent English speaker and familiar with the course context. The inter-annotator agreement between two annotators was measured by Cohen's κ coefficient, which is generally thought to be a more robust measure than simple percent agreement calculation [12]. Cohen's κ coefficient for each label is shown in Table 3. The result suggests that the two annotators had almost perfect agreement (>0.81) [12]. Sample annotated comments are provided in Table 2.

[2]https://github.com/expertiza/expertiza

Table 3: Inter-Annotator Agreement (Cohen's κ)

Label	Suggestion	Problem	Tone	Average
Cohen's Kappa	0.92	0.84	0.87	0.88

We define each feature (label) in the context of automated peer-review evaluation as follows:

Suggestion: A comment is said to contain a suggestion if it mentions how to correct a problem or make improvements.

Problem: A comment is said to detect problems if it points out something that is going wrong in peers' work.

Positive Tone: A comment is said to use a positive tone if it has an overall positive semantic orientation.

3.3 Statistics on the Dataset

The minority class for each label includes more than 20% of samples, and thus the dataset is mildly imbalanced. It consists of 12,053 peer-review comments, and the average number of words for each peer-review comment is 29. We found that most students (over three-quarters) use a positive tone in their peer-review comments. Around half of the review comments mention problems with their peers' work, but only one-fifth of review comments give suggestions. Characteristics of the dataset are shown in Table 4 below,

Table 4: Statistics on the Dataset

Label	Class	%samples	avg.#words	max#words
Sugg.	0	79.2%	22	922
	1	20.8%	58	1076
Prob.	0	56.7%	22	479
	1	43.3%	38	1076
Pos. Tone	0	22.2%	28	1040
	1	77.8%	29	1076

4. METHODOLOGY

In this section, we first briefly introduce Transformer [26], BERT [6], and DistilBERT [21]. Then we describe BERT and DistilBERT based single-task and multi-task models.

4.1 Transformer

In 2017, Vaswani et al. published a groundbreaking paper, "Attention is all you need," and proposed an architecture called Transformer, which significantly improved the performance of sequence-to-sequence tasks (e.g., machine translation) [26]. The Transformer is entirely built upon self-attention mechanisms without using any recurrent or convolutional layers. As shown in Figure 2, the Transformer consists of two parts: the left part is an *encoder*, and the right part is a *decoder*. The *encoder* block takes a batch of sentences represented as sequences of word IDs. Then the sequences pass through an embedding layer, and the positional embedding adds positional information of each word.

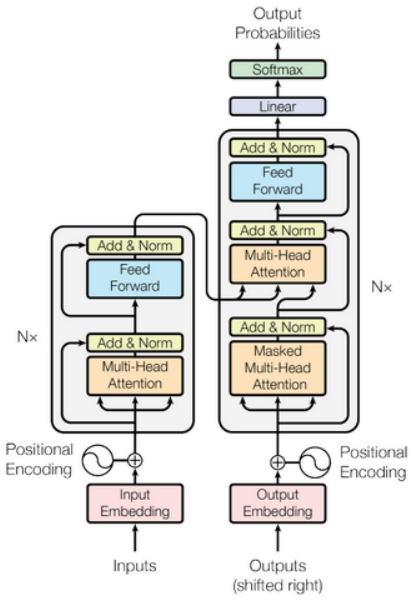

Figure 2: Architecture of the Transformer [26]

The *encoder* block is then briefly introduced since BERT reuses it. Each *encoder* consists of two layers: a multi-head attention layer and a feed-forward layer. The multi-head attention layer uses the self-attention mechanism, which encodes each word's relationship with every other word in the same sequence, paying more attention to the most relevant ones. For example, the output of this layer for the word "like" in the sentence, "we like the Educational Data Mining conference 2021!" will depend on all the words in the sentence. However, it will probably pay more attention to the word "we" than to the words "data" or "mining."

4.2 BERT

BERT is a state-of-the-art pre-trained language representation model proposed by Devlin et al. [6]. It has advanced the state-of-the-art results in many NLP tasks and significantly reduced the need for labeled data by pre-training on unlabeled data over different pre-training tasks. Each BERT model consists of 12 *encoder* blocks of the Transformer model. The input representation is constructed by summing the corresponding token and positional embeddings. The length of the output sequence is the same as the input length, and each input token has a corresponding representation in the output. The output of the first token '[CLS]' (a special token added to the sequence) is utilized as the aggregate representation of the input sequence for classification tasks [6].

The BERT framework consists of two steps: pre-training and fine-tuning. During pre-training, the model is trained on unlabeled data, BooksCorpus (800M words) and English Wikipedia (2,500M words), over two pre-training tasks, Masked language model (MLM) and Next sentence prediction (NSP). For fine-tuning, the BERT model is first initialized with the pre-trained parameters, and then all of the parameters are fine-tuned using labeled data from the downstream tasks (e.g., text classification). For this study, we use HuggingFace pre-trained BERT[3] to initialize models and then fine-tune models with annotated peer-review comments for automated peer-review evaluation tasks.

4.3 DistilBERT

Although BERT has shown remarkable improvements across various NLP tasks and can be easily fine-tuned for downstream tasks, one main drawback of BERT is that it is very compute-intensive (i.e., it takes a huge amount of parameters, ∼110M parameters). Therefore, researchers are attempting to apply different methods for compressing BERT, including pruning, quantization, and knowledge distillation [10]. One of the compressed BERT models is called DistilBERT [21]. DistilBERT is compressed from BERT by leveraging the knowledge distillation technique during the pre-training phase. The authors [21] demonstrated that DistilBERT has 40% fewer parameters and is 60% faster than the original BERT while retaining 97% of its language-understanding capabilities. We will investigate whether we can reduce model size while retaining performance for our task with DisilBERT.[4]

4.4 Input Preparation

Text Preprocessing: First, URL links in peer-review comments are removed. Then, we lowercase all comments and leverage a spellchecker API[5] to correct typos and misspellings. Finally, two special tokens ([CLS], [SEP]) are added to each review comment, as required for BERT. The [CLS] token is added to the beginning of each review for classification tasks. The [SEP] token is added at the end of each review.

Subword Tokenization: The tokenizer used for BERT is a subword tokenizer called "WordPiece" [29]. Traditional word tokenizers suffer the out-of-vocabulary (OOV) word problem. However, a subword tokenizer could alleviate the OOV problem. It splits a text into subwords, which then are converted to token IDs.

Input Representation: The token IDs are padded or truncated to 100 for each sequence and then pass through a trainable embedding layer to be converted to token embeddings. The input representation for BERT is constructed by summing the token embeddings and positional embeddings.

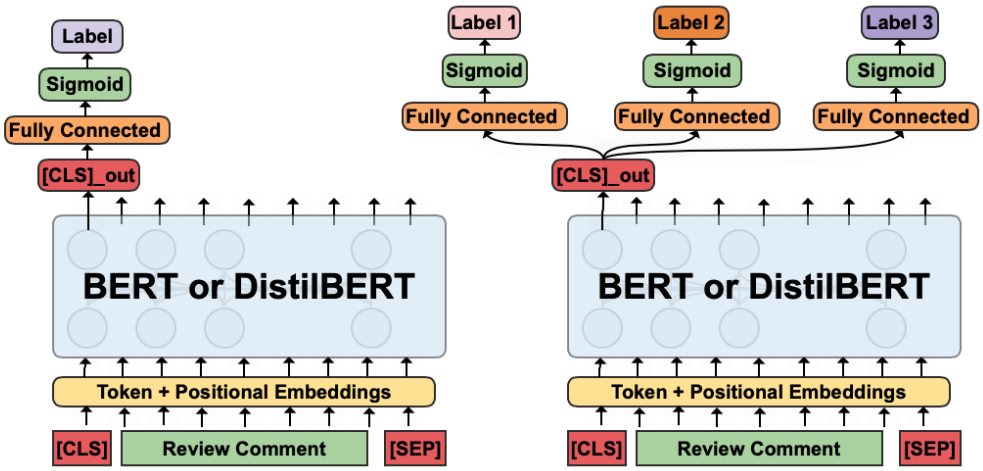

Figure 3: BERT and DistilBERT based single-task and multi-task learning architectures

4.5 Single-Task and Multi-Task Models

As mentioned in the BERT paper [6] and other studies [23], the pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks, including text classification. Therefore, only one dense layer is added on top of the original BERT or DistilBERT model and used as a binary classifier for the single-task learning models. Three dense layers are added to the multi-task learning models, one for each label.

5. EXPERIMENTS AND RESULTS

In this section, we first introduce training details and evaluation metrics and then show experimental results.

5.1 Training

Train/Test split: We find by experiments that increasing training size does not help the classifier when the number of training samples is over 5000. Therefore, 5000/2053/5000 data samples are used for training/validation/testing.

Loss Functions: For BERT and DistilBERT based Single-Task Learning (STL) models, the cross-entropy loss is used. For BERT and DistilBERT base Multi-Task Learning (MTL) models, the cross-entropy loss is used for each task. The total loss will be the sum of the cross-entropy loss of each task.

Cost-Sensitive method: As mentioned in Section 3.3, the dataset is mildly imbalanced (minority class $> 20\%$). Thus, a cost-sensitive method is used in this study for alleviating the problem of class imbalance and improving performance, by weighting the cross-entropy loss function during training based on the frequency of each class in the training set.

Hyperparameters: As we mentioned in Section 4.2 and Section 4.3, we use HuggingFace pre-trained BERT and DistilBERT to initialize models. The hidden size for BERT and DistilBERT is 768. We then fine-tune the BERT and DistilBERT based single-task learning and multi-task learning models with a batch size of 32, max sequence length 100, learning rate 2e-5/3e-5/5e-5, epochs of 2/3, dropout rate 0.1, and Adam optimizer with β_1=0.9 and β_2=0.99.

5.2 Evaluation Metrics

We use accuracy, macro-F1 score (average for each class of each label instead of each label), and AUC (Area Under ROC Curve) to evaluate models. Since the dataset is merely mildly imbalanced, accuracy can still be a useful metric. The Macro-F1 instead of F1-score for the positive class is used, since both positive class and negative class for each label are important for our task. For this study, we mainly use accuracy and macro-F1 to compare different models.

5.3 Results

Table 5 shows the performance of all models when training with a different number of training samples (1K, 3K, and 5K). The first column indicates the models (GloVe, BERT, DistilBERT) and training settings (single-task learning (STL), multi-task learning (MTL)).

RQ1 Does BERT outperform previous methods?
We first implemented a baseline single-task learning model by leveraging pre-trained GloVe (Global Vectors for Word Representation)[6] [18] word embeddings. We added a BatchNormalization layer on top of GloVe, and the aggregate representation of the input sequence for classification was obtained by AveragePooling the output of the BatchNormalization layer. A dense layer was added on the top for performing classification.

We compared GloVe and BERT for every single task. As shown in Table 5, the results clearly showed that a BERT-based STL model yields substantial improvements over the previous GloVe-based method. The STL-BERT model trained with 1000 data samples outperformed the STL-GloVe model trained with 5000 data samples on all tasks. This suggests that the need for labeled data could be significantly reduced by leveraging a pre-trained language model BERT.

RQ2 How does multi-task learning perform?
By comparing MTL-BERT with STL-BERT and MTL-DistilBERT with STL-DistilBERT when trained with a different number of training samples, we found that jointly learning

5 MTL-DistilBERT	94.2%	.914	.980	90.4%	.902	.964	90.6%	.852	**.951**

Table 6: The # of parameters for each setting

Setting	# of parameters
STL-BERT * 3	328M
STL-DistilBERT * 3	199M
MTL-BERT	109M
MTL-DistilBERT	66M

related tasks improves the performance of the suggestion-detection task and the positive-tone detection task, especially when we have limited training samples (i.e., when training with 1K and 3K data samples). This suggests that MTL can increase data efficiency. However, for the problem-detection task, there is no significant difference between the performance of the STL and MTL settings.

Additionally, MTL can considerably reduce the model size. As shown in Table 6, three BERT-based STL models would have more than 328M parameters, and this number would be 199M for the DistilBert-based models. However, if we employ the MTL models for evaluating peer-review comments, the number of parameters would be reduced to 109M and 66M, respectively. This demonstrates that using MTL to evaluate reviews can save considerable memory resources and reduce the response time of peer-review platforms.

RQ3 How does DistilBERT perform?
By comparing DistilBERT and BERT on both STL and MTL settings, we found that BERT-based models slightly outperformed DistilBERT-based models. This result implied a trade-off between performance and model size when selecting the model to be deployed on peer-review platforms. If we focus on high accuracy instead of memory resource usage and response time of the platforms, the MTL-BERT model is the choice. Otherwise, the MTL-DistilBERT should be deployed.

6. CONCLUSIONS

In this study, we implemented single-task and multi-task models for evaluating peer-review comments based on the state-of-the-art language representation models BERT and DistilBERT. Overall, the results showed that BERT-based STL models yield significant improvements over the previous GloVe-based method on tasks of detecting a single feature. Jointly learning different tasks simultaneously further improves performance and saves considerable memory usage and response time for peer-review platforms. The MTL-BERT model should be deployed on peer-review platforms, if our focus is on high accuracy instead of memory resource usage and response time of the platforms. Otherwise, the MTL-DistilBERT model is preferred.

There are three limitations to this study. Firstly, we employed three features of high-quality peer reviews to evaluate a peer-review comment. However, it is still unclear how MTL will perform if we learn more tasks simultaneously. Secondly, we mainly focused on a hard-parameter sharing approach for constructing MTL models. However, some studies have found that the soft-parameter sharing approach might be a more effective method for constructing multi-task learning models. Thirdly, the performance of the model has not been evaluated in actual classes. We intend to deploy the model on the peer-review platform and evaluate the model extrinsically in real-world circumstances.

These preliminary results serve as a basis for our ongoing work, in which we are building a more complex all-in-one model for comprehensively and automatically evaluating the quality of peer review comments to improve peer assessment. In the future, we will attempt to evaluate peer reviews based on more predetermined features and use fine-grained labels (e.g., instead of evaluating whether a peer-review comment contains suggestions, we will evaluate how many suggestions are contained in a review comment).

ABSTRACT

The prevalence of online education systems provides opportunities to deliver personalized learning at scale. Educational systems need to assess students so that they can provide better curricula tailored to each student's unique needs. Since there is a limited amount of time for quizzing a student, we need to test each student using those questions that capture the most information about their level of understanding of various concepts. In this paper, we formally pose the problem and present multiple approaches for learning a quizzing policy to determine a personalized sequence of questions for each student that best predicts their knowledge state. We first introduce simple heuristics including random selection and an uncertainty sampling approach inspired by an active learning framework. We then develop a reinforcement learning (RL) approach for designing a quizzing policy. Using simulations of students' knowledge states, we provide initial evidence that an RL-based approach can improve over simple heuristics. We further demonstrate the effectiveness of our approaches using a real-world dataset consisting of over 1.5 million examples of students' answers to mathematics questions from Eedi, an online educational platform.

Keywords

reinforcement learning, knowledge state, quizzing policy

1. INTRODUCTION

Online education systems are making high-quality education more accessible for students across the globe. These systems provide various educational resources such as instructional videos and exercises. To provide personalized curricula for improving the learning outcomes of students, an online education system needs to accurately infer each student's knowledge state (i.e., their level of understanding of various concepts) by quizzing them. This is a challenging task because the quizzing time is limited. To make the most efficient use of each student's time, it is important to prioritize those questions that reveal the most information about the student's knowledge.

We focus on a specific goal for student assessment: *given a limit to the number questions we are allowed to ask each student, how can we determine a sequence of questions for each student that best predicts their knowledge state?* Specifically, when an education system needs to assess a student for inferring their knowledge, the system suggests a personalized question to query for the student and gets their response to the question. Based on the student's response history (i.e., a sequence of question-response pairs), the system selects another question to query for the student until it has exhausted its query budget (i.e., the maximum number of queries allowed). We refer to the function that provides the next question to query based on students' response histories as quizzing policy (QP).

We define the task of learning a QP in the context of the NeurIPS 2020 Education Challenge [27] launched by Eedi [6], an online educational platform with thousands of active users daily around the globe. We consider a set of 948 multiple-choice mathematics questions that correspond to 57 different concepts. Specifically, the task is to obtain a limited set of answers from each student for inferring the student's knowledge on the 57 concepts and then predict the student's performance on unseen questions based on the inferred knowledge state.

The key challenge in designing a QP is related to a crucial task in machine learning: active learning (AL). For many learning tasks (e.g., image classification, text classification), obtaining sufficient labeled data for training high-performance models is costly [16, 18, 32]. AL aims to reduce the amount of annotated data needed by having the model carefully select which data points should be labeled.

Existing methods for AL include heuristics such as selecting the data points about which the model is most uncertain (i.e., uncertainty sampling) [15, 26, 31, 24], picking the instances about which a set of possible different models disagree the most (i.e., query by committee) [23, 10], or choosing the example that can lead to the most immediate improvement in model performance (i.e., estimated error reduction) [22, 12].

In addition to these heuristics for AL, recent studies [30, 19, 9] have explored how to use reinforcement learning (RL) to learn the AL strategy itself. RL [20, 25] is a powerful

framework where an agent learns how to make good decisions (actions) in different situations (states) through trial and error. In the RL terminology, the action space provides the set of actions that can be taken by the RL agent at a given point in time; the state space defines the "state of the world" that is visible to the RL agent; and the reward function assigns a value to the outcome of each action taken by the RL agent. In this case, the set of possible instances to be labeled defines the action space; the state space is a representation of the sequence of instances that have already been annotated; and the gain in prediction accuracy as a result of an action defines the reward. The RL agent learns to improve its decision-making over time based on the reward signals it receives. Inspired by these studies, we investigate using RL to learn a QP for personalized student assessment.

1.1 Our approach and contributions

In this paper, we formalize the problem of learning a QP for inferring the student knowledge state and present several different approaches including simple heuristics and an RL-based approach. Our contributions are:

- We formulate the problem of learning a QP to infer student knowledge.
- We propose simple heuristics (i.e., random selection, uncertainty sampling) and an RL-based approach for learning a QP.
- We evaluate the performance of different QPs on a synthetic dataset and a publicly available dataset consisting of over 1.5 million examples of students' answers to mathematics questions from Eedi.

For the reproducibility of experimental results and facilitating research in this area, the code and dataset are publicly available.[1]

1.2 Related work

AL is a popular methodology in machine learning that aims to reduce the amount of annotated data needed by having the model carefully select which data points should be labeled. The task of designing a QP is closely related to AL because the goal is to optimally select a set of questions to ask students to gain the most information about their knowledge states. Uncertainty sampling [15, 26, 31, 24] is one of the most popular heuristics for AL because it is straightforward and computationally efficient. Specifically, it suggests labeling instances that are closest to the model's decision boundary (i.e., the most uncertain). Woodward and Finn [30] propose the first application of RL to the task of AL for image classification. Other studies [19, 9] explore how to train an AL policy that can generalize across diverse datasets.

RL has also been applied to various tasks in education such as learning an instructional policy [2, 3, 5, 13, 17, 21, 28], learning a hint policy for helping students solve multi-step problems [7], and generating new educational tasks [1]. We introduce a different policy, a quizzing policy for inferring the student knowledge state, which has not been designed using RL in previous literature.

[1]https://github.com/joyheyueya/quizzing-policy

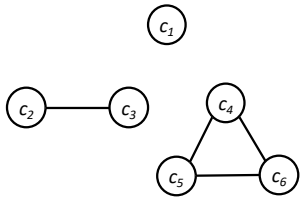

Figure 1: Graphical representation of knowledge. This is an example of an undirected graph where each node (circle) represents a concept, and each edge connects a pair of similar concepts: c_1 is an independent concept, c_2 and c_3 are similar, and c_4, c_5, and c_6 are similar.

There is prior work on the efficient assessment of knowledge [8]. Our student knowledge model is inspired by the knowledge components (i.e., concepts / skills) used in Bayesian Knowledge Tracing (BKT) [4], which represents the state for each knowledge component as a binary variable: 1 if the knowledge component is known, 0 otherwise.

2. PROBLEM FORMULATION

In this section, we formalize the problem of learning a quizzing policy (QP) for inferring the student knowledge state.

2.1 Student knowledge state

Our goal is to infer student knowledge on a set of n concepts $C = \{c_1, ..., c_n\}$ associated with a set of m questions $X = \{x_1, ..., x_m\}$. For simplicity, each question corresponds to a single concept, but each concept might be associated with more than one question ($m >> n$). A student's knowledge state h is defined as $h = [v_1, ..., v_n]$ where $v_1, ..., v_n$ are binary variables that indicate whether or not the student knows each concept in C: $v_i = 1$ if c_i is known, and $v_i = 0$ otherwise. Formally, we define a hypothesis space $\mathcal{H}$ for all possible knowledge states: $\mathcal{H} = \{0, 1\}^n$. We assume h is fixed during the assessment.

2.2 Graphical representation of knowledge

We consider two assumptions that are useful for inferring the student knowledge state: 1) difficult concepts are more likely to be unknown, and easy concepts are more likely to be known; 2) similar concepts are more likely to have the same value (i.e., a student who knows one concept is also likely to know the other concepts that are similar to the one that is already known). These influences can be represented by an undirected graph where each node corresponds to a concept, and each edge connects a pair of concepts that are similar (see Figure 1). In the Eedi dataset (described in Section 4.2.1), we consider every pair of concepts that share the same super-concept to be similar (e.g., there is an edge between "Rearranging Formula and Equations" and "Substitution into Formula" because they are both under the same super-concept "Formula"). Based on this graphical structure, we model a student's knowledge state using a Markov Random Field (MRF).

An MRF is a probability distribution over a set of variables that satisfy certain properties defined by an undirected graph. In our case, we define a probability distribution p over binary variables $v_1, ..., v_n$ defined by an undirected graph $G = (V \cup F, E)$ where V is the set of nodes (con-

cepts), F is the set of factors that define a set of functions over the variables that they are connected with, and E is the set of edges (see Figure 2).

An MRF allows us to calculate the probability of each way of assigning values to binary variables $v_1, ...v_n$, which represent the knowledge state of the corresponding concepts $c_1, ..., c_n$. The probability p has the form:

$$p(v_1, ..., v_n) = \frac{1}{Z} \prod_{\psi_\alpha \in F} \psi_\alpha(v_\alpha) \quad (1)$$

where α represents a subgraph of G, and ψ_α denotes a factor that defines a non-negative function over the set of variables v_α in α. Z is a normalizing constant that ensures the distribution sums to one:

$$Z = \sum_{v_1,...v_n} \prod_{\psi_\alpha \in F} \psi_\alpha(v_\alpha) \quad (2)$$

We specify factors for an MRF based on two assumptions about variables $v_1, ..., v_n$. For our first assumption that difficult concepts have a higher probability of being unknown, we define unary factors:

$$\psi_i(v_i) = \begin{cases} 1 - \textit{difficulty}_{c_i} & \text{if } v_i = 1 \\ \textit{difficulty}_{c_i} & \text{otherwise} \end{cases}$$

where $\textit{difficulty}_{c_i}$ is a real number that represents the difficulty of the concept c_i that v_i corresponds to, and $0 \leq \textit{difficulty}_{c_i} \leq 1$. A higher $\textit{difficulty}_{c_i}$ value means c_i is more difficult.

For our second assumption that variables corresponding to similar concepts are more likely to have the same values, we define binary factors between every pair of nodes (v_i, v_j) that are connected by an edge in graph G:

$$\psi_{\{i,j\}}(v_i, v_j) = \begin{cases} \textit{influence} & \text{if } v_i = v_j \\ 1 - \textit{influence} & \text{otherwise} \end{cases}$$

where *influence* represents a constant that satisfies $0.5 \leq \textit{influence} \leq 1$. A greater *influence* value means we want to assign a higher probability to an assignment that gives the same values to variables corresponding to similar concepts. In our work, we fix *influence* to be 0.7. We also tried similar values, and they lead to similar results.

2.3 Quizzing policy for knowledge inference

Since there is a cost associated with each question we query students (e.g., time, student's energy), we need to select a limited number of questions that reveal the most about their knowledge state. Thus, student knowledge prediction can be framed as a pool-based active learning (AL) task with a given query budget T. For simplicity, we assume querying each exercise leads to the same cost and define T to be the total number of queries we are allowed.

We describe the AL framework in detail, see Algorithm 1. At a given time step t, we have a labelled set L that consists of all the questions we have asked the student and their responses. Formally, $L = \{(x^i, y^i)\}_{i=1}^t$ where $x^i \in X$, and $y^i \in \{0, 1\}$ is the student's response to x^i ($y^i = 0$ if the response is incorrect, $y^i = 1$ if the response is correct). We also have an unlabelled set U consisting of all the questions that we have not asked). Based on L, we have a belief B_h about the student's knowledge h. Formally, $B_h = [b_1, ..., b_n]$ where b_i is the probability of knowing the concept c_i (i.e., $v_i = 1$ with a probability of b_i). We define $Binary(B_h)$ as a function that converts probabilities into binary values using a threshold of 0.5 (1 if $b_i \geq 0.5$ and 0 otherwise). $Binary(B_h)$ gives the inferred binary knowledge state. We update B_h based on L by running the Loopy Belief Propagation algorithm (LBP) [11] on our graph defined in Section 2.2. LBP takes L as input and outputs the probabilities $b_1, ..., b_n$ ($0 \leq b_i \leq 1$). Additionally, we have a QP that takes B_h as input and outputs the next question to ask the student. Specifically, a policy $\pi(\cdot|B_h)$ provides a probability distribution with support over all questions in U given B_h. We can then sample a question from $\pi(\cdot|B_h)$.

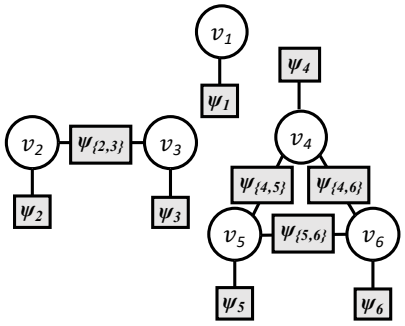

Figure 2: Modeling graphical student knowledge using MRF. This models the knowledge representation in Figure 1 as a factor graph. Each node v_i is a binary variable that represents the knowledge state of the corresponding concept c_i. Factors are represented by rectangles. There is a unary factor for every node and a binary factor between every pair of nodes connected by an edge to model the dependency between variables.

Algorithm 1: Active learning for inferring knowledge

Input: budget T, quizzing policy π
Output: $\hat{h}$
Initialize $L_0 \leftarrow \emptyset$, $U_0 \leftarrow \{x_i\}_{i=1}^m$
for $t = 1, 2, 3, \ldots, T$ **do**
  $B_{h_t} = \text{LBP}(L_{t-1})$
  $x^t \sim \pi(\cdot|B_{h_t})$
  $L_t \leftarrow L_{t-1} \cup (x^t, y^t)$
  $U_t \leftarrow U_{t-1} \backslash x^t$
end
$\hat{h} \leftarrow Binary(B_{h_T})$

Algorithm 1 runs as follows: at each time step t, we first get our current belief B_{h_t} based on the previously labelled set L_{t-1} (i.e., the set of all the questions we have asked the student before time step t and their responses). We then select a question x^t from the previously unlabelled set U_{t-1} to ask the student by sampling from $\pi(\cdot|B_{h_t})$, which defines a probability distribution with support over all questions in U_{t-1} given B_{h_t}. Then, we update U_{t-1} to U_t by removing x^t from U_{t-1} and update L_{t-1} to L_t by adding x^t and its label y^t to L_{t-1}. The quizzing process terminates when the query budget is exhausted. In this work, we fix $T = 10$ as required

by the NeurIPS 2020 Education Challenge [27]. The final output of the algorithm $\hat{h}$ is the student's knowledge state at time step T, which is inferred based on B_{h_T}.

2.4 Evaluation

We evaluate our QPs using two methods. First, we create a synthetic dataset consisting of simulated students (see Section 4.1). We predict each student's knowledge state using Algorithm 1. Given a prediction result $\hat{h}$, we calculate the prediction accuracy using the following equation:

$$Acc(\hat{h}) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}(\hat{h}[i] = h^{\star}[i]) \tag{3}$$

where $h^{\star}$ is the actual knowledge state.

Second, we apply our QPs to the NeurIPS 2020 Education Challenge (see Section 4.2). The challenge is to obtain a limited set of answers from each student for predicting the correctness of their answers to the remaining questions. Our approach to this challenge is to first infer a student's knowledge state using Algorithm 1 and then predict the student's responses to the remaining questions based on the inferred knowledge state. Specifically, we design an additional model (see Section 4.2.2) that takes in our belief about the student's knowledge state at the final time step B_{h_T} and outputs the student's response to each of the m questions. Formally, the vector $\hat{\mathcal{Y}} \in \mathbb{R}^m$ denotes the output of the model. We calculate the prediction accuracy as:

$$Acc(\hat{\mathcal{Y}}) = \frac{1}{|U_T|}\sum_{x_i \in U_T} \mathbb{1}(\hat{\mathcal{Y}}[i] = \mathcal{Y}^{\star}[i]) \tag{4}$$

where U_T is the set of unlabelled questions at the final time step (unseen by the model), $\mathcal{Y}^{\star}[i]$ is the student's actual response to x_i, and $\hat{\mathcal{Y}}[i]$ is the predicted response.

3. DESIGNING QUIZZING POLICIES

In this section, we present heuristics-based approaches and a reinforcement learning (RL)-based approach to designing a quizzing policy (QP) that takes in a belief B_h about a student's knowledge state and outputs the next question to ask the student.

3.1 Heuristic approaches

We present two simple heuristics for designing a QP: random selection (QP-Random) and uncertainty sampling (QP-Uncertain). QP-Random is straightforward: we always randomly select a question from the unlabelled set U (i.e., $\pi(a|B_h) = \frac{1}{|U|}$ for each $a \in U$). QP-Uncertain suggests picking a question corresponding to a concept that our current model is most uncertain about (i.e., the concept with a probability of being known that is closest to 0.5). Formally, we define:

$$b^{\star} = \arg\min_{b_i \in B_h} |b_i - 0.5|$$

We first pick a concept $c^{\star}$ with a probability of being known that is equal to $b^{\star}$. We break ties randomly. We define $U_{c^{\star}}$ as the set of questions that have not been asked and are associated with $c^{\star}$. We then define the policy:

$$\pi(a|B_h) = \begin{cases} \frac{1}{|U_{c^{\star}}|} & \text{if } a \in U_{c^{\star}} \\ 0 & \text{otherwise} \end{cases}$$

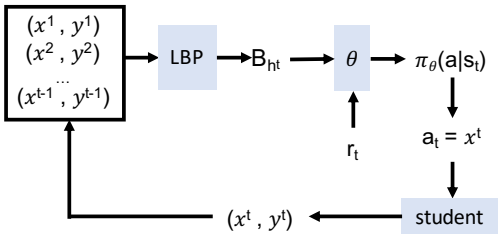

Figure 3: QP-RL approach.

3.2 RL-based approach

We now propose an RL-based approach (QP-RL) for learning a QP. An RL agent learns how to make good decisions over time by interacting with an environment that is typically modeled as a Markov Decision Process (MDP). In our problem setting, we define the MDP $M = (S, A, P, R, s_0)$ as follows:

- The state space S is the set of beliefs B_h about student knowledge (i.e., $S = \{[b_1, ..., b_n] | 0 \leq b_i \leq 1\}$);
- The action space A is the set of questions that have not been asked;
- The transition dynamics $P : S \times A \times S \to \mathbb{R}$ define the probability of transitioning from one state to another by taking a particular action. In our case, we transition to state s_{t+1} from s_t based on the student's response y^t.
- The reward function $R : S \times A \times S \to \mathbb{R}$ is defined as the difference in prediction accuracy between the current time step and previous step: for predicting student knowledge, given the inferred knowledge state h_{t+1} after taking action a_t, we calculate the reward for time step t as $Acc(h_{t+1}) - Acc(h_t)$;
- The initial state s_0 corresponds to the initial belief about student knowledge: each concept has a 0.5 probability of being known.

Figure 3 shows an overview of the QP-RL approach. For training the RL agent, we consider an episodic, finite-horizon setting. During each episode, we train on one student's data, and the length of the episode is the query budget T. At each time step t, we run the LBP algorithm that takes in the student's response history $L_{t-1} = \{(x^i, y^i)\}_{i=1}^{t-1}$ to update our belief about the student's knowledge state B_{h_t}. Then, the RL model, which is a neural network with parameters θ, takes B_{h_t} as input (i.e., $s_t = B_{h_t}$) and outputs a vector $\mathbf{p_c} \in \mathbb{R}^n$ which represents the probability of selecting a question corresponding to each of the n concepts. We first select a concept c_i by sampling based on $\mathbf{p_c}$ and then randomly select one question from U_{c_i} (a set of questions that have not been asked and are associated with c_i). We then define the final policy parametrized by θ: $\pi_\theta(a|B_{h_t}) = \frac{\mathbf{p_c}[i]}{|U_{c_i}|}$ for $c_i \in C$ and $a \in A$. Our policy $\pi_\theta(a|B_{h_t})$ allows us to select the next question to query and add the next question-response pair (x^t, y^t) to the response history. We then update B_{h_t} based on the updated response history using the LBP algorithm. We calculate the reward for the current time step $r_t = Acc(Binary(B_{h_{t+1}})) - Acc(Binary(B_{h_t}))$.

We use REINFORCE policy gradient method [25, 29] to learn our policy π_θ parametrized by θ. In each episode corresponding to a single student, the RL agent performs an update as follows. First, an initial state s_0 (the initial belief that each concept has a 0.5 probability of being known by the student) is generated. Then, the policy π_θ is executed until the episode ends, generating a sequence of experience given by $(s_t, a_t, r_t)_{t=1,2,...,T}$. Then, in this episode, for each $t \in \{1, 2, ..., T\}$, we use the following gradient update with η as learning rate:

$$\theta \leftarrow \theta + \eta \cdot \underbrace{\left(\sum_{\tau=t}^{T} r_\tau\right) \cdot \left(\nabla_\theta \log\left(\pi_\theta(a_t \mid s_t)\right)\right)}_{\text{gradient at time step } t \text{ in an episode}} \quad (5)$$

In experiments, we use the architecture used in [7]. Specifically, the policy network is a 3-layer fully connected neural network with the following architecture: the input layer has $n = 57$ units for B_h; the first and second hidden layers have 128 hidden units; and the output is a vector $\mathbf{p_c} \in \mathbb{R}^n$ where $n = 57$ to produce a probability of selecting each of the 57 concepts. The first two hidden layers use ReLU activations, and the final layer uses the softmax function to ensure probabilities sum to 1. We use ADAM [14] optimizer for training.

4. EXPERIMENTAL EVALUATION

We first evaluate and compare our quizzing policies (QPs) using a synthetic dataset. We then apply our QPs to the Eedi dataset from the NeurIPS 2020 Education Challenge.

4.1 Simulations

We simulate virtual students taking the assessment quiz and test how well we can predict students' knowledge states in a controlled setting using different QPs.

4.1.1 The synthetic dataset

We generate a dataset consisting of 24,000 simulated student knowledge states. To do so, we first construct a graph for representing the student knowledge state that we aims to infer (see Section 2.2) and then get a probability distribution over the binary variables in the knowledge state that satisfies a set of assumptions about the student's knowledge. We then sample ground-truth student knowledge state values from the probability distribution. In this simulation, we use the same 57 concepts in the Eedi dataset (described in Section 4.2.1) for constructing the graph. We assume some of these concepts have different levels of difficulty, and similar concepts are more likely to be assigned the same knowledge state values.[2] Based on these assumptions, we assign a value of difficulty to each of the 57 concepts. We define $\textit{difficulty}_{c_i}$ = 1− the average correctness of the concept c_i across all students' answers in the Eedi dataset.[3] We run the LBP algorithm on the constructed graph to get a probability distribution from which we sample student knowledge states. Specifically, the output of the LBP algorithm gives the probability of knowing each concept, and we sample values of 0 or 1 for each concept to generate the ground-truth student knowledge states in our synthetic dataset.

[2]Although our assumptions might not hold in a real-world setting, the goal of this experiment is to compare different QPs and investigate the potential of QP-RL for learning a strategy tailered to a pre-defined knowledge structure. For instance, compared to the heuristic approach QP-Uncertain, QP-RL should learn to select the questions that are not only uncertain but can also give more information about other questions that are not selected (e.g., selecting questions corresponding to concepts that are connected with a lot of the other concepts).

Table 1: Test performance of different QPs on the synthetic dataset. QP-Uncertain achieves a better performance than QP-Random, and QP-RL improves over QP-Uncertain significantly.

QP	Accuracy
QP-RL	0.721 ± 0.004
QP-Uncertain	0.700 ± 0.002
QP-Random	0.675 ± 0.003

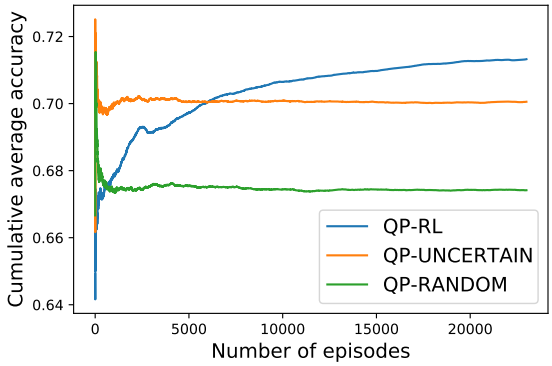

Figure 4: Training performance of QP-RL on the synthetic dataset compared to heuristics. QP-RL improves over QP-Random and QP-Uncertain after about 6,000 episodes of training. The cumulative average accuracy at each episode is calculated as the average accuracy across all previous episodes. It is important to note that QP-Random and QP-Uncertain are fixed policies that are not being trained. The cumulative average accuracy for the first few episodes might seem noisy due to small sample size.

4.1.2 Results

We split the dataset into 23,000 students as the training set and 1,000 students as the test set. We train QP-RL until the cumulative average accuracy converges. Figure 4 shows the training performance of QP-RL compared to fixed heuristics. After training, we run each QP 10 times on the test set to calculate the average accuracy and standard deviation across these 10 trials, see Table 1. Although QP-RL leads to a 2% gain in accuracy compared to QP-Uncertain, it requires a moderate amount of training data ($> 6,000$ students in this case). QP-Uncertain is a less optimal strategy but can achieve a reasonably good performance without any training data. These results provide initial evidence that QP-RL can learn an effective QP, and the performance can be improved further with more data.

[3]For simulations, one could also try other difficulty values, but it does not matter which specific difficulty value we assign to each concept because the goal is to model a setting where we have concepts of varying levels of difficulty.

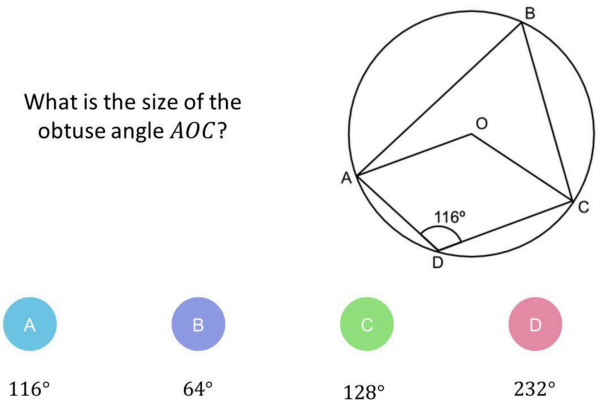

Figure 5: An example of a question in the Eedi dataset [27]. For each multiple-choice question, exactly one choice is correct.

4.2 NeurIPS 2020 Education Challenge

We then apply our QPs to one of the tasks in the NeurIPS 2020 Education Challenge (see Section 4.2), which is to obtain a limited set of answers from each student for predicting the correctness of their answers to the remaining questions. Our approach to this challenge is to first infer a student's knowledge state using Algorithm 1 and then predict the student's responses to the remaining questions based on the inferred knowledge state.

4.2.1 The Eedi dataset

The Eedi dataset contains student responses to multiple-choice questions (see Figure 5) on various math topics, which was collected between September 2018 and May 2020. It contains 948 questions and a total number of 1,508,917 responses to these questions from 6,148 students. The dataset is split into the training set (4918 students), the validation set (615 students), and the test set (615 students).

Each question in the dataset is associated with a list of subjects. Each subject covers an area of mathematics. These subjects are arranged in a tree structure by experts based on the generality of the subjects. For instance, "Fractions" is the parent subject of "Multiplying Fractions" and "Simplifying Fractions". For simplicity, we only consider the most granular subject (i.e., the leaves in the tree) as the concept that each question corresponds to. The 948 questions correspond to 57 unique concepts. We consider concepts that share the same super-concept (i.e., parent) to be similar (see Figure 1).

4.2.2 Student performance prediction

To predict a student's responses to unseen questions based on the inferred knowledge state, we propose a neural network-based model that takes in the belief about the student's knowledge B_{h_T} at time $T = 10$ (our belief about their knowledge after we have asked 10 questions) and outputs the probability of answering each of the 948 questions in the dataset correctly. The student performance prediction model is a 3-layer fully connected neural network with the following architecture: the input layer has $n = 57$ units for B_{h_T}; the first hidden layer has 256 hidden units; the second hidden layer has 512 units; and the output is a vector $\hat{\mathcal{Y}} \in \mathbb{R}^m$ where $m = 948$ to represent the probability of correctness for each of the 948 questions. The first two hidden layers use ReLU activations, and the final layer uses the sigmoid function to ensure the output values are between 0 and 1. We use ADAM [14] optimizer for training. We convert the output probabilities into binary values of 0 or 1 (0 if the probability is less than 0.5, 1 otherwise) and calculate the prediction accuracy using Equation 4. We train the model using randomly selected queries until the validation accuracy converges. The model parameters are updated based on binary cross-entropy loss.

Table 2: Test performance different QPs on the Eedi dataset. QP-RL improves slightly over QP-UNCERTAIN.

QP	Accuracy
QP-RL	0.690 ± 0.005
QP-UNCERTAIN	0.680 ± 0.003
QP-RANDOM	0.684 ± 0.003

4.2.3 Results

Given a trained performance prediction model from Section 4.2.2, we then train QP-RL using the difference in final prediction accuracy between time steps as reward signals: $r_t = Acc(Binary(\hat{\mathcal{Y}}_t)) - Acc(Binary(\hat{\mathcal{Y}}_{t-1}))$. After training, we run each QP 10 times on the test set to calculate the average accuracy and standard deviation across these 10 trials. Table 2 shows that QP-RL improves slightly over QP-UNCERTAIN, but the difference between QP-RL and QP-RANDOM is not significant. Results in Section 4.1.2 show that in a more controlled setting, QP-RL already requires a moderate amount of training data ($> 6,000$ students) to improve over heuristics. However, we only have training data from about 5,000 students in this experiment. Learning a QP from real students' data that are noisy is more challenging, and it may be the case that improving QP-RL further would require a much larger dataset. Even though QP-RL seems to require a substantial amount of training data, this is a one-time training, and the learned policy can be applied to future students.

5. CONCLUSION

Student assessment is a crucial component of many online education systems for improving student learning outcomes. Inferring student knowledge state by quizzing poses a technical challenge: maximizing accuracy while minimizing the quizzing cost. In this paper, we show initial evidence that reinforcement learning (RL) provides a potential solution, improving over heuristics given sufficient training data.

There are several research directions for future work. Further gains in accuracy could be achieved by exploring more powerful RL techniques and more complex student knowledge modeling techniques. In this work, we model all concepts that share the same super-concept as having the same relationship; however, there could be prerequisites as well as weaker and stronger relationships in reality. It would be important to study whether varying the influence values between concepts would lead to gains in model performance.

ABSTRACT

The distributed practice effect suggests that students retain learning content better when they pace their practice over time. The key factors are practice dosage (intensity) and timing (when to practice and how in between). Inspired by the thriving development of image recognition, this study adopts one of the successful techniques, multiresolution analysis (MRA), to model distributed and spaced practice (SP). We consider a sequence of practice sessions as a signal of the student's learning strategy. Then, we apply the stationary wavelet transform (SWT) to extract practice patterns spaced by three periods: small, medium, large. The result reveals a positive correlation between the small-spaced practice and the exam grade. The benchmark against baseline feature models shows that the SP patterns significantly improve the goodness-of-fit and complements the baseline models. This work successfully demonstrates 1) the use of MRA in modeling sequential patterns by event intensity and event timing; 2) the MRA approach can be used as an alternative method to improve existing student models of practice effort.

Keywords

distributed practice effect, testing effect, stationary wavelet transforms, signal multiresolution analysis, feature extraction

1. INTRODUCTION

In the midst of blended and distance learning environments, it is increasingly important for students to manage their time efficiently. Numerous researchers have proposed and developed various student models to capture how students utilize their time during the learning process. The results have shown that distributed practice is a simple but effective time-management strategy for learning [5]. Essentially, distributed practice comprises the testing and spacing effects, which suggest that the retention of information increases when the learner practices retrieving it in multiple spaced-out practice sessions [3].

Optimal distributed practice requires a combination of both the *intensity* and the *timing* of the practice events. In other words, an expressive student model must capture the intensity of practice sessions spaced by different periods. Although the two features appear to be straightforward, it is not easy to incorporate them in a sequential behavior model. For example, typical sequence analysis or sequential pattern mining would expect discrete input data and extract common patterns in the data according to the sequence support (the number of occurrences). Finding a meaningful and interpretable threshold is usually an ad-hoc process and particularly challenging [4]. A great threshold value may increase the chance of losing detail, and a small value may introduce more noises and miss the context. In the case of distributed practice, when the practice sessions are far apart, such a frequency-based approach will require more data to ensure sufficient within- and between-sequences support for a pattern of interest. To address this modeling challenge, we are motivated to explore an alternative computational method to capture the detail as well as the context, which can capture both the intensity and the timing of events at the same time.

We rationalize that a student's practice sessions distributed over a timeline resemble a signal to her/his learning process where the strength of learning is quantified as the increasing or decreasing values about the occurrences of the underlying events. With this definition, we can utilize a signal processing tool to extract the structural variation which approximates distributed practice patterns. In this work, we adopt the stationary wavelet transform (SWT) algorithm for this purpose. SWT is a widely-used signal processing tool in an application such as image pattern recognition. The algorithm decomposes an input signal into multiple components and represents the original signal by information at different resolutions. With the emphasis on the structure, we believe that SWT will allow us to overcome the challenge where the amount of sequential data may not be big enough to maintain the sequence support. Additionally, applying SWT as a feature extraction method also allows us to examine structural nuances in behavior sequences.

2. RELATED WORK

2.1 Sequence Analysis in Educational Data Mining

Cheng-Yu Chung and I-Han Hsiao "From Detail to Context: Modeling Distributed Practice Intensity and Timing by Multiresolution Signal Analysis". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 540-546. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

A *behavior sequence* is a chronicle of an activity. It describes a collection of events, and the order of them is meaningful. We can choose different features to characterize such a sequence, e.g., types of events, arrangements of events, time gaps between events. The features directly affect what we can find out from the analysis. Sequence analysis, in general, can refer to any data model that involves a kind of behavior sequences its characterization. Extensive research in EDM has been using behavior sequence analysis to model students' development of knowledge or skills.

The most intuitive approach is sequential pattern mining, which aims to discover repeated string patterns, alignments, or the very next possible items [11]. For example, Gitinabard et al. characterize behavior sequences by students' interactions with online tools [7]. They map the interaction sequences to study habits and use sequence patterns to differentiate the high-performing and low-performing students. Dermy and Brun argue that the time interval is the key to model students' activities [4]. They characterize behavior sequences by time intervals between events and formalize the temporal information in sequential pattern mining. Their experiment suggests a strong correlation between the students' activities and the time information.

One research gap we notice is that most of the reviewed works focus on the behavior sequences at a single time scale. For example, for a given behavior sequence $e_1, e_2, ..., e_t$ where e_i is an event that occurs at time i. A typical sequence analysis focuses on the relationship of adjacent events e_{j-1}, e_j, e_{j+1} where $j \in 1, ..., t$. Since the step size is 1, sometimes such a sequence is called 1-sequence. Following this setting, a pattern must be a consecutive 1-sequences that meets predefined criteria, e.g., the support. One limitation of 1-sequences is that they cannot capture an inconsecutive event. Such an inconsecutive event can provide a coarser view of the behavior sequence, therefore the context. Indeed, we can try to increase the step size to have 2-sequences, 3-sequences, or k-sequences where $k \in \mathbb{Z}$. Nonetheless, the increment of step size inevitably reduces the number of k-sequences we can find in a dataset. This situation may exclude potential sequences of interest due to the threshold of the support or the shortage of data. To tackle this challenge, we investigate an alternative model that focuses on the structural information of behavior sequences.

3. MULTIRESOLUTION SIGNAL ANALYSIS

In pattern recognition, the information of a given object usually is determined by the variations of signal intensity. For example, we can recognize a building as a building in an image because the distinct contours and shapes are formulated by their unique signal value sequences and different from the other objects. Such signal *features* are essentially sequences of values (sets of numbers) where a variation of intensity could suggest a potential event of interest, e.g., a change of shapes or colors. However, because the objects to analyze may have different shapes and sizes, the feature extraction must consider "how far away" an event is from its neighborhood to recognize the objects' structures at multiple resolutions. The field of computer vision and signal processing have developed various methods to address this challenge. One of which is the multiresolution analysis and wavelet transforms, which fit in the scope of this research.

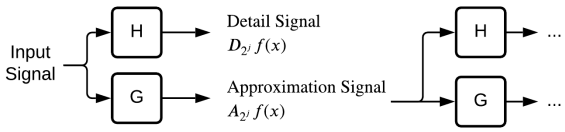

Figure 1: The Decomposition of Multiresolution Analysis. The process consists of two filters: the high-pass filter H and the low-pass filter G. They iteratively extract the detail signal and the approximation signal at the resolution 2^j from the input signal $f(x)$ until a maximum level L. We can associate the interpretation of the detail signal to the underlying time scale. For example, say the sampling rate of the input signal is 1. The detail signal at level 1 (a coarser level) denotes the information from the frequency band $[1/2, 1/4]$.

The multiresolution analysis (MRA) is a hierarchical framework that describes how to decompose a signal from fine to coarse levels [12]. The decomposition consists of a high-pass filter (H) and a low-pass filter (G). They are a pair of quadrature mirror filters and have the following relationship: $g(n) = (-1)^{1-n} h(1-n)$ [12]. The high-pass filter extracts impulses, and meanwhile, the low-pass one retains the other information. This process is also known as Discrete Wavelet Transform (DWT). By convolution ($*$), the filtering process iteratively produces series of detail signals ($D_{2^j} f(x)$) and approximation signals ($A_{2^j} f(x)$) for the input signal $f(x)$:

$$D_{2^j} f = (f(u) * \psi_{2^j}(-u))(2^{-j} n) \tag{1}$$

$$A_{2^j} f = (f(u) * \phi_{2^j}(-u))(2^{-j} n) \tag{2}$$

where $n \in \mathbb{Z}$. The high-pass and low-pass filters rely on a wavelet function (ψ) and a scaling function (ϕ) that translate and scale the input signal at different resolutions, respectively. We illustrate the whole filtering process in Figure 1 for reference. See [2] and [12] for more details about the math properties of the wavelet function and the scaling function.

3.1 Analyzing Distributed Practice via Signals

In this study, we focus on the practical implication of MRA and illustrate how it can help identify students' distributed practice patterns. Students, especially those in an online learning or a blended learning environment, usually have greater flexibility in self-pacing their studies. In other words, they can watch the lecture videos and practice quiz questions anytime at their convenience. This nature makes it challenging to analyze their behaviors on the timeline.

For example, in scenario A, when a semester is two to three months long, we may find out that the students' practice sessions are sparse and do not follow one unified schedule. This makes the time of sessions less discriminating in finding common behavioral patterns. Thus, the researcher may choose to ignore the time feature. An alternative approach (scenario B) is aggregating the practice sessions by a priori

assumption (e.g., students always study on a week-by-week basis or right before a deadline). However, all the above approaches may inevitably lose some detail about how exactly the students utilize their schedules, either missing discriminating patterns over time (scenario A) or limited to those strictly abiding by the class-paced schedule (scenario B).

To model students' distributed practice behavior over time, his/her behavior can be denoted as a sequence of the events, f with T discrete time steps: $f = \{e_1, e_2, ..., e_T\}$ where e_i for $1 \leq i \leq T$ can be any activity event of our interest. A student distributes his/her practice sessions at different rates or frequencies according to his/her preferences, path, or pace. This representation is like a signal and enables the feasibility to apply a signal processing algorithm.

Similar to the pattern recognition in computer vision, a student's practice sessions are like the shapes and colors that may evolve according to the sequences of signals. The sessions may have different sizes, i.e., time gaps between any two sessions. In other words, we aim to extract *distributed spaced practice* (SP) that are subsets of the input behavior sequence: $SP_k \subseteq f$ where $k \in \mathbb{N}$ and any two consecutive event items $\{e_i, e_j\} \subset SP_k$ are spaced by k time steps. Following this idea, MRA is used to extract such a "feature" from sequences of practice sessions, and thereby interpret the output as distributed practice patterns. For a practice signal at sampling rate = 1/day, the output signals can represent the information at coarser rates, e.g., 1 per 4 days and 1 per 8 days.

3.2 Stationary Wavelet Transform

The output of DWT are signals that represent information at different resolutions (or frequencies). The typical implementation of DWT keeps downsampling the input signal to obtain the detail signal and the approximation signal at each resolution [12]. Therefore, the transform is time-variant. The detail signal at one level is a half shorter than the one at the previous level. This property may cause a misalignment in time/frequency, which will make the decomposition generate fewer feature values for analysis. In this study, we follow an alternative implementation of MRA, Stationary Wavelet Transform (SWT), which is time-invariant. SWT replaces the downsampling by upsampling at each step [6]. Research has shown that SWT can improve the approximation and a preferred approach for applications like breakdown point detection and denoising [1].

4. DATASETS

To evaluate the method, we use two semesters' datasets from the same undergraduate class offered in a four-year university in the United States: Spring 2018 (SP18) and Fall 2018 (FA18). Both sessions lasted about 3-month. The class was a typical lecture-style in-person class with weekly assignments and monthly exams. The two sessions were practically identical, having exactly the same syllabus, same instructor, same teaching assistants, except for minor adjustments to the exam questions. Note most students in FA18 shared a similar background in engineering because the class was a required class for first-year engineering students. In SP18, there were more students from non-engineering schools, which resulted in much more diverse student background.

An online practice platform was introduced to the students at the beginning and available throughout the semester. On the platform, students could take multiple-choice questions to practice and review the class content. For any given practice question, the students had unlimited chances to retry; for any attempt, the corrective feedback (correct answer) would be provided upon submission. The questions served like so-called "tasks" in the context of tutoring systems [16]. Each of the tasks aims to help the student master some knowledge (or embedded knowledge components). However, the practice activity is different from working with assignments: there is no "hard deadline" by which the students must complete the practice questions. The students can practice on the platform as a kind of self-assessment [13]. In other words, the activity is "self-paced" [18] and aligned with the actions of reviewing slides, taking quizzes, or other practices that students can do for their benefit whenever they want.

The students' practice activities were logged as transactions of events, including the timestamps, the questions, and the correctness of the attempts. We processed and transformed the data into sequences of daily practice intensity. Here, the term "intensity" refers to the number of unique questions solved by a student. Each day is assumed to be a complete practice session. The sequence of daily intensity thereby resembles a discrete-time signal sampled at a constant rate equal to 1 sample per day. We excluded some students' data from the analysis due to low usage (those who only had only one practice session throughout the semester). An overview of the datasets is described in Table 1.

In this study, the exam letter grade is used as the students' learning performance index. The exam letter grade ranges from A ($M \geq 90$), B ($80 \leq M < 90$), to C/D/F ($M < 80$) where M is the raw average of three exam scores.

5. REPRESENTING DISTRIBUTED PRACTICE BY SWT SIGNALS

There are several parameters required for our model pipeline: the wavelet for SWT, the padding scheme, the maximum decomposition level, and the penalty of change point detection. The Haar wavelet is adopted in the SWT algorithm implementation, due to the simplest form of wavelet [14]. It creates a shape like a step function that produces 1, 0, and -1, following the formula

$$\psi(x) = \begin{cases} 1 & \text{if } 0 \leq x < \frac{1}{2} \\ -1 & \text{if } \frac{1}{2} \leq x < 1 \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

This property makes it a good option for detecting edges (e.g., sudden signal transitions or changes) [17] in discrete signals like the datasets in this study. The implementation of SWT used in this study requires the length of input to be a multiple of 2^L where L is the maximum number of levels to decompose [9]. To meet this requirement, we preprocessed all input sequences by adding a prefix of zeros. In our experiment, we found that the SWT signals at $L > 3$ did not work. It was likely due to short input sequences. Therefore,

Dataset	# of Students	# of Included	Max Length of Sequence (Days)	# of Questions	M (SD) of Intensity
SP18	121	76 (63%)	93	96	0.26 (0.36)
FA18	200	67 (34%)	82	95	0.32 (0.49)

Table 1: Statistics of the Two Datasets

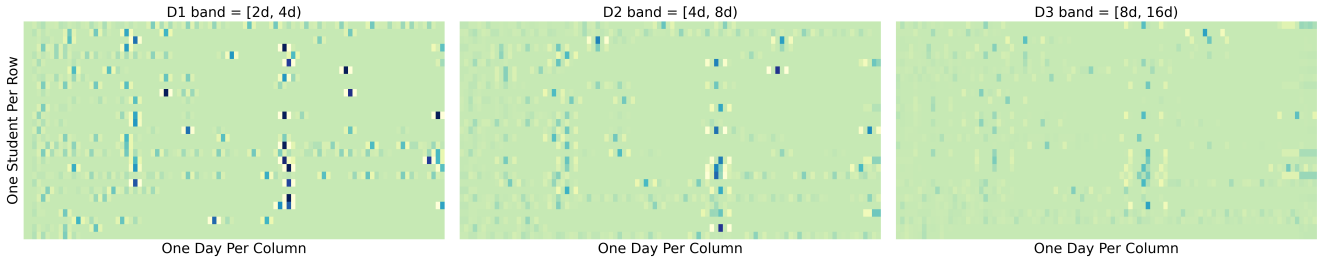

Figure 2: The SWT Signals in the SP18 Dataset. From left to right, the SWT signals D1, D2, D3 capture practice sessions in the period bands [2d, 4d], [4d, 8d], and [8d, 16], small-, medium- and largely-spaced respectively. These signals capture practice sessions spaced by different periods. From D1 (more detail) to D3 (more context), we can see the focus gradually spreads out when the level increases. For readability, the plot excludes practice sequences not having any change points in the SWT signals.

we set L = 3 in our experiment. Once the SWT algorithm is built, we applied the change point detection algorithm with the penalty = 0.5 to search for sudden changes in the SWT signals [8]. We decided on this penalty value by maximizing the group difference (Section 5.2) and the goodness-of-fit of regression (Section 6.2). The experiment program and data are available at the link for future work[1].

5.1 Characteristics of SWT Signals

The SWT algorithm decomposes the input signal by multi-level filtering. Filtering at a level k extracts information at the frequency band $[1/2^k f, 1/2^{k+1} f]$ where f is the sampling rate of the input. In our datasets, because the sampling rate is 1 sample per day (1 cycle per day), the three decomposition levels (Dk where k = 1,2,3) filter the input in the frequency bands $[1/2, 1/4]$, $[1/4, 1/8]$, and $[1/8, 1/16]$. In other words, the algorithm filters the input into the period (the duration of time of one cycle) bands D1=[2(d)ays, 4d], D2=[4d, 8d], and D3=[8d, 16d]. We map these three bands to small-spaced, medium-spaced, and largely-spaced practice patterns, respectively. Following this interpretation, we expect the SWT signals to identify students' practice sessions spaced by different periods. For example, D1 can identify sessions spaced by 2 to 4 days, which are small-spaced practice.

To further illustrate this characteristic, Figure 2 demonstrates what the algorithm found in the SP18 dataset. The visualization shows the SWT signals at the three levels. We can see that D1 highlights small-spaced practice sessions. The D2 and D3 signals spread their focus and "blur" the sequences not fitting their period bands. Note, there may be redundancy in the information captured by different components. For example, an input sequence having meaningful change points in D3 can also have ones in D1. Overall, the information about practice sessions at different levels provides an insight into how the students distribute their practice over time. In our analysis of distributed practice patterns, we use the number of change points as the *feature* to represent the information from the three SWT signals.

For readability, we use the lower bound of the frequency band to denote the spaced practice patterns. We call the practice patterns found in the D1, D2, D3 signals *2SP* (2-day spaced practice), *4SP*, and *8SP* patterns, respectively. For reference, the input daily practice sessions are called 1SP. In the SP18 dataset, the means (M) / standard deviation (SD) from the three levels are 2SP = 1.83/2.68, 4SP = 1.79/2.63, and 8SP = 1.75/2.63. In the FA18 dataset, the values are 2SP = 1.12/2.29, 4SP =1.27/2.14, and 8SP = 1.37/2.30.

5.2 Marginal Relationship of Spaced Patterns with Exam Grades

We analyzed the relationships between the practice patterns and student grades by the marginal distribution. The Kruskal-Wallies H-test was applied to test if the groups had the same population median (Figure 3). The method was selected because the sample size was small, and therefore the sample might not follow the normal distribution. The results showed that there was only 2SP that appeared to be significant for both datasets (SP18: H=8.89, p=0.01; FA18: H=7.95, p=0.02). The visualization of the distribution showed that in SP18 A students had a higher 2SP (M = 3.12, SD = 3.11) than C (M = 1.50, SD = 2.32) and B (M = 0.72, SD = 1.79); in FA18, the B students had a higher value (M = 2.17, SD = 3.05) than A (M = 0.62, SD = 1.50) and C (M = 0.41, SD = 1.14).

There are more spaced patterns discovered for B students in FA18 but not A students, which suggests there could be other factors in the correlation of their practice with even higher exam grades. For example, engineering and non-engineering students may have/need different practice strategies adapted to their learning conditions. Despite this slight difference across the two semesters, if we focus on the difference between the higher-performing students (A/B) and the C/D/F ones, the result consistently suggests a positive correlation between exam grades and small-spaced prac-

[1]https://github.com/rickchung/edm21-msa

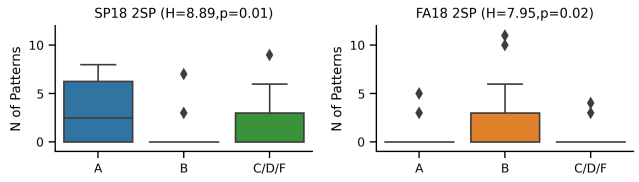

Figure 3: Marginal Distribution of the SP patterns from the Three Grade Groups. The Kruskal-Wallies H-test found that only 2SP was significant in both datasets. The result consistently showed that higher-performing students (A in SP18 or B in FA18) had more small-spaced practice than the C/D/F ones in SP18 and FA18.

tice.

5.3 Quantifying the Schedule of Distributed Practice

We have seen how the SP patterns can help identify practice spaced by different periods. However, this feature alone does not depict the entire picture of distributed practice strategies. Another key factor in the distributed practice effect is the timing of practice. We develop an index to quantify the skewness in practice schedules and investigate its correlation to exam grades. One simple measure of the skewness is the *lag time*. We can use the *lag time* between the occasion of a practice session and a specific event of interest (e.g., exam dates, assignment deadlines) to model the schedule skewness. Due to programming is inherently accumulative, a later exam covers the content from all the previous exams, we cannot assert that a practice session only affects the upcoming exam. Considering this case, we focus on the time lag since the beginning of the semester. Specifically, for an SWT signal at level i, D_i, we can compute the lag of days between the start of the semester and the occurrences of change points. Then, we can transform a practice sequence into a sequence of lags $\{T_1^{D_i}, T_2^{D_i}, T_3^{D_i}, ..., T_n^{D_i}\}$. To know where on the timeline the student has more practice, we compute the sample mean, $\mu_T^{D_i}$. The number, therefore, represents how far the schedule is away from the beginning of the semester. We further divide the number by the total number of days (N_{day}) in the semester for interpretation. The equation of the schedule skewness is defined as

$$SS = \frac{\mu_T^{D_i}}{N_{days}} \tag{4}$$

When a student has all his/her practice sessions early in the semester, SS will be close to zero. If s/he has more practice sessions over the middle of the semester, SS will be some value over 0.5. We can apply the formula to the input signal (1SS) and the SWT signals (2SS, 4SS, 8SS). The result will indicate the schedule of different spaced-practice patterns.

6. MIXED PRACTICE EFFECTS IN MULTIVARIATE ANALYSIS

A distributed practice strategy is multifaceted. The univariate analysis is insufficient because it does not consider the confounding variables. There are two cases remain unclear.

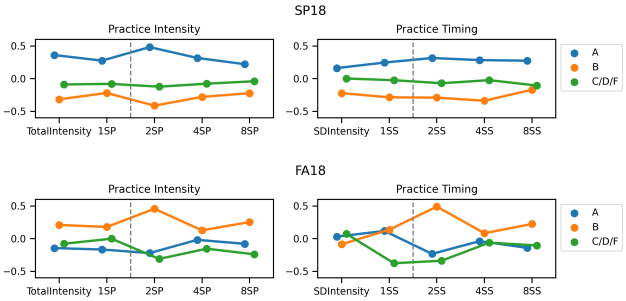

Figure 4: The Standardized Values (Means) and the Interactions of the Basic and Experiment Features. The plot groups the features into intensity and timing according to their functions. The y-axis shows the standardized values (by $(X - M_X)/SD_X$ in each feature category X) for between-features comparison. The vertical dashed lines separate the basic and experiment features. The A students in SP18 have the highest TotalIntensity. On the contrary, the B students in FA18 have the highest TotalIntensity. Although the basic features somehow correlate with the experiment features, we can find more discriminating differences in the experiment spaced-practice patterns.

First, the C/D/F students from SP18 do not have better performance, even though they put efforts into practice just like the better performing students do (A students). Second, in FA18, the analysis does not explain the practice strategy of the A students. They achieve a good grade but do not show significantly more SP. These cases suggest that there could be other factors in the distributed practice effects.

Following this idea, we try to use multivariate analysis that includes experiment SWT features and commonly-used basic features. The basic set comprises the following. For the practice intensity, we use the total number of questions solved (TotalIntensity) and the total number of daily practice sessions (1SP). For the practice schedule, we use the standard deviation of the daily intensity (SDIntensity) and the SS of daily practice sessions (1SS). For reference, we plot the standardized values of the features in Figure 4. The figure shows that although the basic features correlate with the experiment features, we can potentially find more discriminating difference in the spaced practice patterns between the grade groups.

6.1 Assessing the Marginal Effects by Multinominal Logit Regression

To understand the relationship between multiple feature and exam grades, we use the multinominal logistic regression and investigate the marginal effects of the feature values. The *multinominal logistic regression* (MLogit) is a generalized version of the logistic regression for multiclass classification problems [15]. We can use MLogit when the dependent variable in a query is nominal (categorical) and has more than two possible categories. The setup of MLogit is similar to the logistic regression. We assume a linear relationship between the independent variables (predictors), X, and the dependent variable (response), Y, and model the probability of the $Y \in \{y_1, ..., y_k\}$ by the logistic function (*sigmoid*)

and k-1 sets of weights (w_k for the label y_k):

$$P(Y = y_k|X = X_1, ..., X_n) = \frac{exp(w_{k0} + \sum_i w_{ki}X_i)}{1 + \sum_j exp(w_{j0} + \sum_i w_{ji}X_i)} \quad (5)$$

We can obtain the prediction by picking up the class with the highest probability. The main advantage of MLogit over other classification techniques is the interpretability. We can explain the contribution of individual features to the output probability (dx/dy) similar to the linear regression [15]. In the analysis, we set Y as the grade groups (A, B, C/D/E) and examine the marginal effects with respect to X when the model fits different sets of predictors.

6.2 Comparing Alternative Models

To understand the capability and limitation of the SWT model of distributed practice, we use MLogit to fit various baseline and experiment feature sets. Afterward, we benchmark the quality of these models by the goodness-of-fit. Due to MLogit does not use the standard R^2, we use the measure of the goodness-of-fit by *McFadden's pseudo* R^2 [10]. McFadden's pseudo R^2 uses the formula

$$R^2 = 1 - \frac{\ln L(M_{full})}{\ln L(M_{intercept})} \quad (6)$$

where L is the estimated likelihood. A small ratio of the two log-likelihoods (or a large McFadden's pseudo R^2) suggests that the full model is better than the intercept model. We can use this measure to benchmark one model against another if they fit the same data.

We compared the experiment and alternative baseline models. The result showed that none of the baseline models were competitive with even the simplest SWT model (using only 2SP, 4SP, 8SP). The best baseline model ($M_{BaseAll}$) used all the baseline variables and achieved $R^2 = 0.04$ in SP18 and $R^2 = 0.07$ in FA18. The simplest SWT model ($M_{ExpDose}$) achieved $R^2 = 0.07$ in SP18 and $R^2 = 0.09$ in FA18. The best experiment model (M_{ExpAll}) used all the SWT variables and achieved $R^2 = 0.12$ in both SP18 and FA18. Using all the baseline and experiment variables, the ensemble model ($M_{Ensemble}$) unsurprisingly outperformed all the other models and achieved $R^2 = 0.13$ and $R^2 = 0.23$ in SP18 and FA18, respectively.

6.3 Marginal Effects in the Regression Models

In SP18, $M_{ExpDose}$ found 2SP was a significantly-positive predictor for the A students (dx/dy = 0.07, p = 0.01). M_{ExpAll} also found that 2SP was a significant predictor for the A students (dx/dy = 0.10, p = 0.00). Besides, it found 4SS and 8SS were significant for the C/D/F students (dx/dy = 2.55, p = 0.02; dx/dy = -2.58, p = 0.03). In FA18, $M_{ExpDose}$ found 2SP was significantly-positive predictor for the B students (dx/dy = 0.12, p = 0.00). M_{ExpAll}, however, did not find any significant predictor.

Part of the result is similar to the analysis of marginal distribution. In SP18, an increase of small-spaced practice adds to the likelihood of A. In FA18, the same effect works for B. It is worth noting an additional finding in $M_{Ensemble}$ from SP18. When we control the intensity and SS, the model shows two extra significant predictors for the grade C/D/F: 4SS and 8SS. The marginal effect suggests that an increase/decrease in 4SS/8SS adds to/reduces the likelihood of C. Since an increase in SS means the schedule becomes later in the semester, these two findings somewhat suggest the same thing: students who practice early and space the practice largely are less likely to obtain C/D/F.

It is also worth noting that the one in FA18 improves the most from the best experiment model and reaches R^2 = 0.23. When predicting the A students, the model shows 1SS (dy/dx = 1.01, p = 0.00) and the total intensity (dy/dx = -0.02, p = 0.04) are significant predictors; when the model predicts the C students, 1SS is the only significantly-negative predictor (dy/dx = -0.90, p = 0.01). We do not find the same effect in any of the baseline models. The result complements a missing part of our analysis about the A and C students' practice strategies in FA18. It suggests that an increase in 1SS adds to the likelihood of A. Conversely, the same increase reduces the one of C/D/F. In other words, more early or late practices in the semester may reduce or improve the probability of C/D/F or A, respectively.

7. CONCLUSIONS

Students' practice behavior is challenging to model because they can practice anytime and do not necessarily follow a unified schedule. This study aims to build such a feature model that can help researchers describe the distributed practice behavior. We adopted the method from multiresolution analysis to extract patterns of our distributed practices, focusing on two factors in the distributed practice effect: intensity and timing. In the experiment, we applied the MRA model and extracted features that could represent practices spaced by different periods, including small (2-4 days), medium (4-8 days), and large (8-16 days). These three kinds of practice patterns were analyzed to explain their correlation to the exam grades. We found that students who practiced early and spaced the practice by the small and large periods were more likely to get a higher grade than C/D/F. Also, the students having more small-spaced practices throughout the semester (i.e., practicing more persistently) were more likely to get better exam grades. Additionally, the MRA model was benchmarked against baseline models. The result showed that the MRA model not only achieved a better goodness-of-fit than the baselines when working alone, but it could complement a baseline model and achieve better performance.

ABSTRACT

Similar content has tremendous utility in classroom and online learning environments. For example, similar content can be used to combat cheating, track students' learning over time, and model students' latent knowledge. These different use cases for similar content all rely on different notions of similarity, which make it difficult to determine contents' similarities. Crowdsourcing is an effective way to identify similar content in a variety of situations by providing workers with guidelines on how to identify similar content for a particular use case. However, crowdsourced opinions are rarely homogeneous and therefore must be aggregated into what is most likely the truth. This work presents the Dynamically Weighted Majority Vote method. A novel algorithm that combines aggregating workers' crowdsourced opinions with estimating the reliability of each worker. This method was compared to the traditional majority vote method in both a simulation study and an empirical study, in which opinions on seventh grade mathematics problems' similarity were crowdsourced from middle school math teachers and college students. In both the simulation and the empirical study the Dynamically Weighted Majority Vote method outperformed the traditional majority vote method, suggesting that this method should be used instead of majority vote in future crowdsourcing endeavors.

Crowdsourcing, Similarity, Community Detection, Hierarchical Clustering

1. INTRODUCTION

Within online learning platforms and intelligent tutoring systems there is a tremendous opportunity to utilize knowledge of content similarity. Similar problems can help prevent cheating during exams by randomly selecting from multiple similar problems when students receive the exam, measure students' learning gains by spreading out similar problems between assignments, and measure the effects of instructional interventions by comparing a student's scores on similar problems before and after the intervention. Similar instructional material can be used to offer students choices in which instructional material they receive, which has been shown to increase engagement and achievement [7]. While it is possible to implement these methods with general knowledge of content similarity, such as similarity in prerequisite knowledge or difficulty, if a more informed definition of content similarity is used, the success of these methods is likely to grow.

Although there is a lot of value in knowing what content is similar to other content, what content should be considered similar is highly dependent on use case. This makes it a challenge for content creators to define the similarity in the content, as they don't necessarily know what their content will be used for. While some content is obviously similar, for example, two mathematics problems that are identical except for the numbers used in the problems, in other situations it is much more difficult, especially when content is being aggregated from multiple sources that may not even use the same metrics for prerequisite knowledge or difficulty.

Crowdsourcing offers a way to derive which content is similar to other content for specific use cases. Crowdsourced opinions on similar content can be gathered each time a new use case for similar content arises. By informing the workers, whose opinions are being crowdsourced, of the specific use case and requirements for similarity, the methods that rely on content being similar are more likely to be successful. However, crowdsourcing opinions on similar content poses some challenges as well. Before an online learning platform or intelligent tutoring system uses crowdsourced assertions of similarity, steps must be taken to assess the trustworthiness of workers whose opinions are being crowdsourced and ensure the truthfulness of the final assertions of similarity.

In this work we present a novel algorithm that both measures the reliability of the workers whose opinions are being crowdsourced, and determines, from these individual's opinions, what content is most likely to be similar to other content. To evaluate this method, we first simulated a wide range of conditions in which assertions of similarity were made, and compared the performance of our algorithm to the traditional alternative. We then performed a case study where teachers and college students were told to identify middle-school mathematics problems that evaluated a simi-

lar skill set. The assertions of similarity collected from the case study were used to identify groups of similar problems and measure the reliability of each worker's assertions.

Ultimately, this work seeks to answer the following three research questions:

1. Can we exploit properties of community detection to more accurately form groups of content from crowdsourced opinions?
2. How does the resulting algorithm perform in a simulation study compared to the more traditional method?
3. How does the resulting algorithm perform in a case study using workers of various expertise to determine which mathematics problems are similar to each other?

2. BACKGROUND

2.1 Ensembling Crowdsourced Opinions

Identifying the truth from crowdsourced opinions is not a new problem. Most of the techniques employed to ensure the accuracy of crowdsourced opinions rely on ensuring that workers have sufficient knowledge of the subject matter. This can be done through testing workers before giving them tasks, tailoring tasks specific to their skill sets, recruiting high quality workers, and educating workers before assigning them tasks. This can also be done through encouragement with extrinsic motivators like money, promotions, or prizes, or intrinsic motivators like a sense of purpose, or by gamifying the crowdsourcing tasks [1].

While there are many methods to encourage individuals whose opinions are being crowdsourced to be accurate, this work is focused on how to validate the quality of individuals' opinions after their task is complete. Current methods for accomplishing this place the burden of validation back onto the workers. Having workers rank the quality of other workers assertions is one method of validation. Another common method for validation is to have multiple workers perform the same task and merge the output of each worker, either as an average or as a majority vote [1].

There are also more advanced ways of algorithmically validating crowdsourced opinions. Item response theory and latent factor analysis based models have out-performed majority voting based validation methods on tasks related to identifying facial expressions and answering questions about geography [6, 10]. These models also determine the quality of individuals whose opinions are being crowdsourced, which can be used to refine the pool of individuals used for future crowdsourcing tasks [6, 10]. The novel algorithm in this work also aggregates crowdsourced opinions while evaluating the quality of each worker.

2.2 Community Detection

The field of community detection is focused around determining groups of similar items from a network of connected items. This has many applications throughout mathematics, physics, biology, computer science, and social sciences. Many things can represented as a network, for example, interstellar objects, neurons, city streets, and social media can all be represented as networks of interconnected items [3]. Finding similar educational content can be framed as a community detection problem by representing educational content as a network in which items are connected by topic, difficulty, language, prerequisite knowledge, or, in the case of this work, opinions on similarity. Structuring the task of identifying similar educational content as a community detection problem allows for the use of various well-established community detection algorithms, such as hierarchical clustering. In hierarchical clustering, each item begins in it's own cluster. Then, clusters are merged based on the merge strategy and distance between clusters [5]. Hierarchical clustering was used in both the simulation and empirical study.

3. METHODOLOGY

3.1 Dynamically Weighted Majority Vote

The Dynamically Weighted Majority Vote (DWMV) method is our alternative to the traditional majority vote method for combining multiple crowdsourced opinions on tasks with binary outputs. The DWMV method calculates the weighted majority opinion for each task, then determines the weight of each worker by how closely their opinion agreed with the majority opinion. The closeness of a worker's opinion to the majority opinion can be determined with any function for comparing two vectors that results in a value greater than or equal to zero. For example, accuracy or Dice coefficient[2]. DWMV initializes all workers' weights to be equal at the beginning of the algorithm, and iteratively updates these weights until the weighted majority vote does not change between iterations. Once the weighted majority vote remains constant from one iteration to the next, the weights of the workers can be interpreted as a measure of confidence in each worker, and the final weighted majority vote can be used downstream in the same way the traditional majority vote would have been used. Algorithm 1 formally defines the DWMV algorithm. In Algorithm 1, the function $s(x, y)$ determines the closeness of worker i's opinion, $(B_{ij}[A_{ij} = 1])_{j=1}^{t}$, to the majority opinion, $(u_j[A_{ij} = 1])_{j=1}^{t}$. The algorithm requires a matrix A of response indicators, in which $a_{ij} = 1$ if worker i completed task j, and $a_{ij} = 0$ otherwise, and a matrix B of worker's responses to tasks, in which b_{ij} contains the binary response of worker i to task j. In Algorithm 1, vector u contains the final weighted majority vote for each task, and vector c contains the final measure of confidence for each worker, based on the similarity between the weighted majority votes and the individual worker's responses.

3.2 Simulation Study

To determine if DWMV had a positive impact on forming groups from crowdsourced opinion, a simulation study was performed to compare the DWMV method to the traditional majority vote method in a variety of conditions. Figure 1 illustrates the simulation process. In the simulation study, hierarchical clustering was used to form groups from simulated workers' opinions of item similarity aggregated using both the majority vote method and the DWMV method. Table 1 lists the different initial parameters and their values used in the simulation. Five trials of every possible combination of the values in Table 1 were simulated for a total of 37,500 simulation runs.

$$c \leftarrow \left(s\Big((u_j[A_{ij} = 1])_{j=1}^{t}, (B_{ij}[A_{ij} = 1])_{j=1}^{t} \Big) \right)_{i=1}^{w}$$

end while

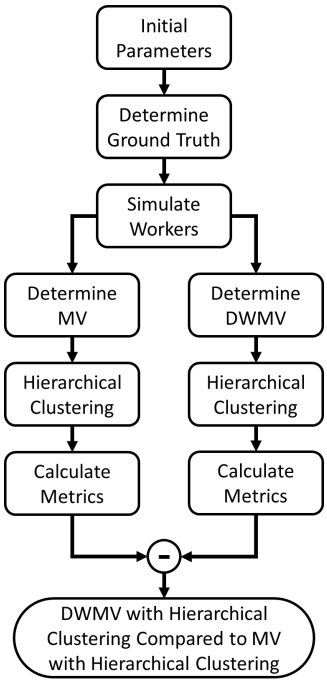

Figure 1: A flowchart of the simulation process, DWMV and majority vote were compared to each other through their use in community detection through hierarchical clustering.

Table 1: Simulation Parameters and Simulated Values

Parameter	Values
i	50, 100, 150, 200
g	5, 10, 15, 20, 25
w_{fp}	0.1, 0.2, 0.3, 0.4, 0.5
w_{fn}	0.1, 0.2, 0.3, 0.4, 0.5
p	20, 40, 60, 80, 100
d	0.25, 0.5, 0.75

The simulation began by randomly placing i items into g groups, where i and g are initial parameters of the simulation. Then the simulation crated ten workers. Each worker had a false positive rate and a false negative rate. These values were calculated separately to make the simulation more true to real life. In real life, it is not often that a worker would have an equal chance of incorrectly asserting that two items are or are not similar. The more likely case is that some workers think there is more similarity and other workers think there is less similarity between items than the actual similarity of items. The false positive and false negative rates of the workers were sampled separately for each worker from a uniform distribution in the range $[0, w_{fp}]$ and $[0, w_{fn}]$ respectively, where w_{fp} and w_{fn} are initial parameters of the simulation. Once the items were randomly placed in groups, and the error rates of the workers were randomly determined, a random p percent of all pairs of items were given to each worker, where p is an initial parameter of the simulation. Each worker then determined whether or not the items in each pair they received were similar to each other, taking into account their error rates.

Once all workers asserted whether or not each item pair they were given contained similar items, the majority vote and DWMV for the similarity of each item pair was calculated. The majority votes and DWMVs of item similarity were then used to form a network of item similarity, where each item is connected to every other item it was voted to be similar to. The majority vote network and DWMV network were both used to form groups through hierarchical clustering with Jaccard Index as the distance metric. Jaccard Index was used as the distance metric because Jaccard Index does not take into account true negatives [8]. Most items are not similar to each other, so a metric that takes into account true negatives would be over-inflated and not as informative in this context. After forming groups from the majority vote and DWMV similarity networks, the difference in accuracy, precision, and recall between the groups formed from the majority vote and DWMV similarity networks were used to determine if the DWMV method improved upon tradition majority vote.

3.3 Empirical Study: Similar Problems

In addition to a simulation, an empirical study was performed to compare DWMV to majority vote on a real crowdsorcing task. In this study, middle school mathematics teachers and college students were given 50 seventh grade mathematics problems from the Engage New York[1], Illustrative Mathematics[2], and Utah Middle School Math Project[3] curricula. Each worker was told to identify problems that evaluate similar mathematics skills. The workers' crowdsourced opinions of similarity were aggregated using both DWMV and majority vote, and then grouped using hierarchical clustering, with Jaccard Index as the distance metric with a threshold of 0.75. The resulting groups were then compared to a ground truth, provided by ASSISTments, an online learning platform [4], in the form of Common Core State Standards Mathematics Skill Codes[4], which each problem

[1]https://www.engageny.org/
[2]https://illustrativemathematics.org/
[3]http://utahmiddleschoolmath.org/
[4]http://www.corestandards.org/

was tagged with. These ground truth skill tags were determined by trained experts and the designers of the above stated curricula. The difference in accuracy, precision, and recall between groups formed with hierarchical clustering from DWMV and majority vote were again used to evaluate the quality of the DWMV algorithm.

4. RESULTS

4.1 Simulation Study

To compare the DWMV method to the traditional majority vote method, the difference in accuracy, precision, and recall as a function of w_{fp}, w_{fn}, i, g, and p, as described in Section 3.2, were calculated. The first positive takeaway from the simulation is that DWMV was almost always more accurate than majority vote, regardless of the simulation parameters. Only when the simulation had more than twenty groups or the maximum false negative rate of workers was 20% or less did DWMV not reliably out perform majority vote, but it did not significantly underperform either. At most, DWMV was slightly less accurate than majority vote when workers had very low false negative rates. Interestingly this increase in performance was not shared by both precision and recall. While recall followed the trend of accuracy and showed almost entirely positive improvements from using DWMV over majority vote, precision did not.

Another interesting finding is that all three performance metrics increased as both the maximum false negative rate and fraction of links seen by workers increased. This implies that as workers answer more problems, and become worse at correctly identifying when items are similar, the benefit of using DWMV over majority vote increases.

Overall, t-tests [9] showed that using DWMV led to a statistically reliable ($p < 0.001$) 0.18% increase in accuracy, a statistically reliable 1.78% ($p < 0.001$) increase in recall, but no statistically reliable ($p = 0.28$) change in precision. While small, these reliable improvements in accuracy and recall over the traditional majority vote method are an indication of the potential positive effects of transitioning to using DWMV instead of majority vote when aggregating crowdsourced opinion.

There were also some interesting differences in how different types of error affected the weights of workers as determined by the DWMV method. Figure 2 shows the average and 95% confidence interval of the DWMV weights of workers as a function of the workers' false positive and false negative rates. The false positive rate of the workers seems to decrease their weight in the final weighted majority vote of the DWMV method much more quickly than their false negative rate. A potential cause of this is that, in the simulated groups of similar items, there were far more pairs of items that were not similar to each other than there were pairs of items that were similar. For example, to have an equal number of items that are similar and not similar to each other, each item would have to be similar to half the items. The only way to facilitate that in the context of this simulation would be to have only two equally sized groups of items. In the simulation there were always at least five groups, and up to 25 groups of similar items, which caused most problems to not being similar to each other. Therefore, when a worker had a large false positive rate, there were more opportunities for them to make a mistake compared to a worker with a large false negative rate. Additionally, the large number of dissimilar problem pairs compared to the number of similar problem pairs caused workers with very low false positive rates to have higher weights than workers with equally low false negative rates, because workers with low false positive rates, regardless of their false negative rates, had much fewer opportunities to make a mistake. These findings suggest that the distribution of correct responses in crowdsourcing tasks affects which type of worker error has a larger impact on workers' weights in the DWMV method.

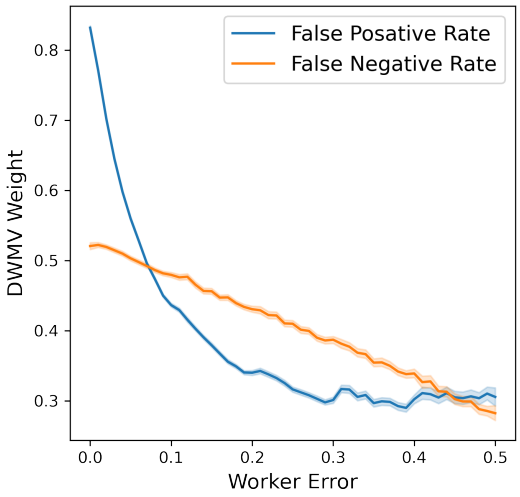

Figure 2: The average and 95% confidence interval of the DWMV weights of workers as a function of the workers' false positive and false negative rates.

4.2 Empirical Study: Similar Problems

In total, six teachers and four students completed the crowdsourcing task of grouping 50 seventh grade mathematics problems. Using each worker's assertions of similarity, the DWMV method and traditional majority vote were used to aggregate the opinions of the workers into a final network of similarity, which was then used to create groups of similar problems using hierarchical clustering. This is the exact same process that was used to form groups in the simulation study. Figure 3 shows the progressive iterations of DWMV. Iteration 1 shows the unweighted average of each workers assertions. The DWMV method's process of iterating between calculating a weight for each worker and calculating the weighted majority vote shifted the weighted average of workers assertions toward the ground truth similarity of problems. This convergence was present in the simulated example in Section 3.1 as well. The benefit of the DWMV method over traditional majority vote lies in this ability to converge towards ground truth. Figure 4 shows the weight of each worker as a function of their error rate. The cohort of middle school mathematics teachers performed much better overall than the cohort of college students. The average accuracy of the teachers was about 97% while the average ac-

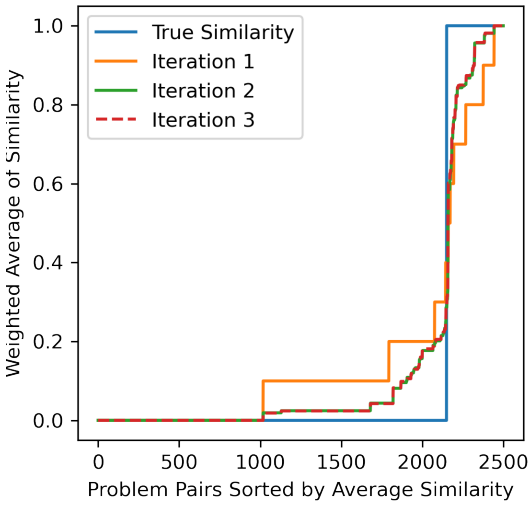

Figure 3: Progressive iterations of DWMV converging on empirical data.

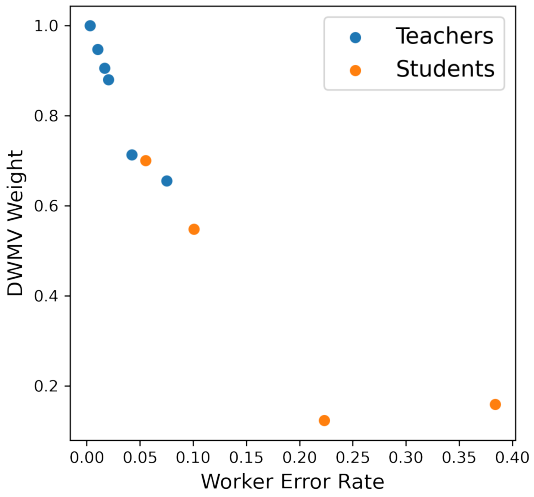

Figure 4: DWMV's confidence in each worker after the DWMV method converged.

curacy of the college students was only about 81%. Based on these weights, it is clear that the DWMV method valued the opinions of middle school mathematics teachers more than the opinions of college students, which is expected given the context and task. While, in this scenario, it might have been easy for a human in the loop to recognize that the teachers' opinions should be valued more, it will not always be the case that one group of workers is clearly more qualified than another group, and thus the DWMV method can help elucidate which workers are the most reliable.

Table 2 shows the difference in accuracy, precision, and recall between groups formed through hierarchical clustering from the assertions of similarity aggregated using DWMV and traditional majority vote. Similar to the simulation results, DWMV had the largest positive impact on recall, the second largest positive impact on accuracy, but no impact on precision. In this empirical study, both the traditional majority vote method and the DWMV method led to perfect precision, meaning all problems that were placed in groups together were similar to each other. However, traditional majority vote led to worse recall than DWMV. When tradition majority vote was used, three of the 50 problems were not placed in a group with any other problems, which is why the recall was so low. However, when DWMV was used, only one problem was not placed in a group of similar problems. This outlier problem, that neither traditional majority vote nor DWMV was able to correctly identify as similar to other problems in its group, had the following text:

> 22% of 65 is 14.3. What is 22.6% of 65? Round your answer to the nearest hundredths (second) decimal place.

Below are examples of problems in the same group as this problem, which were all correctly identified as similar to each other.

> Josiah and Tillery have new jobs at YumYum's Ice Cream Parlor. Josiah is Tillery's manager. In their first year, Josiah will be paid $14 per hour, and Tillery will be paid $7 per hour. They have been told that after every year with the company, they will each be given a raise of $2 per hour. Is the relationship between Josiah's pay and Tillery's pay rate proportional?

> To make a punch, Anna adds 8 ounces of apple juice for every 4 ounces of orange juice. If she uses 32 ounces of apple juice, which proportion can she use to find the number of ounces of orange juice x she should add to make the punch?

> A recent study claimed that in any given month, for every 5 text messages a boy sent or received, a girl sent or received 7 text messages. Is the relationship between the number of text messages sent or received by boys proportional to the number of text messages sent or received by girls?

Although all these problems are related to ratios and proportions, the other problems in the group with the outlier problem are longer word problems that do not explicitly use percentages. The teachers and students whose opinions were crowdsourced could have missed the connection due to the different wording in the problems, or they could believe that calculating percentages is a different skill than calculating proportions from word problems. Based on the differences between this single outlier problem and the other problems in its group, it is possible that the outlier problem was consciously excluded from its group and not simply an oversight.

The impact of using DWMV was larger in this empirical

Table 2: A comparison of majority vote to DWMV used to form groups of similar problems from crowdsourced assertions of similarity.

Metric	Majority Vote	DWMV	% Increase
Accuracy	0.987	0.997	1.054
Precision	1.000	1.000	0.000
Recall	0.903	0.977	8.228

study than it was in the simulation. In the simulation there was a larger than average improvement in accuracy and recall when the workers had very low false positive rates. Given that in this empirical study both sets of groups of similar problems had perfect precision, it is likely that the workers in this study had very low false positive rates, which likely contributed to why the positive impact of using DWMV instead of majority vote was larger in this empirical study than in the simulation as a whole. The results of this empirical study suggest that not only can DWMV out-perform traditional majority vote in simulations, but can also improve the recall and accuracy of groups of similar problems formed from crowdsourced opinions on content similarity in real-life scenarios as well.

5. CONCLUSION

Within online learning platforms and intelligent tutors, there is tremendous utility to knowing what content is similar to other content within the platform, but each application of similar content is likely to have different criteria for what is considered similar. Crowdsourcing opinions on the similarity of content is an accessible way for new applications to recognize similar content. However, crowdsourcing poses some difficulties, namely, how to identify reliable workers and properly aggregate opinions from multiple workers. This work has demonstrated the ability of the Dynamically Weighted Majority Vote method, a novel algorithm for aggregating crowdsourced opinion while rating workers, to accomplish those goals. DWMV has been shown, in both a simulation study and an empirical study, to lead to higher accuracy and recall that the traditional majority vote method on crowdsourcing tasks related to identifying similar content. In the simulation study, using DWMV before identifying groups of similar items through hierarchical clustering resulted in a statistically significant 0.18% increase in accuracy and a 1.78% increase in recall over using majority vote. The simulation study also revealed how the distribution of correct responses in the crowdsourcing tasks effects how the false positive and false negative rates of workers effects their weight in the DWMV method. In the empirical study, using DWMV before identifying groups of similar problems through hierarchical clustering resulted in about a 1% increase in accuracy and an 8% increase in recall over using majority vote, and provided perspective on the differences in accuracy between the expert middle school math teachers and the novice college students. Moving forward, when faced with the need to aggregate crowdsourced opinions, the learning science community can look to the DWMV method as an alternative to the traditional majority vote method. The DWMV method is a promising tool for increasing the reliability of crowdsourced opinion and, when paired with hierarchical clustering, identifying groups of similar content.

ABSTRACT

Measuring similarity of educational items has several applications in the development of adaptive learning systems, and previous research has already proposed a wide range of similarity measures. In this work, we provide an experimental evaluation of selected similarity measures using a large dataset. The used items are alternate-choice questions for the practice of English grammar for second language learners; the dataset contains thousands of items and over 10 million student answers. Our results provide warnings about the generalizability of results presented in EDM works: 1) the results vary significantly between knowledge components and 2) the size of available data is an important factor.

Keywords

item similarity, evaluation, generalizability

1. INTRODUCTION

Learning environments often contain thousands of educational items (questions, problems). A useful data mining contribution is to quantify the pairwise similarity of these items [9]. Such similarity measures have many applications. There are useful particularly for the management of the content, e.g., adding and deleting new items, preparing and revising explanations and hints, or deciding when to split knowledge components. Similarity measures can also be used in algorithms that guide the presentation of the content, e.g., in the presentation of error explanations, it may be useful to group similar items together; in sequencing items, we may want to avoid giving students two very similar questions in close succession. Item similarities may also be used for student modeling [6, 12].

Item similarity can be computed in many ways [9]; the basic two approaches are to use the item content data (e.g., the text of the question) and student performance data (e.g., the correctness of answers and response times). The content-based measures are, to a large degree, dependent on the specific type of data. The techniques based on student performance data are content-agnostic and widely applicable; the disadvantage is that they require (potentially large) student data. Previous research has proposed several specific measures [11, 7, 10].

In this work, we focus on the evaluation of previously proposed measures on a large and interesting dataset. The used items are alternate-choice questions for the practice of English grammar for second language learners (see examples in Table 1). The dataset contains thousands of items, which are categorized into knowledge components and difficulty levels. The items are alternate-choice questions, i.e., they consist of a stem, correct answer, and a single distractor. Items also have explanations, which are written in the Czech language. The dataset contains approximately 10 million student answers.

For this dataset, we evaluate various similarity measures and explore their relations. We focus particularly on the relation between performance-based measures and measures based on the text of explanations. We explore the issue of the sufficient size of data on student performance. In EDM research, this issue is often neglected; the performance of techniques is often studied using a fixed dataset ("all available data"). Our experiment shows that the studied methods are quite data-hungry; they require thousands of answers per item and the amount of available data seems to be more important than differences caused by choice of a measure (which is a type of result common with other machine learning applications [2, 4]). Experiments also show large differences in results between different knowledge components, even though all of these knowledge components come from a single domain (English grammar) and all the used items are of the same, simple format (alternate-choice questions). This result provides a warning about the generalizability of research results in educational data mining.

2. EXPERIMENTAL SETTING

In this section, we describe the data we used for experiments and the specific similarity measures.

2.1 Data

For the evaluation, we use data from the adaptive learning system Umíme anglicky, `umimeanglicky.cz`. The system contains various exercises for English grammar and vocabulary learning for second language learners (for Czech native speakers). We use only one type of exercise—alternate

Jaroslav Čechák and Radek Pelánek "Experimental Evaluation of Similarity Measures for Educational Items". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 553-558. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Table 1: Examples of items from the knowledge component *Present simple vs. present continuous*. For the sake of readability, explanations are given here in English; in the used data, they are in the Czech language.

item stem	correct	distractor	explanation
I _ to the gym once a week.	go	am going	When talking about periodical events, we use present simple tense.
I _ the film that we're watching.	hate	am hating	The verb to hate is not used in continuous form. We use present simple form instead.
I can't hear you! Everybody _ so loudly.	is talking	talks	When the activity is still in progress, we use present continuous tense.

choice question of the form fill-in-the-blank with two options (the correct answer and a distractor). The number of options is not crucial and our analyses could also be applied to questions with multiple distractors. The questions have explanations (in the Czech language).

The questions are divided into *item sets*. Each item set contains questions of similar difficulty from a single knowledge component. The system uses three difficulty levels. An example of an item set is *Present simple vs. present continuous, medium difficulty*, for which examples of questions are provided in Table 1.

Our dataset consists of 54 knowledge components divided into 68 item sets that in total contain 4 348 items. Some item sets share the same knowledge component, and they only differ in the difficulty of items. Concerning student performance, we use the answer (correct or incorrect) and response time (measured in milliseconds). We have 9 752 957 answers from 151 904 students.

Since details of data collection can often have a nontrivial impact on the results of the evaluation [8], we provide a basic description of the core aspects of system behavior that influence the collected data:

- In the system, students answer a sequence of items from a single item set in random order.
- The system uses mastery learning on the level of item sets. Students are motivated to answer a sufficient number of items correctly to satisfy the mastery criterion.
- The choice of an item set that a student solves can be done in a variety of ways: student free choice, assignment by a teacher (homework, assignment within a class), or recommendation by the system (based on past activity).
- The item sets differ widely in their difficulty. The samples of solvers may differ significantly for individual item sets (e.g., *Second conditional, hard* is solved by more advanced students than *Present simple tense, easy*).
- Items may move between difficulty levels ("design level adaptivity" [1]). This aspect may be important for some measures.

2.2 Similarity Measures

In our experiments, we use similarity measures that are variations on previously studied measures [9].

2.2.1 Measures Based on Item Content

One type of measure utilizes that available data about items. One possibility is to utilize item statements, e.g., to measure the similarity of item texts or match on options (the correct answer and distractor). In the case of grammar learning, this approach is hard to use: two questions that practice the same grammar rule can have completely different texts, answers, and distractors. We have performed preliminary experiments with various measures based on item text; these experiments showed very weak results. Therefore, we do not discuss these measures in more detail.

A more applicable content data are explanations. In the used dataset, each item has an associated explanation shown as feedback to students (particularly when they make a mistake). To quantify similarity based on explanations, we compute the text similarity of the explanations. To do so, we considered two common methods: Levenshtein edit distance [5] and Jaccard index.

Both methods compute the pairwise similarity of two explanations. Levenshtein edit distance operates at the character level and computes the minimal number of edits (character addition, removal, and substitution) required to transform one explanation into another explanation. Jaccard index only compares sets of words appearing in the two explanations regardless of their position. It is defined as

$$\frac{|E_1 \cap E_2|}{|E_1 \cup E_2|}$$

where E_1 is a set of words in one explanation and E_2 is a set of words in another explanation.

2.2.2 Measures Based on Student Performance

For computing similarity based on student performance, we consider two basic aspects: the correctness of answers and response times. These aspects are easy to collect and relevant for a vast range of items. In our experiments, we use similarity measures based on either of the two types of data and their combination.

Answer Correctness. The correctness of a student's answer is a simple binary indication of whether the student has answered an item correctly (selected the correct option

Table 2: Agreement matrix for items i and j. Values a, b, c, and d are numbers of students that answered both items in a particular way. For example, c is number of students that answered item i correctly but answered item j incorrectly.

$n = a+b+c+d$		item i correct	item i incorrect
item j	correct	a	b
	incorrect	c	d

$$S_p = \frac{(ad-bc)}{\sqrt{(a+c)(a+b)(b+d)(c+d)}}$$
$$S_c = \frac{(P_o - P_e)}{(1-P_e)}$$
$$P_o = \frac{(a+d)}{n}$$
$$P_e = \frac{((a+b)(a+c)+(b+d)(c+d))}{n^2}$$
$$S_{kl} = \frac{(ad-bc)}{(a+c)(c+d)}$$

in our case). Similarity measures based on the answer correctness then measure "agreement" between answers given by the same students to different items. This is best illustrated on an agreement matrix for two items i and j. There are only four possible ways a student can make binary responses to two items, as illustrated in Table 2. Similarity measures then differ in how exactly they compute the agreement from the individual components of the matrix. In our experiments, we use Pearson correlation coefficient (S_p), Cohen's Kappa (S_c) [3], and Kappa Learning [7] (S_{kl}).

Answer correctness measures can be extended by including a "second step" [9], i.e., computing similarity of similarities. In the first step, binary vectors of student answers for two items are compared to obtain the two items' similarity. The result is a similarity matrix with real-valued elements $s_{i,j}$ equal to the similarity of items i and j. The second step compares real-valued vectors $s_{i,*}$ and $s_{j,*}$ to obtain similarities of items i and j. In our experiments, we use Pearson-Pearson which is a Pearson correlation coefficient used in both first and second step.

Response Time. Response time is measured as the time it takes a student to answer the item (read the item statement and click on one of the options in our case). Student response times can vary due to external distractions during answering or even technical reasons like unreliable internet connection. To make the measure more robust, we opted to bin each item's response times into percentiles. The similarity of two items i and j is then measured as Pearson correlation coefficient of student response time percentiles vectors for items i and j.

Combined. Both correctness and response time can be combined to extract more bits of information. There are multiple ways to combine correctness and response time into a single score [9]. In our experiments, we use linear time transformation for correct answers as a combined score defined as $r = c \cdot max(1 - t/2\tau), 0)$ where $c \in \{0, 1\}$ is correctness, $t \in \mathbb{R}^+$ is response time, and τ is the median time for a given item. Similarities of items i and j are then Pearson correlation coefficient of score vectors for items i and j.

Table 3: Overview of all item similarity measures used in this study.

name	measure type	data used
Levenshtein edit distance	content	explanations
Jaccard index	content	explanations
Pearson corr. coef.	performance	correctness
Cohen's Kappa	performance	correctness
Kappa Learning	performance	correctness
Pearson-Pearson	performance	correctness
Response time percentile	performance	response time
Response time score	performance	correctness + response time

3. RESULTS

In this section, we present our findings. We use the explanations as "ground truth" for item similarity. The reasoning is that explanation describes the aspect of knowledge component that the item is practicing, and similar aspects are described in a similar way (e.g., same tense or conditional). This approach has its limitations, and it is heavily dependent on the quality of explanations. Not all explanations are necessarily ideal (different granularity between knowledge components, human errors), but it is a reasonable proxy.

For intuition behind the performed evaluation, Figure 1 provides an illustration using two knowledge components. The figure shows a PCA projection of items into plain based on the Pearson similarity measure that uses only the correctness of answers. The color of points is based on the explanations provided in the system. As we can see, these two approaches to measuring item similarity to a large degree agree—the points with the same color (similar with respect to explanations) are close to each other (similar with respect to performance). We now explore these relations in a more qualitative manner.

3.1 Relations Among Measures

Table 3 provides an overview of measures introduced in Section 2.2. Other measures can be defined in a similar fashion. An obvious question is whether they differ in any significant way or measure the same thing. To explore relations among measures, we first look at how much they are correlated. The correlation of two measures is computed as the Pearson correlation coefficient of item similarity matrices, each produced by applying item similarity measure to all pairs of items. A high correlation of two measures means that they generally agree on which pairs of items are similar.

Figure 2 shows correlations among measures based on performance and explanation averaged across all item sets. Both explanation-based item similarity measures are strongly correlated, and they also have comparable correlations with all performance-based measures. Therefore, it is not important

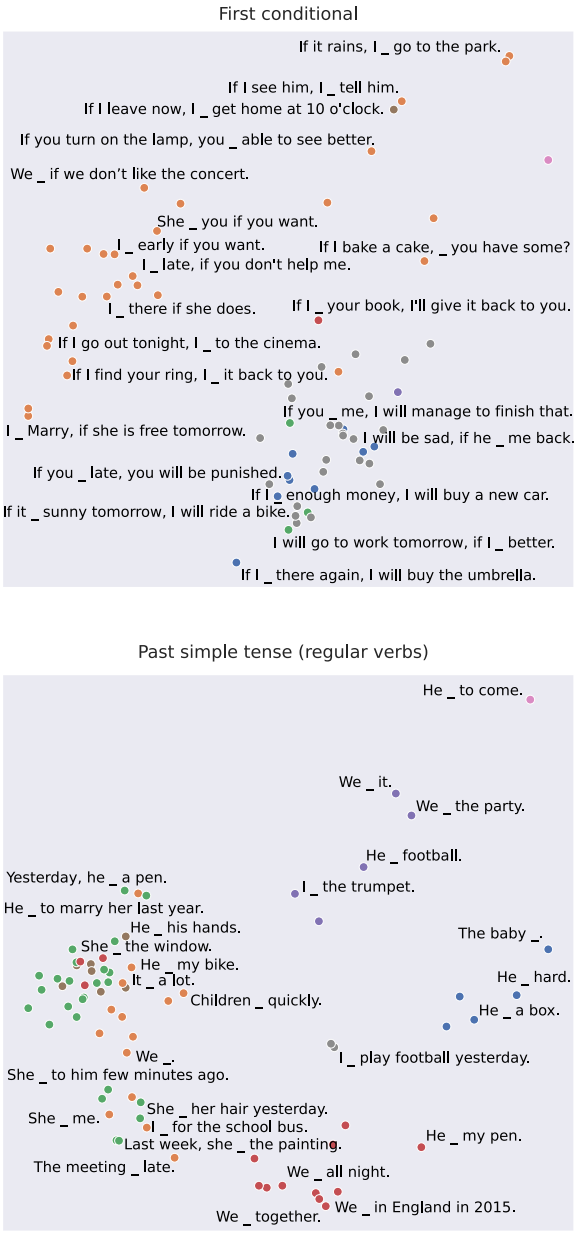

Figure 1: PCA projections based on measures using performance data (Pearson correlation). Points with the same color share the same explanations.

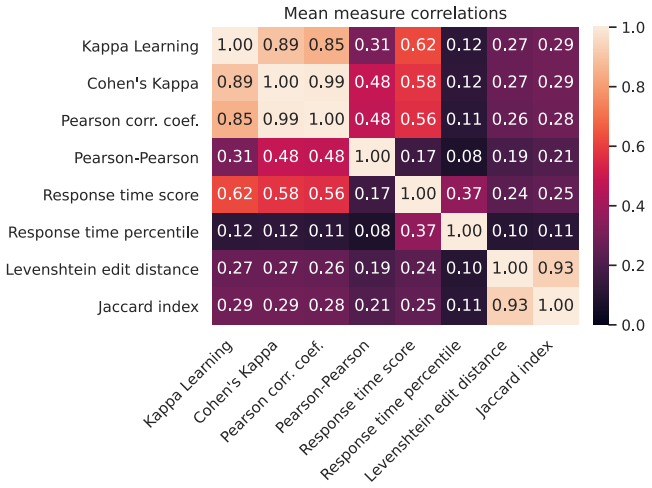

Figure 2: Heatmap of correlation among measures averaged across 68 item sets.

which one we choose as the ground truth for later experiments. This result is not surprising as both measures quantify text similarity, albeit in a different way.

Answer correctness measures Cohen's Kappa and Pearson behave almost identically, and their correlations across item sets are 0.96 or higher. The Kappa Learning measure also behaves similarly and has high correlations with both measures dropping below 0.75 only for one item set. When compared to explanation-based measures, all three measures achieve the same result. In most cases, it is not important which of the three we choose, and the amount of available data is a much more important factor (more details in Section 3.2). This result is in contrast to previous research [7], which argued that the Kappa Learning measure brings important improvement.

The second step similarity Pearson-Pearson has mostly the same or worse correlation with explanation-based measures compared to the previous three measures. It is related to Pearson and Cohen's Kappa, with correlation ranging from 0.3 to 0.8 for most item sets. The correlation with explanation-based measures is weaker compared to other measures using correctness. Thus for the used dataset, the second step does not seem useful. This observation is in contrast to previous research in another context [11].

The measures with response time do not provide any tangible benefits. When compared to explanation-based measures, they achieve either similar correlations in case of Response time score or very poor and mostly zero correlation in case of Response time percentile. A combination of answer correctness and response time in Response time score results in the best correlation for some item sets, but it is not significantly different on average. These results suggest that answer correctness might be a better indication of item similarity for our dataset.

3.2 Size of Data

Item similarity measures based on student performance are based on statistics of student performance data. All statistics need at least some amount of data to become stable and to start approximating the true statistical feature of the underlying data generating process. The question is then, how much data, i.e., answers per item, is required to obtain a good stable approximation?

In Figure 3, we have visualized the stability of performance-based measures in terms of correlation with the explanation-based measure. To simulate different numbers of answers, we have started with knowledge components with a sufficient amount of data and randomly subsampled each item's answers. We report correlation with an explanation-based measure; we report only the Jaccard index as it is highly cor-

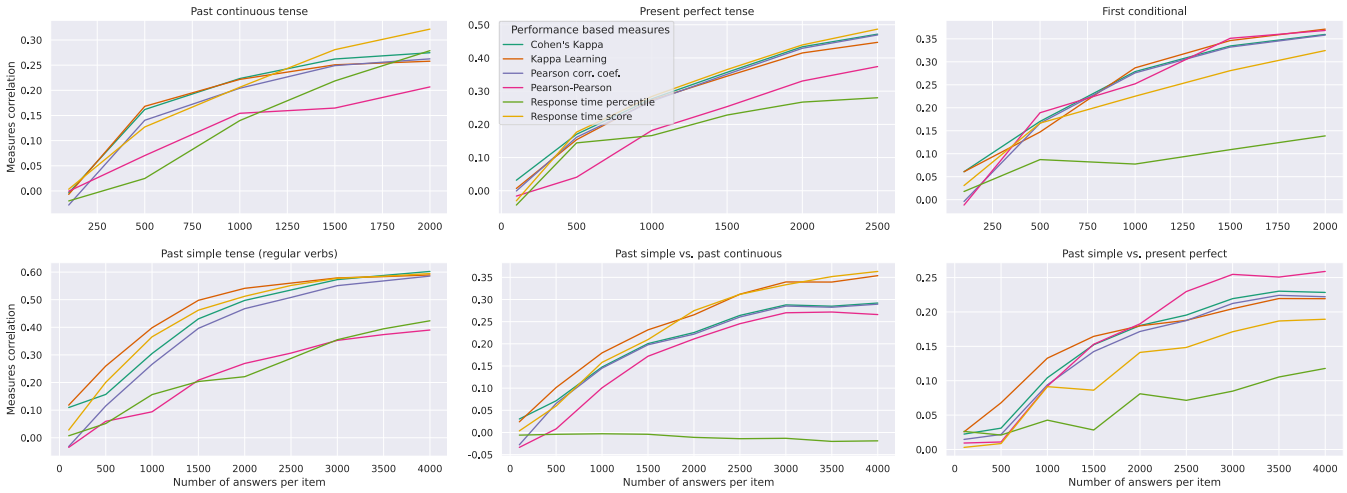

Figure 3: Correlation between performance-based measures and Jaccard index with an increasing number of answers per item across multiple knowledge components. Note that y-axis ranges differ between plots.

related with Levenshtein edit distance and has higher mean correlations with performance-based measures.

Figure 3 shows that performance-based measures are data-hungry. There are nontrivial differences in correlations until 2000 answers per item, and some improvement can be observed even for more data. The general shape of the curves is mostly similar across multiple knowledge components and final achieved correlations. There are a few changes in the relative ordering of measure, but these could be partly attributed to random noise for low data quantities. Different answer correctness measures have similar correlations regardless of data available. Response time score measures utilize more information from the data, and thus we expected them to converge faster. This, however, does not happen.

3.3 Differences among Knowledge Components

There are significant differences in the best achieved correlations among knowledge components. The best correlation achieved between any performance-based measure and explanation-based measure for a given knowledge component ranges from 0.06 to 0.67. Even if we filter out item sets with fewer than 2000 answers per item, the best correlation achieved are still between 0.25 and 0.67. Moreover, the ordering of performance-based measures in terms of achieved correlation with explanation measures differs between knowledge components. For example, Response time score with Levenshtein edit distance has the best correlation 0.61 for *Present simple tense* but the same pair has the worst correlation 0.06 for *Passive voice*. Therefore, the choice of knowledge component is more significant than the choice of similarity measures.

There is a multitude of factors causing these differences. We have identified some of these factors and give examples of their effect on correlations. The identified factors are features of the knowledge component, differences in student populations, and biases in data caused by the addition of content to the system.

Features of knowledge components describe how students use the knowledge component to answer an item. One such feature is how much the component is rule-based. There are more factual components, e.g., *Past simple tense of irregular verbs*, and more rule-based components, e.g., *Past simple tense of regular verbs*. In our data, more rule-based components achieve higher correlations on average. For example, *Past simple tense of regular verbs* achieved a correlation of 0.63 while *Past simple tense of irregular verbs* achieved only a correlation of 0.32.

The difference in student populations is especially important in systems that target a wider audience. The audience of item sets in our dataset range from grades 4 to 10, and thus the student population solving each item set differ. Simpler item sets for grades 4 to 7 achieve a better correlation of performance and explanation-based measures, while more advanced item sets for grades 8 to 10 achieve lower correlations.

Our dataset comes from a system that continuously evolves and has its content modified. These modifications also include the addition of new items among existing items. This poses a challenge for measuring similarity from performance data. Groups of items with varying amounts of collected data can make recently added items artificially different from the rest. For example, item set *Past tense: questions and negative* has 63 items with around 1700 answers per item and 20 newly added items with only around 800 answers per item. The best correlation between performance- and explanation-based measures rises from 0.3 to 0.36 when we filter out newly added items.

4. DISCUSSION

In this work, we have evaluated previously proposed measures for quantifying educational items' similarity based on students' performance. We have used a large dataset from a widely used learning system. The results provide important warnings for both practitioners and researchers.

Many educational data mining techniques require a large size of data for good performance. However, research papers often do not provide any indication of what size of data is good enough. Our results show that performance-based measures are data-hungry and may require upwards of 2000 answers per item before converging. Results reported on smaller datasets thus may be misleading in some aspects. Note that even a large university class would mean only around 200 answers per item which is still an order of magnitude smaller than the required 2000.

Another understudied issue is the generalizability of results across knowledge components. Our dataset is in many aspects very homogeneous: we consider only alternate-choice questions for English grammar. Nevertheless, there are non-trivial differences between the knowledge components (rule-based vs. fact-based, simple vs. advanced), and we have observed significant differences in results depending on the choice of a knowledge component. This observation raises a question of the generalizability of results reported on just a few knowledge components.

ABSTRACT

Many modern anatomy curricula teach histology using virtual microscopes, where students inspect tissue slices in a computer program (e.g. a web browser). However, the educational data mining (EDM) potential of these virtual microscopes remains under-utilized. In this paper, we use EDM techniques to investigate three research questions on a virtual microscope dataset of $N = 1,460$ students. First, which factors predict the success of students locating structures in a virtual microscope? We answer this question with a generalized item response theory model (with 77% test accuracy and 0.82 test AUC in 10-fold cross-validation) and find that task difficulty is the most predictive parameter, whereas student ability is less predictive, prior success on the same task and exposure to an explanatory slide are moderately predictive, and task duration as well as prior mistakes are not predictive. Second, what are typical locations of student mistakes? And third, what are possible misconceptions explaining these locations? A clustering analysis revealed that student mistakes for a difficult task are mostly located in plausible positions ('near misses') whereas mistakes in an easy task are more indicative of deeper misconceptions.

anatomy education, clustering, item response theory, performance modeling, virtual microscopes

1. INTRODUCTION

Histology is a core subject that all medicine students have to pass in their studies. An important part of classic histology training is the microscopy course where students examine a large number of slides of human or animal tissue with an optical microscope in order to identify cellular structures with the aim of establishing structure-function relationships [21]. In recent years, more and more virtual microscopes (VMs) have been developed and integrated into teaching [21]. Such VMs reduce the need for resources (students only require a computer and a software), offer the opportunity to annotate slides with teacher notes, and enhance the student learning experience [21]. Prior work has provided numerous case studies of VMs being successfully integrated into anatomy education around the globe, e.g. [5, 6, 10, 13, 21, 22]. Moreover, several evaluation studies have shown that students using VMs perform at least as well as students using optical microscopes [11, 15].

To the best of our knowledge, no study to date has considered the educational data mining potential of VMs. For example, VMs enable us to record which slides students have seen, which areas on the slides they have focused on, etc. In this work, we consider the MyMi.mobile VM that is used in anatomy courses at two German universities [10]. In this VM, students can view a slide with expert annotations (exploration), and they can test their knowledge by either locating a structure in a slide (structure search; refer to Figure 1), or identifying the tissue sample and staining (diagnosis).

We analyze the performance of $N = 1,460$ students in structure search tasks with respect to three research questions:

RQ1: Which features predict student success?

RQ2: What are typical locations of student mistakes?

RQ3: What are possible misconceptions explaining these locations?

To answer RQ1, we analyzed the collected learning data with a generalized item response theory [2, 12] model, which consists of a difficulty parameter for each task, an ability parameter for each student, and four weights for additional features (see section 3.2). To answer RQ2 and RQ3, we employed a Gaussian mixture model [7] on the locations of mistakes and interpreted the resulting clusters with the help of domain experts. Our results can contribute to enhanced teaching quality in VM courses as well as establish interpretable models to analyze data from such courses.

In the remainder of this paper, we cover related work, our experimental setup, the results, and a conclusion.

2. RELATED WORK

Prior work on machine learning on virtual microscope data has focused on applications outside education. For example, major prior work has been done in training convolutional neural networks to solve classification tasks on microscope images such as detecting fluorescence on images [4]. Successful applications can assist anatomy experts in predicting carcinogens in human cells [23]. Due to the high accuracy of these models [1], they are helpful in cancer diagnostics.

Related to education, prior work of virtual microscopes can be roughly distributed into two categories. First, there are case studies describing how virtual microscopes were integrated into anatomy curricula and the requirements for successful integration, e.g. [5, 6, 10, 13, 21, 22]. Second, several studies have investigated whether students with optical microscopes have higher learning gain compared to students with a virtual microscope and found that this is not the case, e.g. [11, 15].

One of our research questions in this paper is to identify factors that are related to success in locating structures in a virtual microscope. Models that predict student success are a common topic of educational data mining research [3]. For example, Dietz-Uhler et al. [8] summarized which kind of data is often used to predict students success, classified into data gathered from the Learning Management System (e.g. clicks on resources) and performance data (e.g. feedback or grades, created by the instructor or respectively the system). Other papers use demographic data and prior success to predict success rates, e.g. [16]. Prior work has shown that, depending on the knowledge domain, different features have high importance to predict students' success. For example, Ramos et al. [20] found that hits in a discussion forum have high importance to predict students success. Yukselturk et al. [24] used a correlational research design and concluded that self-regulation variables have a highly statistically significant relation to learning success using interpretable methods. To our best knowledge, there is no prior work on success prediction in virtual microscopes. We want to close this research gap.

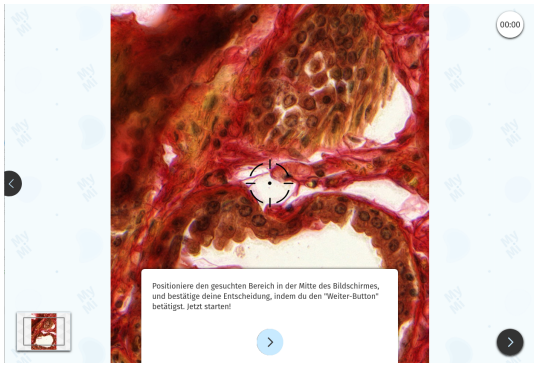

Figure 1: Screenshot of the MyMi.mobile structure search mode.

To do so, we turn to item response theory. Item response theory is concerned with modeling the probability of success of a student i at a task j via a logistic distribution over the difference between a student's ability parameter θ_i and a task's difficulty parameter b_j [2, 12]. Generalizations of this model include more parameters and other distributions [2, 12]. In this paper, we use the standard logistic distribution but include auxiliary parameters for features that capture student behavior.

To analyze the locations of typical mistakes, we perform a clustering analysis using Gaussian mixture models [7]. Clustering is a well-established technique in educational data mining [3], e.g. to identify groups of student solutions that may warrant similar feedback [9]. Our reasoning is similar: We wish to identify typical locations of mistakes in structure searches such that we have a reasonably sized set of representative locations that a teacher can inspect and for which feedback may be developed.

3. METHOD

3.1 MyMi.mobile VM and Dataset

The MyMi.mobile VM provides three modes: *exploration*, which shows expert annotations, *structure search*, where students need to locate a structure in a slide, and *diagnosis*, where students need to identify the slide and the stain. The structure search mode is shown in Figure 1. Students see a tissue slice and are supposed to move the field of view (by panning and zooming) until the crosshair is located over the correct structure. Then, they confirm their choice by clicking the arrow on the bottom right. As additional interface elements, students see an explanatory text at the bottom of the screen ("Position the area to be searched in the center of the screen and confirm your decision by pressing the 'continue-button'. Start now!"), a 'minimap' of the slide on the bottom left, and a timer on the top right. Students can select structure searches in any order from a list sorted alphabetically according to the slides (e.g. armpit, eye, colon)[1]. Students can attempt the same search as many

[1]The alphabetical ordering probably introduces an ordering bias. In particular, we observe that the two most attempted

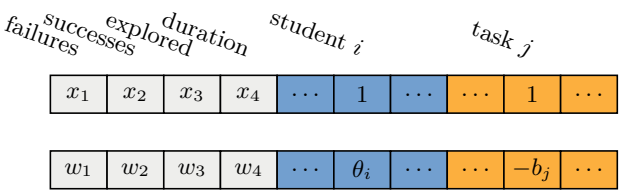

Figure 2: Illustration of the feature vector $\vec{x}$ (top) for an attempt of student i on task j, and the parameter vector $\vec{w}$ (bottom) of the item response theory model.

times as they want.

We consider a dataset of 19,525 structure search attempts by 1,460 students recorded in the summer term 2020 at two German universities. Most students were second semester undergraduate students of medicine, with some students from fourth semester dentistry (45) and molecular medicine in the second or fourth semester (39). Most students (817) did not attempt any structure search. Of the 643 who did, most attempted few structure searches (median 7) with some 'heavy users' making hundreds of attempts (mean 30.37, maximum 649). 68.19% of attempts were successful.

For the purpose of validating our model, we also asked four anatomical teachers using the VM to rate the difficulty of the 30 most attempted structure search tasks on the platform. The teachers received the following instruction: any structure search that at least 65% of students are expected to solve on their first try should be rated as 'easy'; any structure search between $40-65\%$ should be rated 'moderate'; and any structure search below 40% should be rated as 'difficult'. These boundaries were chosen based on the actual success rates of students: 10 of the tasks had an actual success rate over 65%, 10 had an actual success rate between $40\%-65\%$, and 10 had an actual success rate below 40%.

3.2 Item Response Theory

In order to investigate RQ1, we trained a generalized item response theory model implemented via logistic regression. In particular, we pre-processed each structure search attempt to be represented as a 1,859 dimensional, highly sparse feature vector (see Figure 2). The first four dimensions (gray) contain auxiliary features, namely: 1) How often has the student failed on the same structure search? (*failures*) 2) How often has the student succeeded on the same structure search? (*successes*) 3) Has the student already seen the same slide in the exploratory mode? (*explored*), and 4) How many minutes has the student spend on the current structure search? (*duration*). The next 1,460 dimensions (blue) indicate which student made the attempt, i.e. feature $x_{4+i} = 1$ if the current attempt was made by student $i \in \{1, \ldots, 1460\}$ and 0 otherwise. The remaining 395 features (orange) indicate which task the attempt was made on, i.e. feature $x_{1464+j} = 1$ if the current attempt was made on task $j \in \{1, \ldots, 395\}$ and 0 otherwise.

structure searches are both on the alphabetically first slide.

Our model, then, has the form

$$P(1|\vec{x}) = \frac{1}{1+\exp(-\vec{w}^T \cdot \vec{x})} \tag{1}$$
$$= \frac{1}{1+\exp(b_j - \theta_i - w_1 \cdot x_1 \ldots - w_4 \cdot x_4)}$$

where $\vec{x}$ is the sparse feature vector of an attempt and $\vec{w}$ is the parameter vector (see Figure 2). Note that we obtain a classic IRT model if the first four features x_1, x_2, x_3, and x_4 are 0. We used the implementation of logistic regression from the scikit-learn library [19].

3.3 Clustering

To investigate RQ2 and RQ3, we applied clustering on the locations of mistakes. More specifically, we used a Gaussian mixture model with K components, which approximates the probability density over locations (x, y) of mistakes in an image as

$$p(x,y) = \sum_{k=1}^{K} \mathcal{N}\big((x,y)\big|\vec{\mu}_k, \mathbf{\Sigma}_k\big) \cdot \pi_k, \tag{2}$$

where $\mathcal{N}((x,y)|\vec{\mu}_k, \mathbf{\Sigma}_k)$ denotes the 2D Gaussian density with mean $\vec{\mu}_k \in \mathbb{R}^2$ and covariance matrix $\mathbf{\Sigma}_k \in \mathbb{R}^{2\times 2}$; and where $\pi_k \in [0,1]$ is the prior for the kth Gaussian component. Compared to other clustering algorithms, Gaussian mixtures have at least two advantages. First, they can deal with non-spherical clusters by adjusting the covariance matrix accordingly. Second, they provide a probability density of the data. Moreover, they remain fast to train with an expectation maximization scheme [7]. We use the scikit-learn implementation of Gaussian mixtures [19]. To select the optimal number of components K, we use the Bayesian information criterion [18].

4. RESULTS AND DISCUSSION

In this section, we present the results of our experiments. We begin with the teacher difficulty ratings, then continue with the item response theory model (regarding RQ1), and conclude with the clustering analysis (regarding RQ2 and RQ3).

4.1 Teacher difficulty ratings

As the result of our teacher survey, we obtained difficulty ratings ('easy', 'moderate', or 'difficult') for the 30 most attempted structure search tasks. We observe that the teachers agreed moderately. On average, the Kendall τ for pairwise agreement is 0.4 and the overall Krippendorff's α is 0.44. To enhance reliability, we consider the average rating of each task in the subsequent analysis. On average, teachers ranked most tasks as 'easy' (about 55%), fewer as 'moderate' (just below 35%), and very few as 'difficult' (about 10%; refer to blue bars in Figure 3). Recall that, according to actual success rate, all blue bars would have height 1/3. This indicates that teachers tended to underestimate the actual difficulty, which may be an instance of the 'expert blind spot', i.e. the phenomenon that experts may fail to imagine the difficulties of novices [17]. We will use the teacher ratings as reference to further validate our item response theory model below.

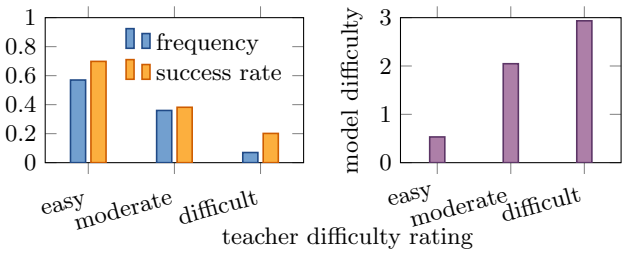

Figure 3: Left: The frequency (blue) and the mean actual success rate (orange) of tasks rated as easy, moderate, or difficult by teachers. Right: The average difficulty parameter assigned by the model to tasks rated as easy, moderate, or difficult by teachers.

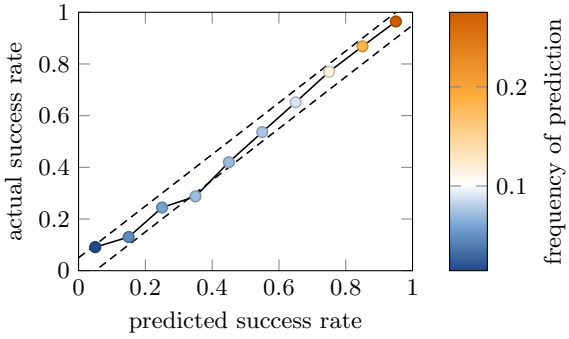

Figure 4: Calibration plot of the IRT model. Dashed lines indicate bin width. The color indicates how full each bin is.

4.2 Factors of student success

In order to investigate which factors contribute to student success (RQ1), we trained an item response theory model (refer to Section 3.2) on our data.

Model validation To validate the model, we performed three analyses. First, we performed a 10-fold cross-validation over attempts, yielding 80.19% ± 0.13% training accuracy and 77.73% ± 1.83% test accuracy on average ± standard deviation. Because our data is imbalanced (with less failures than successes), we also considered AUC (0.86 ± 0.001 in training and 0.82 ± 0.02 in test), and F1 score (0.69 ± 0.003 in training and 0.66 ± 0.024 in test with a test precision of 0.73 ± 0.06 and a test recall of 0.60 ± 0.03). All measures indicate good generalization from training to test set. For the remainder of this section, we consider a model trained on all data.

Second, we assessed model calibration. *Calibration* means that the predicted success probability of a student corresponds to the actual success rate [14]. To analyze this, we aggregated data into bins according to the predicted success probability (each bin had a width of 10%) and then computed the actual success rate within each bin. Figure 4 shows the corresponding calibration curve, where the dashed lines indicate the width of each bin in the analysis. Given that the curve remains within the dashed zone, we conclude that our model was well-calibrated. Most predictions

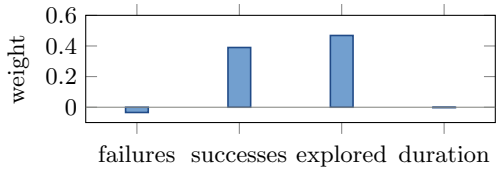

Figure 5: The scaled weights of auxiliary features.

(27.5%) were in the 90% – 100% bin (orange dot), i.e. our model predicted successful attempts with high confidence.

Third, we compared the difficulty parameters of our model with the human ratings from Section 4.1. Figure 3 (right) displays the average difficulty parameter assigned by the IRT model for each difficulty class. We observe that tasks rated as more difficult by teachers were also rated as more difficult by the model. Tasks rated as 'easy' by the teachers have a mean difficulty parameter of 0.5, tasks rated as 'moderate' have a mean difficulty parameter of 2, and tasks rated as 'difficult' a mean parameter of 3.

Overall, we note that the model is reasonably accurate, well-calibrated, and agrees with teacher ratings of difficulty.

Factors to Success Next, we inspect the weights of our model to infer which features are predictive of student success. To make the weights comparable, we normalized the auxiliary features to the same scaling as the binary features.

Regarding auxiliary features (Figure 5), we observe that the number of prior failures had a low negative weight, i.e. it is not predictive of student success. This is likely explained by the design of the MyMi.mobile VM. On a failure, students only learned that they were wrong but not where the right answer might be. This ensures that students can not get the right answer by trial and error. Attempt duration also had a low negative weight. This may be because duration is an ambiguous feature. Students may take longer both for productive reasons – e.g. inspecting the slide in more detail to validate the image against the definition of the structure – and unproductive reasons – e.g. being distracted. Accordingly, duration may not provide predictive information either way.

By contrast, we obtained positive scaled weights for the *successes* (0.39) and *explored* (0.47) features. The explanation for the former is obvious: If you have found the correct solution for the task once, chances are you memorized the location and can find it again. An explanation for the latter is that having seen an annotated example of the structure helps to find another instance of it in a structure search. That being said: We can not make causal inferences in this model. It is also possible that students who are more likely to succeed for other reasons are also more likely to consult the exploratory slides. On the other hand, we account for a general underlying student ability via the student ability parameter (Figure 6).

We observe that student ability parameters vary in the range from −1.97 to 1.55 and most parameters are clumped around

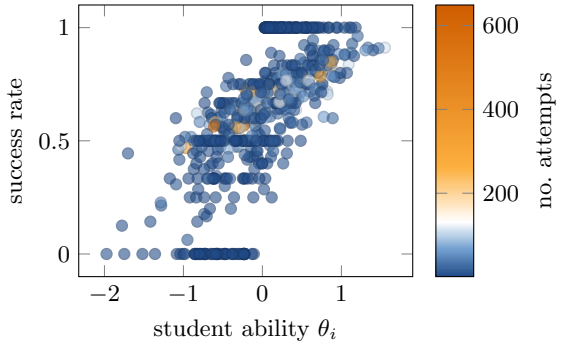

Figure 6: The success rate vs. the student ability of structure searches. Each dot represents a student. Color indicates the number of attempted structure searches by a student.

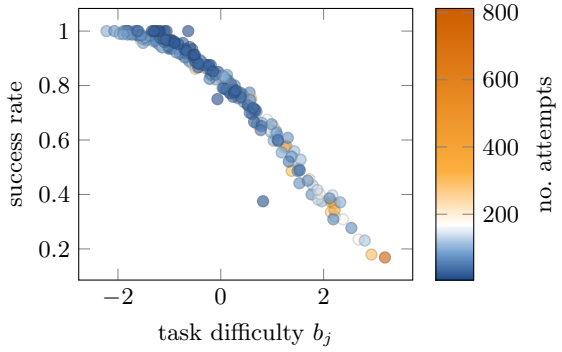

Figure 7: The success rate vs. the task difficulty of structure searches. Each dot represents a task. The heatmap colors indicate the number of attempts of a given task.

0 ± 0.54 (Figure 6). We also observe that the correlation between the ability parameter and actual success rate is relatively weak (Kendall $\tau = 0.52$). To further investigate the role of student ability, we performed another 10-fold cross validation over students instead of attempts, i.e. we tried to generalize to students that the model had never seen before and who thus had an ability parameter of 0. In this setting, we still obtained an average training accuracy of $80.19\% \pm 0.13\%$ and an average test accuracy of $77.93\% \pm 1.83\%$, indicating that the student ability parameters contributed little to an accurate prediction. We have two possible explanations for this finding: First, it may just be that the underlying 'true' student ability is relatively uniform because almost all students were in the same semester at the same two universities. Second, student ability may change during usage of the microscope, such that a single parameter may not be able to capture student ability particularly well.

Finally, we find that the task difficulty had the clearest relation to success compared to the other features. As shown in Figure 7, parameters range from -2.22 to 3.19 (mean 0 ± 1.19) and anti-correlate very well with the actual success rate (Kendall $\tau = -0.91$). This indicates that tasks had a roughly consistent difficulty across students. It also explains how our IRT model generalized well to new students.

In summary, we observe that prior success on the same task, having seen the corresponding exploratory slide, and task difficulty were most predictive of student success, whereas student ability was only moderately predictive and prior failures as well as duration were not predictive.

4.3 Typical mistakes

To investigate RQ2 and RQ3, we consider the two most attempted structure search tasks, namely searching for the nucleus of a myoepithelial cell and searching for an apocrine gland in human armpit tissue (refer to Figure 8 left and right, respectively).

The myoepithelial cell search (Figure 8, left) was the hardest task in the whole dataset with only 16.87% correct guesses (shown as green dots), with a difficulty parameter of 3.19, and unanimous consent of all four experts that it is difficult. Figure 8 (left) illustrates why the task is difficult: The correct regions (in green) are small and hard to spot.

By contrast, the slide for the apocrine gland task (Figure 8, right) exhibits many and large correct regions. Accordingly, 57.72% of guesses were correct (green dots), the model assigned a lower difficulty rating (1.28), and all experts agreed that this task is easy.

To identify typical mistakes, we trained a 10-component[2] Gaussian mixture model to cluster all the mistake locations (shown as blue dots). The cluster means are plotted as orange shapes in Figure 8. Interestingly, most clusters for the myoepithelial cell search task, namely the orange squares in Figure 8 (left) could plausibly be cell cores of myoepithelial cells. The bottom-most orange diamond is also located near a correct region. Only the remaining orange diamonds are clearly wrong because they are not located at cell cores. Generally, many students seemed to have a correct understanding of the structure to be found but failed to spot unambiguously correct locations.

By contrast, the cluster means for the apocrine gland search (Figure 8, right) indicate deeper misconceptions. All cluster centers are clearly wrong. More specifically, the diamond in the bottom right corresponds to an eccrine instead of andocrine gland, and the center diamond corresponds to a broken structure.

In both tasks, we can use cluster centers as a tool to find typical misconceptions that need to be discussed in class.

5. CONCLUSION

In this paper, we investigated three research questions regarding structure search tasks in virtual microscopes, namely 1) Which features predict student success? 2) What are typical locations of student mistakes? 3) What are underlying misconceptions explaining these locations?

[2]We observed that only little improvement in Bayesian information criterion could be achieved for more than 10 components. We also observed that 10 components were sufficient such that some components ended up unused in Figure 8. For other slides, different numbers may be needed.

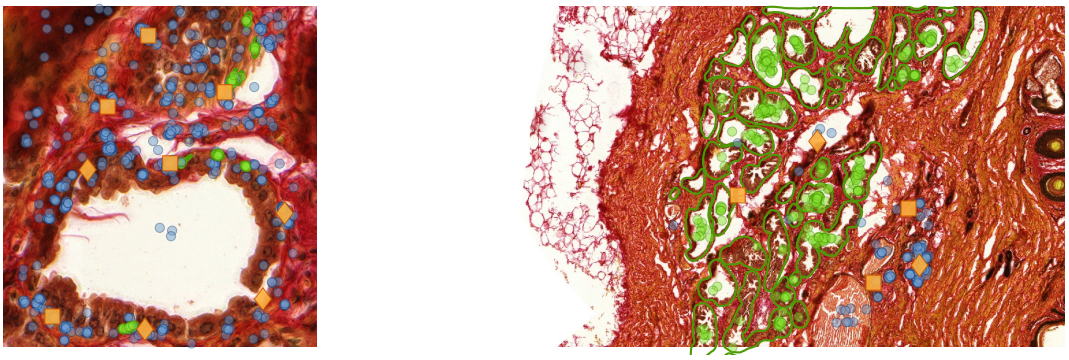

Figure 8: Students' correct (green) and wrong (blue) guesses on structure searches for myoepithelial cell cores (left) and apocrine glands (right). Correct structures are outlined in green. The centers of mistake clusters are orange shapes.

To answer the first question, we trained a generalized item response theory (IRT) model, obtaining 77% accuracy and 0.82 AUC in 10-fold cross-validation as well as solid calibration. Of the features considered, we found that task difficulty was particularly predictive of student success and the obtained difficulty parameters aligned well with actual student success rates and expert ratings. We observed less predictive value of student ability, illustrated by the fact that IRT models could generalize without loss of accuracy to new students. Moreover, prior success on the same task and having seen an annotated version of the same histological slide were predictive of success, whereas prior failures and duration spent on the task were not. This is interesting because it suggests that time stamps could be removed from the data, enhancing the privacy of the system.

Regarding the second and third research question, we applied clustering on mistake locations and interpreted the cluster centers in terms of misconceptions that may have led students to wrongly click at these locations. Such misconceptions can then be discussed in class to improve students' learning, or can be used to provide adaptive feedback in the virtual microscope tool.

Overall, this work represents the first step towards educational data mining on virtual microscope data with results that can be used to improve virtual microscope education, e.g. by ordering structure searches according to difficulty, by discussing typical misconceptions in class, and by enhancing annotations. Further work remains to be done, though. In particular, more features should be included to both enhance accuracy and find educational interventions that support student performance (like the exploratory view). Further, one could include relations between tasks in the model, thus identifying tasks that share an underlying skill, and extend the analysis to more advanced knowledge tracing methods. Finally, convolutional neural networks could be utilized to generalize teacher annotations and to identify regions of images that are easy to confuse with a structure to be searched.

What you apply is not what you learn! Examining students' strategies in German capitalization tasks

ABSTRACT

The ability to spell correctly is a fundamental skill for participating in society and engaging in professional work. In the German language, the capitalization of nouns and proper names presents major difficulties for both native and nonnative learners, since the definition of what is a noun varies according to one's linguistic perspective. In this paper, we hypothesize that learners use different cognitive strategies to identify nouns. To this end, we examine capitalization exercises from more than 30,000 users of an online spelling training platform. The cognitive strategies identified are syntactic, semantic, pragmatic, and morphological approaches. The strategies used by learners overlap widely but differ by individual and evolve with grade level. The results show that even though the pragmatic strategy is not taught systematically in schools, it is the most widespread and most successful strategy used by learners. We therefore suggest that highly granular learning process data can not only provide insights into learners' capabilities and enable the creation of individualized learning content but also inform curriculum development.

Student strategies, Learning type, Online learning, German language, Spelling, Learning analytics

1. INTRODUCTION

The German language is known to be difficult to learn not only for nonnative speakers but also for native speakers who struggle with orthography [26]. However, a high degree of orthographic competence is crucial for successful communication with authorities and for professional success, as studies on employers and personnel selection show [21, 27].

One of the many peculiarities in the German language is capitalization. While nouns and proper names are generally capitalized, there are different linguistic perspectives on which words are considered nouns. Subsequently, learners can apply various redundant strategies to identify nouns.

Nathalie Rzepka, Hans-Georg Müller and Katharina Simbeck "What you apply is not what you learn! Examining students' strategies in German capitalization tasks". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 566-572. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Previous research has further indicated that these cognitive strategies for capitalization result in different patterns of errors that can be distinguished from each other [18]. While some learners consider the entire phrase when deciding whether to capitalize a word, others focus on only the word itself, especially the word ending, as an indication of the correct capitalization. Other learners use the words' meaning or take a pragmatic approach.

This paper aims to contribute to a better understanding of learners' cognitive strategies while processing capitalization tasks in German spelling courses. To this end, we use anonymized learning data on capitalization from the online platform orthografietrainer.net. The dataset consists of 9,647,385 single exercises completed by 30,658 users.

Identifying learners' cognitive strategies for capitalization tasks can enable educators and learning platforms to offer individualized help. Moreover, it can improve learning success by informing the implementation of personalized adaptive learning environments. Furthermore, comparing the predominant cognitive strategies in our large dataset to widely taught strategies in school can help inform future curriculum development. Previous studies of textbooks show that the set of rules taught in school contains semantic, morphological, and syntactic properties but almost completely lacks pragmatic strategy instruction [20]. Nonetheless, we found strong evidence that the pragmatic perspective is the major approach used by students of German.

In summary, we study the following research questions:

- RQ 1: Which cognitive strategies for capitalization are used by learners in grades 5 to 9?
- RQ 2: How does the use of capitalization strategies differ by grade level and gender?
- RQ 3: How do the predominant capitalization strategies used by learners compare to the strategies taught in school?

To answer the research questions, we proceeded as follows: The words used in the capitalization exercises on the online learning platform were manually one-hot encoded with 18 grammatical features associated with the four cognitive strategies for capitalization. In the next step, the four cognitive strategies for solving capitalization tasks were modeled as decision trees. Subsequently, the results of the four decision tree models were compared word by word with the solutions of more than 30,000 users.

2. RELATED WORK

2.1 Grammatical and cognitive approaches to German noun capitalization

The German orthographic system is complex and difficult to master. In contrast to other European writing systems, the difficulties relate less to spelling and more to the indication of grammatical structures. This can be illustrated by the capitalization of nouns, a

peculiarity of the German spelling system. Unlike in many other languages, in German, all nouns are capitalized. The ostensibly simple spelling rule that "nouns have to be capitalized" forces the speller to define precisely what is considered a noun and what is not. On closer examination, this question has a variety of very different possible answers.

On the one hand, there are many obvious nouns, such as people, places, things, and proper nouns. However, beyond that, every part of speech in German can be formally or functionally transformed into a noun. This is sometimes recognizable by a change in suffixes (cf. Ex. 1). In other cases, it can only be inferred from the syntactic context, for example, when articles or prepositions are added (cf. Ex. 2).

Ex. 1: fahren (V)	→	der Fahrer (N)
to drive	→	*the driver*
Ex. 2: fahren (V)	→	das Fahren (N)
to drive	→	*the driving*

The situation is further complicated by idiomatic expressions that formally contain a noun but that, from a pragmatic point of view, have lost their nominal characteristics (cf. Ex. 3). For instance, the supposed noun in Example 3 can still be formally complemented by an adjective, but this otherwise typical procedure for nouns is contrary to what a native German speaker would say. For this reason, the capitalization of such phrases is highly controversial in orthographic theory [5] and is a common source of error among students.

Ex. 3: im Allgemeinen	→ but not:	im *häufigen Allgemeinen
in general	→	*in *common general*

Consequently, all of the nouns in the first sentence of Jane Austen's "Pride and Prejudice" can be identified as nouns across several linguistic levels and work in both English and German:

Ex. 4: "*It is a truth universally acknowledged that a single man in possession of a good fortune must be in want of a wife."*

Ex. 5: *"Es ist eine allgemein anerkannte Wahrheit, dass ein Junggeselle im Besitz eines schönen Vermögens sich nichts mehr wünschen muss als eine Frau."*

Four of the nouns in the sentence occur with articles and in a typical syntactic environment for nouns. In addition, "man" and "wife" are identifiable as nouns by their concrete semantics. The words "truth" and "possession" are also marked morphologically since they were derived from the adjective "true" and the verb "to possess" with the help of a derivative ending.

The difficulties of coherent noun definition thus lie in the fact that a term may have a different extension depending on the linguistic perspective, although the semantic, morphological, syntactic and pragmatic perspectives agree in regard to a broad core of words. On the periphery, however, different perspectives lead to different conceptual boundaries and, consequently, to different orthographic decisions. The ground truth for what constitutes correct writing is therefore a mix between these different perspectives and defined by the Council of German Orthography [15].

The teaching of these different perspectives has been shown by an analysis of different textbooks [18]. The author found that capitalization is practically always introduced semantically. With the beginning of grammatical education in later primary school classes, morphological properties of nouns are added (especially the property numerus and some typical derivational endings), and articles as typical noun companions are introduced. At the secondary level, this knowledge is supplemented more systematically by further morphological and, especially, syntactic properties of the noun group (e.g., gender, case, other determiners besides the article). However, in all courses, noun identification is based exclusively on formal-grammatical grounds. Only one of the textbooks examined also refers to pragmatic properties of the nouns [20].

Müller [20] demonstrated that errors in capitalization correlate strongly with different linguistic perspectives. Thus, some learners are apparently guided more by semantic aspects and others more by morphological, syntactic or pragmatic factors. These findings provide a starting point for our study, in which we attempt to model the different perspectives on noun capitalization using learning analytics methods to test whether different learning types can be distinguished.

2.2 Cognitive strategies of capitalization

Very little literature exists on the differentiation of orthographic strategies. Theoretical models [16, 24] distinguish between lexical and syntactic approaches, which roughly correspond to semantic and morphological strategies on the one hand and syntactic and pragmatic strategies on the other. Studies on the success of both approaches [28] have been limited to very small corpora and have produced partly contradictory results. The proposal of a division into four individual strategies was made by [19], who also found initial indications of different error profiles on the basis of an empirical study.

According to our linguistic considerations, the investigation is based on four theoretically distinguishable capitalization strategies:

The semantic strategy capitalizes words that have a concrete meaning. This strategy is primarily taught in early elementary first grade: "Things that can be touched have to be capitalized."

Katze, Hand	→	but not: *nacht, *meinung,
cat, hand	→	night, opinion

The morphological strategy is to capitalize words that are classified as nouns because of the type of word and the word ending (word derivation):

Läufer	→	but not: (das) *laufen
Runner	→	(the) running

The syntactic strategy is to capitalize words that occur in a typical nominal syntactic environment, preferably in combination with attributes, articles or other determiners.

Die (totale) Dunkelheit	→	but not: *dunkelheit ängstigt mich.
The (total) darkness	→	Darkness frightens me.

The pragmatic strategy is to capitalize words that are used in the current discourse like a nominal unit, which does not apply to all nouns. Pragmatically proper nouns can be supplemented with attributes or substituted with pronouns, which is often not possible with nouns in fixed phrases.

Der Grund	→	but not: im *grunde
the ground	→	in the ground (saying for: "basically")

Typically, the use of several strategies leads to success. Furthermore, there are many words with which capitalization errors are made only very rarely, for example, articles, prepositions, and pronouns. There are only a few words where using only one strategy leads to the correct result, and these words are not representative in the German language. Nevertheless, learners apply the strategies to different degrees and thus arrive at different results.

2.3 Spelling error analysis

We identify the learners' use of the previously introduced cognitive strategies through the analysis of error patterns. The analysis of spelling errors can help in understanding students' cognitive approaches to assignments [2]. Many studies use spelling error analyses to gain knowledge about second language learners; for example, studies [3, 4] analyzed spelling errors of native Arabic speakers in English courses or programs. Others investigate special subpopulations, as the authors of [2, 23] did with dyslexic learners. In addition to differences between native language and foreign language learning and between subpopulations, there are different classification schemes for spelling errors. Some authors have used Cook's classification from 1999 [9], which differentiates between omission, substitution, addition, transposition and sound-based errors [3, 4]. There are major differences between writing systems, and Abu-rabia [1] showed that these differences also affect spelling errors. For the German language, Landerl and Wimmer [14] used the "phoneme distance score" as a scoring method for spelling errors. Defior and Serrano [10] divided Spanish spelling errors into seven different classes of errors, which consist of substitutive spelling, partial spelling, random letters and nonorthographic spelling. Czech spelling errors were divided into phonological errors on the one hand and orthographic, morphological, grammatical, and lexical errors on the other hand [7]. The information gained about the learners can later be used in adaptive environments for different educational approaches to best address each student's abilities [11].

2.4 Learner-Level Adaptation

Adaptive learning environments aim to improve learning success by building personalized models of each student's knowledge, preferences and difficulties [6, 12]. The goal of such an adaptation is to individually optimize the learning path for each student [17]. This can lead to higher motivation, less overload and frustration, and, thus, better results [17]. Personalized adaptation to the student's needs can appear in a variety of forms, including task sequencing, intelligent solution analyses and problem-solving support [6]. The adaptations and the subsequent assessment of adaptive learning environments use a range of different data [8]. The parameters used most often in learner-level adaptation are parameters that refer to the user him or herself and his or her profile as a learner to optimize content [17, 22]. The learner profile consists, among other components, of the learner's behavioral pattern, learner preferences, cognitive traits or learning style as well as performance data [8, 17]. The learner's behavioral pattern can be analyzed by tracing his or her activities on an online platform. Learner preferences thus basically describe learners' preferred materials [22]. Another approach is to adapt a system based on learners' cognitive traits. These traits are their cognitive abilities, for example, their working memory capacity, abstraction ability or analysis ability [22]. There are various definitions of learning style. However, they all agree that there are different ways that learners experience learning [13]. Fang et al. [11] also differentiated between features of a learner's interaction with a system and individual differences between learners in terms of, for example, skill and knowledge.

All this information can be used by teachers to gain a better understanding of their students, leading to opportunities to adapt their teaching, materials or tests [13]. In addition, learners can be provided with appropriate materials and tasks that meet their needs. Finally, learning styles differ in terms of the sequencing of tasks [13]. The relationship between learning styles and the structure of the learning material has been investigated by, for example, the authors of [25], who found that students whose learning styles and multimedia preferences match the material in their online course have higher scores.

In the context of this article, we suggest using the information gained about cognitive strategies for capitalization to display matching tips on online spelling platforms and to evaluate the difficulty of an exercise task in terms of which strategy is used.

3. DATASET

3.1 Orthografietrainer.net platform

The learning platform orthografietrainer.net offers online exercises for improving German spelling skills, including exercises on capitalization, punctuation, and spelling. The platform provides immediate and extensive individual feedback, which is impossible in a classroom setting. The training platform is built based on the pedagogical assumption that spelling requires not only knowledge but also skills. Thus, the focus is not on the regular learning of rules but on repeated practice [18].

The platform offers material for three different user groups: teachers, students and guests. Teachers register themselves and their entire class. They assign appropriate tasks to their students, who work on the tasks. Teachers can view their students' results via a dashboard. Additionally, any interested person can log in as a guest and complete tasks and tests.

A special exercise form on the platform is the competence test, which determines competence levels in capitalization, punctuation and separated or combined spelling. Any identified knowledge gaps are visualized, and appropriate exercises are suggested. A pretest, an intermediate test and a posttest are available and show improvements made over time. For this study, we use only data from competence tests on capitalization, not regular training data, as the test's standardized structure allows for better comparison. Moreover, in competence tests, all sentences are new to users.

3.2 Description of the dataset

For this paper, anonymized, event-level competence test data from orthografietrainer.net from April 1, 2020 to November 17, 2020 are used. Each answer to a sentence corresponds to one record in our dataset. During the analyzed time period, schools in Germany, Austria and Switzerland were closed for several weeks due to the COVID-19 pandemic. In this period, 46,356 users visited the online platform and completed a total of 65,645 capitalization task sessions. When processing the tasks, nearly 50% of the sentences were answered incorrectly, which means that the answers each contained at least one mistake.

The platform was heavily used during the first wave of the COVID-19 pandemic. During the German school holidays in July and August, there was less practice; online training activity increased again in autumn.

The dataset contains information about the class level and gender of users. The German school system includes grades 1 to 13, with 1 being the youngest children and 13 being the oldest (Figure 1).

We decided to exclude all users in grades 1 to 4, as those learners are not well represented in the data set and the difficulty of the capitalization exercises is not adjusted for them. Students in grade 10 and above are also excluded. Older students who are still assigned capitalization exercises are well behind the average learning path and thus represent a marginal group that would bias the data. Most of the users are in grade 7. Our dataset contains slightly more girls (51%) than boys (49%).

Age	School	Class level
18	Secondary School (Second Phase)	13
17		12
16		11
15	Secondary School (First Phase)	10
14		9
13		8
12		7
11		6
10		5
9	Primary School (Sometimes extended to Grade 6)	4
8		3
7		2
6		1

Figure 1. German School System (simplified)

3.3 Using decision trees to replicate different cognitive strategies

The capitalization of German words depends on various grammatical categories, such as the beginning of sentences, word types and clauses. The 180 sentences in the competency test that deal with capitalization contain 2679 words that begin with either lowercase or uppercase letters. These 2679 words were manually categorized into 18 grammatical categories. After one-hot encoding of the labels, we obtained a data frame with dimensions of 2679 x 58.

It cannot be assumed that people use only one strategy; instead, it is likely that each person uses different manifestations of a variety of strategies. To be able to analyze the students' adoption rates of the strategies in regard to capitalization, we first needed to gain insight into how a student would process a word if he or she were only to use one strategy and had only one preferred learning type.

For this purpose, decision trees were used to replicate the four cognitive strategies by attributing to them only the grammatical features corresponding to the given strategy. Afterwards, the sentences from the competence tests were predicted by the decision trees and then validated to determine whether the user classified the words correctly or incorrectly in terms of capitalization. This provided us with the error profiles that would result if only one of the four strategies were used to decide on proper capitalizations. Table 1 shows the strategies and their grammatical features.

Table 1. Strategies with grammatical features

Strategy	Grammatical features
Syntactic	Clause, Article, 2nd person, Determinator, Is prefix, Attribute, Complement of a prepositional phrase, Beginning of sentence, Core nominal pronoun
Semantic	Concrete, Polite form, Semantic word type
Pragmatic	Theme-Rheme, Attributable, Proper name, as an attribute not separable from noun sequence
Morphological	Word type, Noun ending

In the decision trees, 77 % of the words were processed correctly by all four strategies. These are mostly words, where users make only a few mistakes, such as articles, pronouns, prepositions, and conjunctions. They are not interesting for further analyses, as they do not provide insights into differences between the strategies. The beginnings of sentences are also filtered out because they are a special case and cause bias in the data: in the structure of the exercises on the online platform, the beginnings of sentences are in upper case letters per default. Students rarely click on such words to change the letter to lower case. However, as the beginning of a sentence is a syntactical feature, only the syntactic strategy processes these words correctly. Keeping the sentence beginnings part in the dataset would lead to bias, as most users would have a high adoption rate of the syntactic strategy precisely because the sentence beginnings are correct by default.

Table 2. Percentage of correct words per strategy

Syntactic	Semantic	Morphological	Pragmatic
74,11%	32,14%	62,05%	79,69%

The distribution of the remaining 448 words shows that strategies have different success rates (Table 2). The semantic strategy only processes approximately 30% of the words correctly, while the syntactic and pragmatic approaches are much better. This is not surprising, as the meaning of a word is less informative for the determination of capitalization than its grammatical use in a sentence.

Table 3. Sample of a merged data set

Word ID	User ID	Success	Syntactic	Semantic	Morphological	Pragmatic
255	452	1	1	1	1	0
256	128	0	1	0	0	1
257	427	1	0	0	0	1

In the next step, user data and the results from the decision trees are merged. The resulting data frame contains a word processed by a user in each row. For each word, there is information on whether the user capitalized the word correctly and how the decision tree models processed the item. Table 3 shows a sample of the resulting data set. In total, there are 1,355,641 records from more than 30,000 users.

4. RESULTS

To answer the first research question "Which cognitive strategies for capitalization are used by learners in grades 5 to 9", we compare users' error profiles with the error profiles of the decision tree classifiers. That for, we calculated the percentage of answers that matched. The adoption rate was calculated by dividing the sum of matching responses by the sum of processed words for each cognitive strategy. In this calculation, we did not consider whether the word was capitalized correctly. Instead, the result expresses only whether the words were processed in the same way by a user and by one of the four models.

Table 4 presents the average adoption rate per strategy in percentages. The models implementing the syntactic, morphological and pragmatic strategies were in alignment with the users' answers for, on average, 65% to 72% of the words. However, the result for the semantic strategy matched only approximately 40% of users' answers.

Table 4. Adoption rate by strategy

Syntactic	Semantic	Morphological	Pragmatic
65,33%	39,92%	66,32%	72,27%

When interpreting the results, it must be considered that several strategies can be used simultaneously when answering a task. This is always the case if the word cannot be answered exclusively by one strategy. Thus, overall, the adoption rate is over 100%.

4.1 Success rates

Thus far, we have primarily discussed the adoption of the four capitalization strategies. Now, we will examine the successful application of strategies for determining correct capitalization. Figure 2 shows the correlation between the adoption rates and the success rates per strategy.

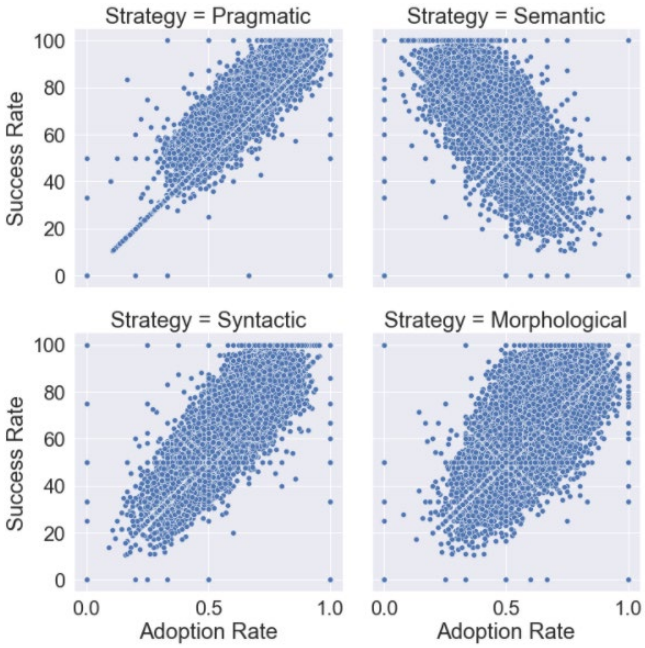

Figure 2. Correlation of success rate and adoption rate by strategy

The adoption of pragmatic, syntactic and morphological strategies led to increased success rates. The correlation is strongest for the pragmatic strategy. In contrast, the higher the share of words solved in agreement with the semantic strategy, the lower the success rate was. These correlations also exist when grade levels are considered in isolation. The success rates of the different strategies are also similar across grade levels.

The success distributed by class level and gender shows that students in higher grades tended to have lower success rates (Figure 3). While grades 5 to 7 had similar success rates, these declined from grade 8 onwards. The lowest success rates were found in grade 9. There is a very small difference between male and female success rates; however, in grades 7 to 9, male students correctly capitalized fewer words than female students did. It is possible that the data in these years reflect cognitive strategy shifts and corresponding temporary uncertainties.

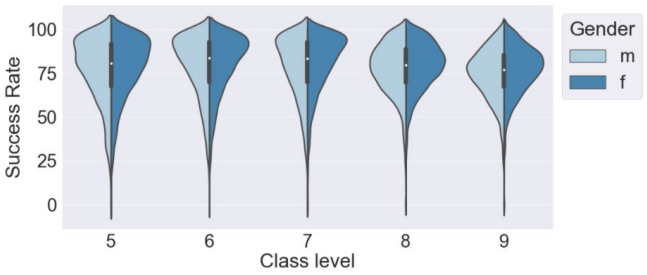

Figure 3. Success rates by class level and gender

4.2 Distribution by class level and gender

The second research question "How does the use of capitalization strategies differ by grade level or gender" is addressed by Figure 4. Looking at the distribution of the average adoption rate by strategy and grade level, we see that preferred strategies evolve over time and shift according to gender.

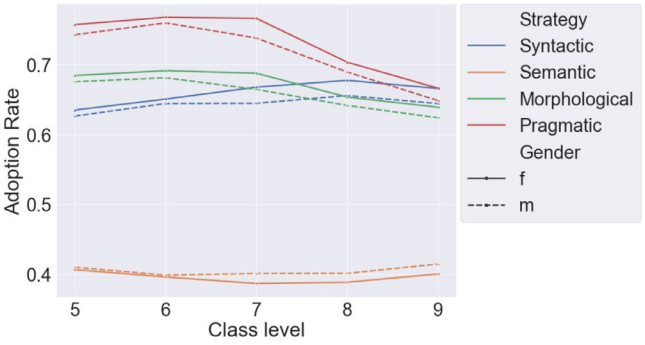

Figure 4. Distribution of adoption rates by class level and gender

The rate of adoption of the pragmatic strategy is very high from the beginning until it decreases sharply after grade 7 for girls and after grade 6 for boys. This is interesting, as the pragmatic strategy is the only strategy that is not explicitly taught in school even though it is very useful for determining correct capitalization (Figure 2). The pragmatic strategy is only surpassed in frequency by the syntactic strategy in grade 9, and the latter increases in use with every grade. Although the use of the syntactic strategy increases more for girls than for boys, in both cases, it ends up being on par with the pragmatic strategy.

Apparently, this reflects stronger grammatical skills among older students. Learners often start a second foreign language in grade 7 (usually Spanish or French), which increases the need for understanding grammatical concepts that are less explicit in their first foreign language, English. At the same time, usage of the morphological strategy also decreases from grade 7 onwards (as early as grade 6 for boys). These findings fit the students' learning biography, as grammatical instruction progresses from morphological to syntactic issues, and therefore orthographic instruction focuses on morphological strategies first. The adoption rate of the semantic strategy decreases until grade 7 but then increases again. This fits with the results regarding the success rate of the semantic strategy, which shows a weakening of knowledge from grade 8 onwards. The increase in semantic strategy use thus goes hand in hand with the students' lower success rates.

Looking at the differences in gender, we have already seen in Figure 3 that boys in grades 7 to 9 answer fewer words correctly than girls. If we now look at the use of the strategies by boys and girls

in Figure 4, we see that boys, especially in grades 7 to 9, use the semantic strategy more frequently, which is the least successful strategy and whose use correlates negatively with the success rate. Girls, on the other hand, use the other three strategies more frequently during this period, which correlate positively with the success rate.

In summary, we can again identify a difference between the semantic strategy and the other strategies. Even though the semantic approach is taught first, most learners do not adopt it for subsequent learning. The adoption rate of the pragmatic and morphological strategy decreases, while the syntactic strategy adoption rate increases. However, the pragmatic approach, which is rarely taught, is applied most frequently.

5. DISCUSSION

We used event-level learning data from an online spelling trainer to analyze cognitive strategies used by students for processing German language capitalization tasks. We built four decision tree classifiers to model capitalization strategies that use only syntactic, semantic, morphological or pragmatic features. As expected, as grammatical information in language is redundant, models often produce overlapping results. We compared the models' output to user error profiles. We found that the strategies are adopted to different degrees and that strong correlations—both positive and negative—between the adoption rates of strategies exist.

Furthermore, the distribution of adoption rates by grade level shows that strategies are represented among older and younger teenagers to different degrees. This variation by grade level is particularly interesting when compared to the rules taught at school, which answers the third research question "How do the predominant capitalization strategies used by learners compare to the strategies taught in school?". The first capitalization strategy taught at school is the semantic strategy: things that can be touched have to be capitalized. Even though this is taught first, students follow it only partly—and rightly so, as the semantic strategy is the least successful in determining correct capitalization. The pragmatic strategy (capitalizing a word if it occurs in a typical textual context for nouns), however, is the only one that is not taught explicitly in school. Nevertheless, this is the strategy with the highest adoption rate and with the highest success rate in our research. The syntactic strategy presupposes a deeper understanding of grammar than the semantic and pragmatic strategies and thus increases with grade level. Although the syntactic strategy and the grammatical knowledge required for employing it begin to be introduced in grade 5, it is only later that students apply it. This may be because students' actual understanding of German grammar increases when they begin learning a second foreign language in grade 7. Since many grammatical concepts are not present in English, a deeper engagement with grammar might only begin when students begin learning a second foreign language. This could lead to a different way of looking at spelling, which is then reflected in the use of the syntactic strategy. The use of the morphological strategy decreases over time as the use of the syntactic strategy increases.

When considering the success rates in combination with the adoption rates, it is particularly interesting that the semantic strategy adoption rate correlates negatively with success rate. This again shows that the teaching of the semantic strategy as the basic rule does not lead to success. The strongest positive correlation with the success rate is the pragmatic strategy adoption rate.

6. CONCLUSION

In this paper, we have contributed to three aspects of learning analytics. We have identified cognitive strategies of learners using error analyses, compared adoption rates and drawn conclusions for curriculum development from the results.

First, we were able to model cognitive strategies for solving German language capitalization tasks. The four strategies (syntactic, semantic, morphological and pragmatic) do partially overlap. We have shown that the different learning strategy adoption rates can be observed in user error profiles (RQ1). This opens up opportunities for individualized training and therefore for higher motivation and learning success for students.

Second, we found that learners prefer different strategies depending on their grade level and gender (RQ2). This information can be used to adapt the online platform orthografietrainer.net to various learner levels. For example, based on this information, the difficulty of the words can be calculated more specifically for each user, and task sequencing can be adjusted to be neither too difficult nor too easy. This reduces the potential for frustration caused by tasks that are too difficult and also increases motivation. Furthermore, with tasks that represent typical sources of error for a user, the platform could display appropriate tips and hints. If the error analysis results are made available to the teacher on the dashboard of the online platform, he or she can see which rules have not yet been observed by the students and can adapt lessons accordingly. Further research could include the implementation and subsequent validation through A/B testing of such improvements.

Finally, our findings lead to a better understanding of how capitalization is learned and taught (RQ3). Our research shows that there is a great discrepancy between which strategies are taught in class and which strategies are used by students. We therefore suggest that highly granular learning process data can not only provide insights into learners' abilities and enable individualized learning content but also inform curriculum development.

Other future analyses could investigate whether the learning strategies can be applied to other grammatical areas, such as separated and combined spelling.

7. ACKNOWLEDGEMENTS

This research was funded by the Federal Ministry of Education and Research of Germany in the framework "Digitalisierung im Bildungsbereich" (project number 01JD1812A).

Integrating Deep Learning into An Automated Feedback Generation System for Automated Essay Scoring

Chang Lu, Maria Cutumisu
Department of Educational Psychology
Faculty of Education, University of Alberta
{clu4, cutumisu}@ualberta.ca

ABSTRACT

Digitalization and automation of test administration, score reporting, and feedback provision have the potential to benefit large-scale and formative assessments. Many studies on automated essay scoring (AES) and feedback generation systems were published in the last decade, but few connected AES and feedback generation within a unified framework. Recent advancements in machine learning algorithms enable researchers to develop more models that explore the potential of automated assessments in education. This study makes the following contributions. First, it implements, compares, and contrasts three AES algorithms with word-embedding and deep learning models (CNN, LSTM, and Bi-LSTM). Second, it proposes a novel automated feedback generation algorithm based on the Constrained Metropolis-Hastings Sampling (CGMH). Third, it builds a classifier to integrate AES and feedback generation into a systematic framework. Results show that (1) the scoring accuracy of the AES algorithm outperforms that of state-of-the-art models; and (2) the CGMH method generates semantically-related feedback sentences. The findings support the feasibility of an automated system that combines essay scoring with feedback generation. Implications may lead to the development of models that reveal linguistic features, while achieving high scoring accuracy, as well as to the creation of feedback corpora to generate more semantically-related and sentiment-appropriate feedback.

Keywords

Automated essay scoring, deep learning, feedback generation, assessment, machine learning, natural language processing

1. INTRODUCTION

Automatic essay scoring (AES), the task of machine-grading essays or constructed-response items, has been gaining attention due to technology-powered advances in educational assessment [16]. The goal of AES is to produce reliable and valid scores using machine scoring rather than human scoring [43]. Previous research has made advances in automatic grading essays with handcrafted features [16, 30, 40]. Currently, with the availability of large volumes of trainable corpora extracted online and the development of models for word representation in the Natural Language Processing (NLP), deep learning approaches have produced highly reliable scores using text classification methods [10, 12, 22]. However, few studies have approached automated essay scoring and automated feedback generation to achieve a fully automated computer-based testing system (CBT).

Earlier attempts at implementing feedback have been made using real-time online tutoring by humans [18, 31]. Findings show that human tutoring is effective at improving students' performance, but it is time consuming and labor intensive. Also, human tutoring is not applicable to large-scale practice and open-ended platforms with large numbers of students. Research on automated feedback generation emerged in the last decade to fill this gap by developing tools to scaffold students within computer-based testing environments [24, 36]. Previous studies have focused on generating formative feedback using rule-based approaches [3, 38]. Although rule-based feedback generation is relatively easy to achieve and the generated sentences can be considered to be appropriate feedback, this approach is usually restricted to pre-designed templates. Recent efforts have been made to engage students in more communicative and adaptive environments and to propose feedback-generation frameworks using sentence generation with constraints, where the constraints are often defined by domain-specific terms [8, 11]. Nevertheless, few studies have empirically examined automated language generation in CBTs. This study proposes a framework that introduces an algorithm based on deep learning models with an unsupervised sentence-generation approach to automatically grade essays and to generate feedback.

2. RELATED WORK

2.1 Automated Essay Scoring

Automated essay scoring constitutes the task of automatically assigning scores to written essays based on features or characteristics in the text. Several systems for Automated Essay Scoring (AES) have already been developed and used in large-scale high-stakes assessments for several decades. Page [33] designed the first intelligent scoring system, Project Essay Grade (PEG), using simple linear regression with hand-crafted features such as essay length and proposition counts to perform text classification tasks based on these features. Since then, other systems for automated essay scoring emerged such as Intelligent Essay Assessor [25], e-rater [6], IntelliMetric [41], and My Access! [41]. Several AES methods have been later adopted to make predictions on student writing scores. Yannakoudakis et al. [44] approached AES as a preference-ranking problem and evaluated essays based on pairwise comparisons of features, such as POS n-grams features and complex grammatical features. Gierl et al. [16] demonstrated the application of AES in medical exams with Support Vector Machine (SVM). Phandi et al. [34] approaches AES with Bayesian Linear Ridge Regression. Taghipour and Ng [40] designed an 'Enhanced AI Scoring Engine' (EASE) based on four genres of

features: length-based features, Parts-of-Speech (POS), word-prompt overlap, and bag of n-grams. These features were fed into several model architectures such as Convolutional Neural Network (CNN) and the Recurrent Neural Network (RNN)-variants, namely Long Short-Term Memory (LSTM) and Bidirectional LSTM (Bi-LSTM), to compare the prediction performance of the models. Phandi et al.'s [34] attempt to employ deep learning models to predict essay scores was later used as a baseline for related studies. Previous studies on automated essay scoring rely heavily on hand-crafted feature engineering and knowledge on linguistic discourse. Inspired by recent advances of deep learning models and word embedding techniques, a substantial body of literature has emerged, which has contributed to applying deep learning methods in automated essay scoring tasks. Alikaniotis et al. [1] implemented a two-layer bidirectional LSTM with score-specific word embeddings to learn essay representations and conduct AES tasks. The proposed model outperformed the baseline SVM model. Later, Dong and Zhang [9] established a three-layer model architecture combining CNN for character representation and LSTM for sentence representation with an extra attention-pooling layer, which performed better than Taghipour and Ng's [40] model and their two-layer CNN model. Taghipour and Ng's attempt of combining feature engineering and deep learning models inspired later trials of applying word embeddings and deep learning methods on AES.

2.2 Automated Feedback Generation

Providing feedback is a key ingredient in performance improvement. In education, feedback is defined as the information provided by an agent regarding aspects of one's performance or understanding [17]. High-quality personalized and timely feedback can improve learners' performance [17], but feedback provision is often reported as the long-standing weakness of ITSs and computer-based assessment systems [27]. On the one hand, students complain that they receive too little quality feedback in the process of learning [5, 13]. On the other hand, students are reported to misuse and abuse the feedback or hints provided by the ITSs [37]. Thus, knowing how and when to provide real-time personalized feedback that guides and motivates students' learning remains a challenge.

Williams and Dreher [42] advocated the potential of fully-automated systems that perform both scoring and feedback provision with machines in tasks such as essay grading. Previous efforts have been made to produce feedback in intelligent tutoring or assessment systems [7, 19, 21] for various disciplines, such as computer science [14, 23], information and communication technology (ICT [7]), and English as a Second Language (ESL [26]). However, most automated assessment systems adopt a template-based method to generate feedback [4, 26, 42], which usually produces feedback that is limited to fixed expressions.

Recent advances on constrained sentence generation shed some light onto flexible feedback generation. For example, Su et al. [39] proposes a Gibbs sampling method to meet the constraints of sentiment control. However, Gibbs sampling is not able to vary the sentence length or handle keywords when generating the sentence. Miao et al. [32] extends the Gibbs sampling to a novel unsupervised sampling approach, named Constrained Generation by Metropolis-Hastings sampling (CGMH). The CGMH is a subtype of the Markov Chain Monte Carlo (MCMC [15]) methods. The CGMH allows for more flexible operations on word tokens in a sentence space, thus it is easier to generate content with constraints and varying sentence lengths. Miao et al. [32] tested the CGMH on three tasks including key-to-sentence generation with hard constraints, paraphrase, and error correction with soft constraints. The CGMH method outperformed state-of-art sentence-generation algorithms. Yet, one of the reasons that the research on automated feedback generation with NLP is lagging behind may be that there is no publicly-available feedback corpus.

2.3 Present Study

We propose an AES and an automated feedback generation framework to support students' performance. Specifically, the current study implements three deep learning models for automated essay scoring: (1) CNN; (2) CNN and LSTM; and (3) CNN and Bi-LSTM. In addition, a novel unsupervised sentence-generation approach uses CGMH to automatically provide feedback for test takers based on their predicted essay scores. The remaining sections are guided by the following research questions:

1. To what extent can the AES algorithms generate accurate performance on essay scoring?

2. To what extent can the CGMH algorithms generate fluent and semantically-related feedback?

The contributions of the present study are three-fold. First, the study advances computer-based testing by incorporating automated feedback generation into the assessment framework, especially for unstructured text (e.g., essays). Second, the flexible unsupervised learning approach creates a corpus of semantically-related and sentiment-appropriate feedback for scaffolding. Third, the scalable automatic assessment and feedback provision system is automated and performs accurately, which paves the way for future implementations of feedback generation for various domains within intelligent tutoring systems.

3. METHOD

3.1 Datasets and Corpus

The dataset for the AES task was retrieved from a Kaggle challenge named Automated Student Assessment Prize (ASAP) sponsored by the Hewlett Foundation in 2012 and detailed in Table 1.

Table 1. Summary of ASAP dataset

Prompt	Genre	Grade Level	Training set size	Score Range	Ave Length
1	persuasive /narrative / expository	8	1783	2-12	350
2	persuasive /narrative / expository	10	1800	1-6	350
3	source dependent	10	1726	0-3	350
4	source dependent	10	1772	0-3	150
5	source dependent	8	1805	0-4	150
6	source dependent	10	1800	0-4	150
7	persuasive /narrative/ expository	7	1569	0-30	250
8	persuasive /narrative / expository	10	723	0-60	650

The ASAP is the benchmark dataset for piloting AES studies. It consists of 8 prompts and 4 genres, including persuasive, narrative,

expository, and source-dependent responses. In total, 12,979 essays were released. Since the ASAP has not made the official test sets publicly available, we used 60% of the training set for training, 20% for validation, and 20% for testing. We first performed text cleaning, tokenization, and padding. Then, we used Stanford's publicly-available GloVe 300-dimensional model to conduct word embeddings [35]. The GloVe 300-dimensional embeddings were trained on 6 billion words scraped from Wikipedia and other web texts. The writing prompts have different score ranges as shown in Table 1. To address the issue of inconsistent score ranges, we followed Phandi et al.'s [34], Taghipour and Ng's [40], and Dong and Zhang's [9] method by approaching the AES as a regression task, rescaling the essay score to [0, 1] in the training, validating, and test stages, and projecting the scores back to their original scales in the evaluation stage.

The corpus used to train language models for sentence generation consisted of the publicly-available IMDB dataset, which contains 25,000 positive reviews and 25,000 negative reviews. The dataset was split into three parts: the training set consisted of 20,000 negative reviews and 20,000 positive reviews, the validation test consisted of 1,250 negative and 1,250 positive reviews, and the test set consisted of 1,250 negative and 1,250 positive reviews. A third-party corpus, the Reuters corpus from NLTK, was used for evaluation of the quality of the generated sentences.

3.1.1 AES Step

The present study was conducted in two steps. Step 1 addressed automated essay scoring, whereas Step 2 addressed automated feedback generation. An essay performance classifier was added to synthesize the two steps into a unified framework.

In the AES task, three deep-learning algorithms were implemented and compared regarding their performance and efficiency to select the optimal algorithm as the foundation of the feedback generation step: CNN, CNN + LSTM, and CNN + Bi-LSTM. The convolutional layer is seen as a function that could learn features from n-grams, and can be represented as:

$$Z_i = f\left(W_z\left[x_i^j : x_i^{j+h_w-1}\right] + b_z\right),$$

where x_i is the ith embedded word, W_z is the weight matrix, b_z is the bias vector, h_w is the window size of the convolutional layer, f is a non-linear activation function (i.e., sigmoid, tanh, or ReLu), and Z_i is the output of feature representation.

LSTM is an RNN model for processing sequence data [20]. The unit or memory cell of LSTM consists of an input gate, a forget gate, and an output gate to control information flow. The gates decide preserving, forgetting, and passing information as a vector sequence at each time step.

More specifically, assuming there are *T* sentences in an essay in total, the composite functions at sentence *t* can be written as:

$$i_t = \sigma(W_i s_t + U_i h_{t-1} + b_i),$$
$$f_t = \sigma(W_f s_t + U_f h_{t-1} + b_f),$$
$$g_t = tanh(W_g s_t + U_g h_{t-1} + b_g),$$
$$c_t = i_t \odot g_t + f_t c_{t-1},$$
$$O_t = \sigma(W_o s_t + U_o h_{t-1} + b_o),$$
$$h_t = O_t \odot \tanh(c_t),$$

in which s_t is the input vector, h_t is the output vector, W_i, W_f, W_g, W_o, U_i, U_f, U_g, U_o are the estimated weight matrices, and b_i, b_f, b_g, b_o are the bias vectors.

Bi-LSTM is an extension of unidirectional-LSTM for deeper representations. Compared with unidirectional-LSTM that can only preserve and pass information from history, Bi-LSTM can also make use of information from future. In AES tasks, Bi-LSTM could process the words in the input vector in both a forward and a backward manner. The composite function for Bi-LSTM is similar with LSTM:

$$y_t = W_{yh}\begin{pmatrix}\overrightarrow{h_t} \\ \overleftarrow{h_t}\end{pmatrix} + b_y.$$

The summary of the model architectures for the three models is shown in Table 2.

Table 2. Model architecture summary

Layer	Hyperparameter	Value
CNN		
Embeddings	dimension	300
Convolutional	filters, kernel size	100, 5
CNN + LSTM		
Embeddings	dimension	300
Convolutional	filters, kernel size	100, 5
LSTM	units	32
CNN + Bi-LSTM		
Embeddings	dimension	300
Convolutional	filters, kernel size	100, 5
Bi-LSTM	layers	16

3.1.2 Feedback Generation Step

The feedback generation phase included two steps. In Step 1 (Corpus Development), we will develop a corpus of feedback using CGMH based on the expert-derived essay descriptors. In Step 2 (Feedback Generation & Provision), we will develop feedback based on the essay scores provided by the AES algorithms.

Table 3 shows the part of the essay-scoring rubrics (the score ranged from 1 to 6) and descriptors developed by experts.

Table 3. Sample descriptor for Essay Prompt 1

Score	Descriptors
1	An undeveloped response that may take a position but offers no more than very minimal support.
Element	Contains few or vague details.
	Is awkward and fragmented.
	May be difficult to read and understand.
	May show no awareness of audience.
2	An under-developed response that may or may not take a position.
Element	Contains only general reasons with unelaborated and/or list-like details.
	Shows little or no evidence of organization.

	May be awkward and confused or simplistic.
	May show little awareness of audience.

To expand the corpus, we will adopt the *Constrained Sentence Generation by Metropolis-Hastings Sampling* method (CGMH [32]) to perform unsupervised paraphrase generation. The CGMH facilitates the generation of content with constraints and varying sentence lengths. Miao et al. [32] tested the CGMH on three tasks, including keywords-to-sentence generation with hard constraints, paraphrase, and error correction with soft constraints. In the present research, we will implement unsupervised paraphrasing to augment the feedback corpus. Specifically, we will first train a language model based on the IMDB review corpus [29]. The IMDB dataset consists of 25,000 positive and 25,000 negative movie reviews. It was selected for the feedback-generation task for the following reasons. First, to date, there is no database of academic feedback, the IMDB was the closest commentary corpus available. More importantly, this corpus is split into positive and negative phrases, which makes it domain-independent. Thus, it can transfer more easily to other domains. Then, we will perform the paraphrase generation.

A Markov model is used to train the language model on the selected corpus. The Markov Chain is commonly used to model natural language as a function of the probability that a word appearing in position *n* is only dependent on the previous *z* ϵ [1, n-1] such that:

$$p(w_1, w_2, \dots, w_n) = p(w_1)\, p(w_2|w_1), \dots\dots, p(w_n|w_{n-z}, \dots, w_{n-1}),$$

where $p(w_1, w_2, \dots, w_n)$ refers to the probability of a specific sentence based on the trained corpus, that is, the joint probability of all words within the sentence. In the present research, we used forward-backward dynamic programming to train the language model.

In Step 2 (feedback paraphrase), we performed the CGMH task of unsupervised sentence paraphrasing. The CGMH is concerned with a goal of stationary distribution that defines the sentence distribution sampled from the corpus and three actions, namely, replacement, insertion, and deletion. Specifically, $\pi(x)$ was set as the distribution from which we plan to sample sentences, where *x* denotes a particular sentence and x_0 refers to the feedback template that is fed to the algorithm at time step 0. The MH sampler either accepts or rejects a word from the given distributions $\pi(x)$ to finally form a desired joint distribution of all words based on a predefined stationary distribution. The process is intuitive, as it mainly involves two actions: accepting or rejecting a word monitored by the acceptance rate α:

$$\alpha = \min\{1, \frac{\pi(x')g(x_{t-1}|x')}{\pi(x_{t-1})g(x'|x_{t-1})}\}$$

At time step *t*, the word sampling is conducted to update the previous state *x* to a candidate distribution x' from a proposed distribution $g(x'|x_{t-1})$, where x_{t-1} refers to the distribution from previous step (*t-1*), thus $x' = x_t$. Therefore, α determines the acceptance or rejection of a sample. In our paraphrase generation, the desired distribution denotes the most likely and logical sentence related to the original sentence.

At each step, a selected word in the sentence will be updated by the actions such as insertion, deletion, and replacement, randomly, where the respective probabilities are $[p_{insert}, p_{delete}, p_{replace}]$. At the first time step, these probabilities are set as being equal. At the following step, if *Replacement* is applied on a selected word w_m in a sentence $x = [w_1, w_2, \dots, w_{m-1}, w_m, w_{m+1}, \dots, w_n]$, then the conditional probability of choosing w_m^{new} to replace w_m to form candidate sentence x' from *x* can be computed as:

$$g_{replace}(x'|x) = \pi(w_m^{new}|x_{-m}) = \frac{\pi(w_1, w_2, \dots, w_{m-1}, w_m^{new}, w_{m+1}, \dots, w_n)}{\sum_{w \in V}(w_1, w_2, \dots, w_{m-1}, w, w_{m+1}, \dots, w_n)},$$

where *V* refers to the vocabulary, and w_m is the selected word. If, on the other hand, *Insertion* is applied, an additional step of inserting a placeholder will be conducted before taking the action *Replacement*, and then a real word will be sampled to replace the placeholder token with the *Replacement* token. Finally, if *Deletion* is applied, the w_m word selected will be deleted, and $g_{deletion}(x'|x)$ =1 if $x' = [w_1, w_2, \dots, w_{m-1}, w_{m+1}, \dots, w_n]$, and 0 otherwise. The detailed settings of the sentence-generation phase, including the hyperparameter values determined in the tuning process are included in Table 4.

Table 4. MCMC hyperparameter

Hyperparameters	**Value**
Dictionary size	50,000
Hidden nodes per LSTM layer	300
Number of steps	50
Maximum sentence length	50
Max epoch	30
Minimum of Sentence Length	7
Initial action probability	[0.3, 0.3, 0.3, 0.1]

3.1.3 Synthesis

One important purpose of the present study is to develop a framework linking automated essay scoring and automated feedback generation. Thus, the study can be decomposed in two parts: a supervised text classification task using CNN and RNN models and an unsupervised learning paraphrase generation task using MCMC sampling method with constraints. In the synthesis, a performance classifier was applied to extract feedback that corresponds to the score that is assigned by the AES algorithms.

3.2 Evaluation Metrics

The objective of the AES training stage is to minimize the mean squared error (MSE) between the scores provided by human raters and the prediction scores generated by the models.

In the automated essay scoring tasks, several measures including the quadratic weighted kappa (QWK [9, 10]), exact agreement, and alternate-form reliabilities [2] have been used to evaluate the performance of AES models in previous studies. In the current study, we present the results of QWK, which measures the degree of agreement between human raters and the machine on one essay and can be calculated by:

$$\text{QWK} = 1 - \frac{\sum_{i,j} W_{i,j}\, O_{i,j}}{\sum_{i,j} W_{i,j}\, E_{i,j}}.$$

where $W_{i,j}$ is calculated by $W_{i,j} = \frac{(i-j)^2}{(N-1)^2}$ (i: represents the human-rated score; j: represents machine-rated score; N: represents the score range), $O_{i,j}$ represents the number of essays that receive a rating i by the human and a rating j by the machine, and E is the outer product of the histogram vectors of the two scores. According to Williamson, Xi, and Breyer [43], QWK scores higher than 0.7 indicate high accuracy.

For the feedback generation task, we used several measures to evaluate the generated sentences. The first step is concerned with language model training, whereas the second step is concerned with generating sentences with the MCMC sampling method. More specifically, we first reported the training process of the language model over epochs. The objective of the first training process is to minimize the perplexity of the language model, which can be calculated by:

$$PPL = 2^{-\frac{1}{N}\sum_{i=1}^{N} \log\, p(w_i)},$$

where N equals the number of words in the corpus and $p(w_i)$ indicates the probability of a word appearing in the position. The lower the PPL is, the more precisely the corpus is modeled.

For the generated sentences, we evaluated the model performance using two measures. First, we computed the Negative Likelihood (NLL) of the sentences to evaluate their fluency using the Reuters corpus released by NLTK modules. The lower the NLL is, the more fluent the sentences are. Second, we invited two volunteers to rate the quality of 50 pieces of feedback in terms of the sentence fluency and relatedness at a scale of 0-1, and the higher the scores are, the more fluent and related the generated feedback sentences are.

4. RESULTS

4.1 Rating Accuracy of AES Algorithms

The results show that, for Prompt 1, the most accurate algorithm is CNN + Bi-LSTM, whereas for Prompts 2 to 8, the most accurate algorithm is CNN + LSTM. The average QWK of CNN + LSTM reaches 0.734, as shown in Table 5. In general, the models that integrate LSTM/Bi-LSTM perform better than CNN. Compared with the baseline [34], the CNN+LSTM model in the present study performs better on Writing Prompt 1-7, but poorer on Prompt 8. In addition, the average QWK of CNN+LSTM also outperforms the baseline model [34].

Table 5. Comparisons of QWK of the implemented models

Prompt	CNN	CNN + LSTM	CNN + Bi-LSTM	Phandi et al., 2015
1	0.81	0.87	0.88	0.76
2.1	0.62	0.64	0.52	0.61
2.2	0.51	0.61	0.51	-*
3	0.73	0.63	0.62	0.62
4	0.83	0.83	0.72	0.74
5	0.77	0.86	0.76	0.78
6	0.77	0.85	0.8	0.78
7	0.72	0.79	0.75	0.73
8	0.35	0.53	0.54	0.62
Ave	0.68	0.73	0.68	0.71

Note: *indicates that prompts 2.1 and 2.2 were combined into a single score.

Results of the average QWK across genres (e.g., persuasive, narrative, and expository) and source-independent writing can be found in Table 6, which shows that CNN+LSTM outperformed CNN and CNN+Bi-LSTM on both genres. However, the three models all performed poorly on the persuasive, narrative, and expository criteria. The results are consistent with previous studies [34], as the models generally have better predictions on the prompts with smaller score ranges. The wide-score range may cause more complexities for the training process of deep learning models. In addition, previous studies on applying deep neural networks in AES yielded similar results showing that models generally performed poorly on Prompts 2 and 8 [9, 10, 34, 40]. The present study also found that the three deep learning algorithms showed higher efficiency on scoring certain types of genres of writing, but less accuracy on Prompts 2, 3, and 8. One possible explanation is that, for Prompt 2, two domain scores instead of one single global score are provided. The inherent inconsistency or low reliability of a single human rater's scoring makes it difficult for machines to learn the scoring pattern. While for Prompt 8, the score range is 0 to 60, as shown in Table 1. Compared with other prompts whose score ranges are narrow (0 to 3 or 0 to 4), this extremely wide range (i.e., the categories of the outcome variable) may hinder the learning process of deep learning models.

Table 6. Average QWK across genres

QWK	persuasive /narrative/ expository (Prompt 1,2,7,8)	source independent (Prompt 3,4,5,6)
CNN	0.601	0.775
CNN+LSTM	0.688	0.793
CNN+Bi-LSTM	0.640	0.726

4.2 Runtime of AES

Prediction accuracy is of utmost priority in machine learning. However, in a fully-automated scoring and reporting system, scoring efficiency represented as the time it took to run one epoch (i.e., the runtime) also plays an important role. Table 7 shows the average runtime for one epoch of the three models: CNN was the fastest of the three on average. Therefore, it can be concluded that CNN+LSTM has the highest performance, but also has relatively high efficiency (i.e., it is the second fastest algorithm of the three). Thus, it was chosen as the AES algorithm for the feedback-generation step.

Table 7. Average runtime and memory

Model	Runtime for one epoch	N of Parameters
CNN	51s	5117233
CNN + LSTM	53s	4988977
CNN + Bi-LSTM	55s	4986929

4.3 NLL of Generated Feedback and Human Ratings

For the sentence generation process, the generated sentences were the ones with the lowest NLL after 50 steps of running. The feedback phrases were generated using a sentence paraphrasing CGMH approach before being passed on to the performance classifier. The feedback templates were sampled from the ASAP rating descriptors and feedback phrases were generated based on the language model trained on the IMDB dataset.

Figure 1 presents the training process of the language model, and Table 8 shows the NLL and human-rater evaluations of the generated sentences regarding *Fluency* and *Relatedness* on a scale of 0 to 1. The higher the scores, the more fluent and related the generated feedback sentences. The results revealed that the MCMC method is able to generate fluent and semantically-relevant sentences.

Table 8. NLL and rater evaluation on sentence generation

Evaluation Methods	Measures
NLL	10.01
Human Rating: Fluency	0.62
Human Rating: Relatedness	0.52

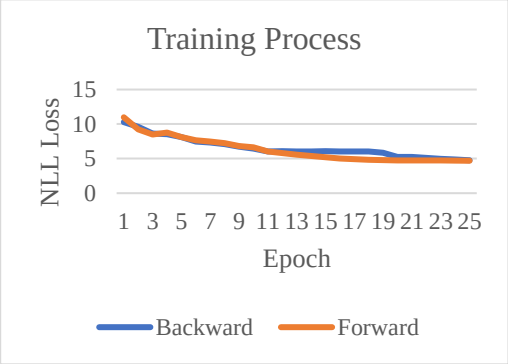

Figure 1. Learning curves of the training process of the language model (NLL convergence w.r.t. epochs).

5. DISCUSSION AND CONCLUSION

This study proposed and implemented a novel framework for an automated assessment and reporting framework with a combination of supervised deep learning models and unsupervised MCMC sampling method. Specifically, this study compared the performances of three models, namely CNN, CNN+LSTM, and CNN+Bi-LSTM, on AES tasks in the same context. Results revealed that CNN+LSTM demonstrated the highest performance on the AES tasks among the three algorithms. Moreover, the CNN+LSTM outperformed the baseline model on seven out of eight writing prompts, which demonstrates the potential of word-embeddings and deep learning models on automated essay scoring.

A recent literature review revealed that text-based feedback was more effective in improving performance [28]. Providing feedback within digital learning and assessment systems is essential for students' self-directed learning. However, it is laborious to manually devise a large amount of expert-derived quality feedback. Compared with sentence-generation supervised-learning methods, the CGMH sentence-paraphrasing unsupervised-learning method can augment the expert-driven feedback template corpus by generating feedback phrases with higher efficiency and flexibility. Thus, the proposed method is promising in promoting text-based feedback generation within automated assessment systems. Results of the current study could facilitate future implementations and validations of personalized automated feedback provision for ITSs and other virtual learning systems.

6. LIMITATIONS AND FUTURE WORK

We identified several limitations in the present study. First, this study does not empirically validate the AES and the automated feedback generation system in educational settings. Future research will be conducted to provide empirical evidence on the validity and efficiency of the framework. Second, the present framework generates feedback using a holistic score for essays. Future research will incorporate linguistic components into AES to enhance the interpretability of the scoring results and to generate more fine-grained feedback.

7. ACKNOWLEDGEMENT

We would like to thank the reviewers for their helpful feedback and the following granting agencies for supporting this research: the Social Sciences and Humanities Research Council of Canada - Insight Development Grant (SSHRC IDG) RES0034954 and Insight Grant (SSHRC IG) RES0048110, Natural Sciences and Engineering Research Council Discovery Grant (NSERC DG) RES0043209, Killam Cornerstone Operating Grant RES0043207, Alberta Innovates, and Alberta Advanced Education.

ABSTRACT

Self-regulated learning (SRL) is a critical 21st-century skill. In this paper, we examine SRL through the lens of the searching, monitoring, assessing, rehearsing, and translating (SMART) schema for learning operations. We use microanalysis to measure SRL behaviors as students interact with a computer-based learning environment, Betty's Brain. We leverage interaction data, survey data, *in situ* student interviews, and supervised machine learning techniques to predict the proportion of time spent on each of the SMART schema facets, developing models with prediction accuracy ranging from *rho* = .19 for translating to *rho* = .66 for assembling. We examine key interactions between variables in our models and discuss the implications for future SRL research. Finally, we show that both ground truth and predicted values can be used to predict future learning in the system. In fact, the inferred models of SRL outperform the ground truth versions, demonstrating both their generalizability and their potential for using these models to improve adaptive scaffolding for students who are still developing SRL skills.

Keywords

Self Regulation, SMART, Self Regulated Learning, Machine Learning, Student Interviews

1. INTRODUCTION

In traditional classrooms, most support for acquiring self-regulated learning (SRL) strategies comes from teachers, who might check in on projects and/or provide advice about next steps [33] in order to keep students focused on their end goals. However, teachers' external regulation alone is insufficient to encourage educational success [24]; the learner must also develop internal regulation schemas. SRL demands may increase when the student is completing a project in a computer-based learning environment that is no longer teacher-led. The software might scaffold learning activities, but identifying the complex behaviors involved with SRL is still not a typical function of most computer-based learning systems.

In most computer-based learning environments, learners must control, manage, plan, and monitor their learning [12], i.e., implement the definitional components of SRL. SRL has consistently been shown to facilitate knowledge acquisition and retention among learners in a structured and systematic way [12]. As such, work has called for a deeper understanding of SRL impacts in online learning [1, 8, 37].

A range of techniques have been used to better understand SRL both in computer-based learning environments (e.g., [1, 5, 12, 34]) and in other contexts (see [17, 27] for meta-analyses). Research in computer-based learning can be split into two groups: supporting SRL and detecting SRL behaviors [46]. Supporting SRL has taken a number of forms, but in general, these approaches typically scaffold students in either their goal-setting, self-evaluation, help-seeking, self-efficacy, or some combination of these [29]. This might be through verbal prompts (e.g. "Take time to read everything,") [7, 22] or more intricate support systems [25], such as progress bars [14], or tools such as notebooks, that better facilitate student reflection [2, 35].

In terms of detecting SRL in computer-based learning environments, Azevedo and colleagues have (using MetaTutor) considered the role that emotion plays in regulation, posing that affect should be considered as we scaffold SRL behaviors [4]. Segedy et al. [36] used interaction data and coherence analysis to measure self-regulation. Learner behaviors were tracked using log files to assess action coherence (i.e., did a student's actions present a coherent strategy relevant to the current tasks), which was shown to predict learning. Winne et al. [45] also leveraged log data in a scalable system that traces student actions, classifying each learning event into SRL categories in order to better understand student cognition, motivation, and metacognition. We build upon this approach in this work.

While interaction data has been successfully used to detect SRL, a number of researchers argue that this data should not be considered in isolation [3, 37, 40]. Instead, we must also consider contextual factors and individual differences not easily inferred from logs. This work combines interaction data with data from targeted in-situ student interviews and student survey data to predict SRL as characterized by the COPES and subsequent SMART models of SRL [42] (discussed in detail below). We examine the impact of SRL on learning, analyzing contextual and student-level factors that may influence SRL behavior and demonstrating the potential of the latent encoding of SRL for identifying students who need further support.

1.1 Related Works

At a high level, SRL is a process in which learners take initiative to identify their learning goals and then adjust their learning strategies, cognitive resources, motivation, and behavior to optimize their learning outcomes [11, 42]. First characterized in

Stephen Hutt, Jaclyn Ocumpaugh, Juliana Ma. Alexandra L. Andres, Nigel Bosch, Luc Paquette, Gautam Biswas and Ryan Baker "Investigating SMART Models of Self-Regulation and their Impact on Learning". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 580-587. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

1989 [47], SRL is now widely acknowledged as an essential skill for learning in the modern knowledge-driven society [23]. In learning technologies specifically, recent work has called for a deeper understanding of SRL and for learning technology that supports the development of SRL strategies [1, 3, 8, 20, 37].

In order to provide insight into how SRL works, researchers have proposed a number of theoretical models (e.g., [30, 47]). Winne & Hadwin's model [43], grounded in information processing theory, characterizes SRL as a series of events that happen over four recursive stages: (1) task definition, (2) goal setting and planning, (3) studying tactics, and (4) metacognitive adaption of studying techniques. Each stage is then characterized by Conditions, Operations, Products, Evaluations, and Standards (COPES). In later work, Winne subcategorized the COPES model further by detailing five kinds of operations—searching, monitoring, assembling, rehearsing, and translating—known as the SMART model [42].

In the context of educational data mining, we can study SRL by measuring these theoretical constructs and studying their relationships to each other and to external measures (such as achievement). SRL constructs can be measured either online (while an activity is happening) or offline (before or after an activity) [34]. Offline assessments typically rely on self-report questionnaires, but student interviews have also been used. These can be implemented either online and offline and can offer advantages over questionnaires that may limit students to pre-defined answers [16, 40].

Trace analysis is perhaps the main approach used (and endorsed [37]) to measure SRL online. Traces (such as log data) capture learning actions along with additional contextual and timing information, providing a detailed window into a learner's processes and behaviors [40]. This data can support microanalytic approaches, as sequences of actions can be aligned with different facets of a self-regulation model [21, 45]. Models that conceptualize SRL in terms of events or student actions (such as the COPES model [43]) lend themselves more to a trace-based analysis [42] than to offline measurement. However, many researchers argue that trace data should be supplemented with additional measurements (e.g., self-reports or think-alouds) when measuring SRL [3, 37, 40].

1.2 Current Study

The current study was conducted within the context of Betty's Brain, a computer-based learning environment for middle school science. We combine multiple data sources (interaction, surveys, and interview data) to analyze SRL patterns through the lens of Winne's COPES and SMART models [42].

We first demonstrate that combining features from different data sources yields the most successful models of the SMART facets. We present a feature analysis to investigate the key interactions in each model. We next examine how the different facets of SRL influence student learning. We consider not only the ground truth calculations of SMART facets but also our predicted models of these facets, showing that the latter better predicts future student outcomes than the original variables.

To our knowledge, this work presents the first exploration of how student interviews, surveys, and interaction data may be used in concert to predict SRL and learning. This approach provides detailed insight into how we may best support students in an environment where external regulation may be harder to provide.

2. DATA

2.1 The Learning Environment

In this project, we used the learning environment Betty's Brain. This system implements a learning-by-teaching model [9], where students teach a virtual agent named "Betty" by creating a causal map of scientific processes (e.g., thermoregulation or climate change). Betty demonstrates her "learning" by taking quizzes, graded by a mentor agent, Mr. Davis. In this open-ended system, students choose how to navigate a variety of learning sources, how to build their maps, and how often to quiz Betty. They may also interact with Mr. Davis, who can support their learning and teaching endeavors [10].

Betty's Brain is a suitable environment for examining SRL behaviors for two reasons. Firstly, students choose when and how to perform each step of the learning process (both their own and Betty's) [20, 33]. Indeed, the pedagogical agents in Betty's Brain are designed to facilitate the development of SRL behaviors by providing a framework for the gradual internalization of effective learning strategies. Secondly, students' interactions with Betty's Brain are logged to an online database with detailed timing information, enabling the microanalysis of student actions [37] for the measurement of SRL behaviors and strategies.

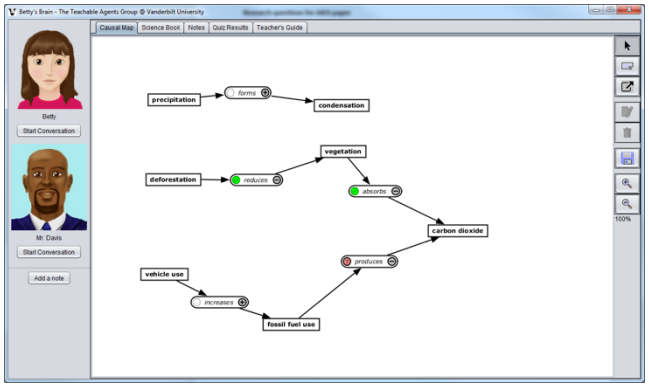

Figure 1. Screenshot of Betty's Brain showing a partial causal map constructed by a student.

2.2 Data Collection

This study examines data from 93 sixth graders who used Betty's Brain during their 2016–2017 science classes in an urban public school in Tennessee. The first data collection occurred over seven school days. On day 1, students completed a 30–45-minute paper-based pre-test that measured knowledge of scientific concepts and causal relationships. On day 2, students participated in a 30-minute training session about the learning goals and user interface. Afterwards (days 2–6), students used the Betty's Brain software for approximately 45–50 minutes each session, using concept maps to teach Betty about the causal relationships involved in the process of climate change. On day 7, students completed a post-test with the same questions as the pre-test. In addition to the data described, we also surveyed students on self-efficacy [31] and the task value [31].

A second data collection period occurred two months later, during which students were asked to model the causal relationships involved in thermoregulation. This was otherwise identical to the first session, but we consider only the learning data (pre – post test) from this second scenario (see section 4.2).

2.3 In-Situ Interviews

As students interacted with Betty's Brain, automatic detectors of educationally relevant affective states [19] and behaviors [26], already embedded in the software, identified key moments in the students' learning processes, either from specific affective patterns or theoretically aligned behavioral sequences. This detection was then used to prompt student interviews through Quick Red Fox (QRF), an app which integrates interview data with Betty's Brain events. Interviewers sought to take a helpful but non-authoritative role when speaking with students. Interviews were open-ended and occurred without a set script; however, students were often asked what their strategies were (if any) for getting through the system. As new information emerged in these open-ended interviews, questions were designed to elicit information about intrinsic interest (e.g., "What kinds of books do you like to read and why?"). Overall, however, students were encouraged to provide feedback about their experience with the software and talk about their choices as they used the software

2.4 Interview Transcription and Coding

A total of 358 interviews were conducted during this study and stored on a secure file management system. Interviews were manually transcribed by three members of the research team, preserving all metadata but scrubbing any identifying information.

The code development process followed [38]'s 7-stage recursive, iterative process: conceptualization, generation, refinement, codebook generation, revision and feedback, implementation, and continued revision. The conceptualization of codes involved a literature review to capture experiences relevant to affect and SRL. Using grounded theory [13], we worked with the lead interviewer (2nd author) to identify categories that were (1) theoretically valid and pertinent to the conditions in the COPES model and (2) likely to saliently emerge in the interviews.

We iteratively refined the coding scheme until the entire research team reached a shared understanding. Following the coding manual's production, external coders reached acceptable inter-rater reliability with the 3rd author before coding all of the transcripts. All codes had Cohen's kappa > .6, and the average Cohen's kappa across codes was .83. See Table 1 for details.

Table 1. Interview codes

Code	N	Description
Helpfulness	51	Utility of system resources for learning, and positive evaluations of the resources. κ=.643
Interestingness	11	Interestingness of system resources and continued desire to use the platform. κ=.726
Strategic Use	205	Indicates plan for interacting with the platform, or changes in strategy or interaction based on experiences. κ=.911
Positive Mr. Davis Attribution	8	Explicitly mentions interactions with Mr. Davis as positive experiences. κ=.838
Positive Science Attribution	26	Explicitly (positively) mentions science in relation to books, future careers, school subjects, and overall evaluations. κ=.837
Positive Persistence	105	Expression of a desire for challenge and that the current task is a challenge; there is active pursuit of a goal, and repeated attempts to complete a step/problem. κ=.911
Procedural Strategy	225	Step by step approach to the learning activity, active use of within-platform tools, reference to previous or upcoming step. κ=.862
Motivational Strategy	151	Explicit indication of expected outcome from behaviors/actions, explicitly mentions a pursuit for mastery, contains positive attribution/emotion for completion, and/or mentions desire to meet task demands. κ=.870
Self-Confidence	174	Positive description of own progress or ability, self-assessments of learning progress, willingness to encounter learning challenges/, recognition of helpful resources. κ=.877

2.5 SMART Encoding

We operationalized SRL behavior within the log data using the COPES and SMART SRL frameworks [42]. In this work, we categorize all student actions recorded in the log files as "operations" within the COPES model (defined as "cognitive and behavioral actions applied to perform the task"). We then evaluate these operations using the SMART model, which subcategorizes actions by the information taken as input and product generated [39]. Specifically, the SMART model presents five primitive cognitive operation subcategories: Searching, Monitoring, Assembling, Rehearsing, and Translating [39]. Each category is briefly described below; for more details, see [39, 41, 42, 45]. Examples specific to Betty's Brain are shown in Table 2.

Searching is the operation where a learner focuses their attention on a knowledge base or resource to update their working memory.

Monitoring considers two types of information: (1) learner perceptions (current understanding, quiz answers, etc.), (2) standards for performance. In monitoring activities, the learner evaluates their perceptions compared to the standards.

Assembling involves building a network of internal links between acquired information to understand relationships (X precedes Y, Y causes Z, etc.). Assembling activities help students to connect individual items of knowledge in working memory.

Rehearsing operations repeatedly direct attention to information that the learner is currently working on. These actions reinforce the same information and prevent decay in working memory.

Translating operations reformat information into a new representation, providing the potential for alternate interpretations and understanding. Examples include converting a diagram to plain text or answering a question about a diagram.

To enable a trace analysis of student SRL patterns [37] we first assigned each of the possible student operations within Betty's Brain to one SMART category. We categorized operations that added new items to the concept map within Betty's Brain as *assembling*, and operations that edited existing items as *monitoring*. In ambiguous cases, such as between translation and monitoring tasks, we considered student agency. Specifically, actions initiated by the system were classified as *translating* even if they had an evaluative component. In our operationalization of the SMART model, we found that Betty's Brain logged no rehearsing actions; thus, this category was not analyzed.

3. MODEL TRAINING METHODS

We built supervised machine learning models to detect each facet of the SMART model. We leveraged a combination of activity, survey, and interview data (described further below).

Table 2. Example Betty's Brain actions by SMART facet.

SMART Facet	N	Example
Searching	8	Searching the virtual textbook (initiated by the student)
Monitoring	22	Reviewing and updating the label of a causal link (initiated by the student)
Assembling	2	Adding a causal link to the map (initiated by the student)
Rehearsing	0	-
Translating	3	Responding to a system-initiated multiple-choice questions (vs. those initiated by the student)

3.1 Features

We split features into three groups based on their origin. Each group is described in detail below. Due to differences in scale, we *Z*-scored each feature prior to model training.

(Other) Student Activity Features (N = 4). These features provide a high-level description of student actions: the raw number of student actions, the proportion of links made that were ineffective, time spent off-task/idle (as characterized in [36]), and number of successful quizzes. These features were designed to be more coarse-grained than the log data used to derive the SMART variables. None of the fine-grained features used to calculate the SMART encoding are included in this feature set.

Student Interview Codes (N = 9). These were derived from the transcribed student interviews (described in section 2.3). In cases where students had multiple interviews, codes were averaged to provide one feature per code per student.

Survey Features (N = 2). Survey features come from the two survey measures described in section 2.2: self-efficacy and task value. While each measure consisted of multiple survey questions, both were summarized down to one variable, respectively.

3.2 Dependent Variables

We initially considered four dependent variables, the proportion of the time a student spent on each of the SMART variables discussed in section 2.5. We considered time spent rather than raw action counts for a more standardized comparison and to avoid misinterpretation. For example, there are more monitoring actions than searching actions; however, it is common for students to spend considerably more time searching than monitoring. Due to time spent idle (at least 30 seconds of inactivity [36]), the sum of these four variables for any given student may not be 1. The most common category was searching (M=0.65, SD=0.07), followed by monitoring (M=0.16, SD=0.06), translating (M=0.10, SD=0.02), and assembling (M=0.09, SD=0.04).

We also considered a second set of dependent variables related to student learning. We derived two variables, one for the current scenario from which the rest of the data was collected, and one for the future scenario. In both cases, learning was characterized by post test – pre test. We consider both scenarios to examine how well our approach generalizes to future interactions and understand how immediate context may influence prediction.

3.3 Regression Models

We used scikit-learn [28] to implement Bayesian ridge regression, linear regression, Huber regression, and random forest regression, and also implemented XGBoost with a separate library [15]. Hyperparameters were tuned on the training set using scikit-learn's cross-validated grid search [28] where appropriate.

All models were trained using 4-fold student-level cross-validation and repeated for ten iterations, each with a new random seed. For evaluation, predictions were pooled across folds, and averaged across iterations. These models then underwent a decision tree based secondary analysis, discussed below.

4. RESULTS

We compare model accuracy by computing the correlation between the model predictions and the ground truth values derived from student logs. We measured the Spearman *rho* correlation coefficient in the test folds to evaluate models. In the majority of cases, random forest regressors yielded the best results. As such, results from these models are reported below.

4.1 Predicting SMART Operations

We first consider results predicting the proportion of time a student spent on each of the four SMART operations. For each operation (i.e., searching, monitoring, assembling, and translating), we developed models drawn from various combinations of our feature types (actions, surveys, and interview codes). Thus, we were able to test the modeling potential of seven different combinations of features for each SMART operation (see Table 3). To provide a point of comparison, we generated a chance baseline for each variable by shuffling the ground truth values. This allowed us to estimate a random baseline that still preserved the original distribution.

Table 3. Spearman correlations predicting ground truth labels of self-regulated learning operations

Features	Searching	Monitoring	Assembling	Translating
Chance Baseline	0.01	0	0.01	0
Individual Feature Sets				
Student Surveys (Surveys)	0.28	0.29	0.28	0.08
Student Interviews (Int)	0.31	0.37	0.35	0.09
Student Actions (Act)	0.27	0.47	0.59	0.11
Combined Feature Sets				
Int + Surveys	0.35	0.42	0.62	0.13
Act + Surveys	0.29	0.47	0.63	0.12
Act + Int	0.34	0.51	0.64	0.1
Act + Int + Surveys	0.39	0.55	0.66	0.19

We note that all models outperformed baseline, and that models consistently performed worst at predicting Translating. This may be due to the low variance between students as noted above. We note that the best model performance was achieved by combining the three feature sets (Actions + Interviews + Surveys). This suggests that even though these operations are derived from student log data, additional context from interviews and surveys can improve SRL predictions.

4.1.1 Feature Interaction Analysis

Our most successful models were tree-based, meaning that they may contain nonlinear relationships that would be unsuitable for linear feature analysis. Therefore, we trained one decision tree regressor per outcome and examined each tree's top two levels to observe the most important interactions, each of which was classified as "High" or "Low."

As Table 4 shows, Self-Confidence and Self-Efficacy frequently occur in these interactions, implying students' self-regulation

Table 4. Top 8 interactions for predicting SMART facets

Feature 1			Feature 2			Predicted Value	
Low	Self-Confidence	+	Low	Successful Quizzes	=	High	Searching
High	Self-Confidence	+	Low	Off Task Time	=	Low	Searching
Low	Off Task Time	+	Low	Self-Efficacy	=	High	Monitoring
High	Off Task Time	+	High	Self-Efficacy	=	High	Monitoring
Low	Action Count	+	Low	Self-Efficacy	=	High	Assembling
High	Action Count	+	Low	Ineffective Links	=	Low	Assembling
Low	Procedural Strategy	+	Low	Self Confidence	=	Low	Translating
High	Procedural Strategy	+	Low	Motivational Strategy	=	High	Translating

hinged on their perception of themselves. For example, students with high Self-Confidence who spent less time off task were still likely to have lower searching values, ostensibly because they may not feel the need to consult external resources.

4.2 Predicting Student Learning

Next, we explored how the four SMART facets predicted student learning (operationalized as post-test – pre-test) in both the *current* scenario (from which all the data used in the models was collected) and then the *future* scenario (collected in a second round of data collection with the same students; see section 2). In this future scenario, the content was different (climate change vs. thermoregulation), but the software remained the same.

We consider three feature sets: 1) the three feature sets used in section 4.1 combined; 2) the ground truth values for the SMART encodings (dependent variables in section 4.1); 3) predicted values for each of the SMART operations generated using the best models from section 4.1.

For both learning outcomes, we tested both the Ground Truth values collected from the first scenario (i.e., the actual searching or monitoring behaviors from that scenario) and Predicted SMART values (as predicted by the Act + Int + Survey models from the current scenario). This allowed us to examine how data collected in the current scenario generalizes to a future learning session.

As Table 5 shows, each learning model outperformed chance, demonstrating both predictive validity and generalizability. These results also present two findings of note. Firstly, learning models constructed from Predicted SMART values outperformed those constructed from the Ground Truth SMART values for both scenarios. It is possible that our models in fact, smooth over some of the noise that is present in the ground truth, thus presenting a more robust measure than the raw encodings [6].

Second, we note that for the future scenario, the predicted SMART values outperform model constructed directly from the Act + Int + Survey variables, despite this being the values from which the SMART predictions are made. The SMART values may provide a latent encoding of this data, which is more generalizable than the raw values to future occurrences, however further study would be required to confirm this hypothesis.

Table 5. Spearman rho for models predicting learning gains. All features are derived from the current scenario

Features	Current Scenario	Future Scenario
Chance Baseline	.01	.01
Act + Int + Survey	.45	.37
Ground Truth SMART	.21	.29
Predicted SMART	.32	.43

4.2.1 Feature Interaction

Using the same feature analysis methods described in section 4.1.1 we again examined the interactions involved when predicting learning gains. These results are shown in Table 6.

We note the need for the balance between SMART operations. For example, *high* monitoring and low translating resulted in lower learning on the current scenario, but so did high searching with *low* monitoring, suggesting it would be insufficient to simply increase monitoring activities; we must encourage more effective combinations of operations. Similarly, these results imply the need for a careful structure approach to assembling.

The results shown for the future scenario focus on more transferrable features than results for the current scenario. This makes sense given that we are no longer considering the immediate context. We found that students who had low off task time and high persistence in the first scenario were more likely to perform well in the second. Students with lower monitoring but high translating were likely to have lower learning, indicating it is not enough to simply test your knowledge, it is also important to review feedback and compare work to standards.

5. DISCUSSION

Adaptive learning technology that responds to students' learning patterns can improve both immediate and long-term goals by supporting the internalization of appropriate self-regulated learning behaviors. In this paper, we infer SRL using a combination of data mining and interviews/surveys.

5.1 Main Findings

Automated detection of SRL behaviors poses several challenges, as many of the processes it entails are highly internal [42]. In this work, we demonstrate that a combination of activity data, data from surveys, and student interviews provides a more robust prediction of SRL than any individual data stream. We find that predicted SRL behaviors (from students' first system interactions) predict future performance. In fact, models based on our inferred SRL measures outperform models constructed from the original features used to train them (action, interview, and survey data) and the SMART ground truth values. This finding is important for environments where detailed trace analysis may not be possible, but coarser-grained activity can be distilled.

Further, we show that a balanced combination of SRL behaviors is required for successful learning. For example, students with low learning are likely not spending enough time monitoring, but simply requiring them to check their work more often may not create improvement if they have not yet fully assembled the knowledge necessary to effectively examine their previous efforts. Future work should design scaffolds to create this balance.

Table 6. Top interactions for predicting learning. * indicates a predicted value

Scenario	Feature 1			Feature 2			Predicted Value	
Current Scenario	High	Monitoring*	+	Low	Translating*	=	Low	Learning
	High	Searching	+	Low	Monitoring	=	Low	Learning
	High	Successful Quizzes	+	High	Self-Efficacy	=	High	Learning
	Low	Successful Quizzes	+	High	Ineffective Links	=	Low	Learning
Future Scenario	High	Monitoring*	+	Low	Assembling*	=	High	Learning
	Low	Monitoring*	+	Low	Assembling*	=	Low	Learning
	Low	Off Task Time	+	High	Positive Persistence	=	High	Learning
	Low	Monitoring	+	High	Translating	=	Low	Learning

These results demonstrate the importance of considering log data in the context of other measures when understanding student SRL. This, in turn, underscores the need for more automated measures of complex noncognitive measures such as self-efficacy and persistence. Our work shows that these codes collected from interview data boost SRL detection. In order to scale SRL detection, we must first consider how we might automate the detection of some of the constructs discussed here (see future work below). These results offer the potential for designing pre-emptive interventions, providing a more informed, asset-based intervention as opposed to responding to a negative event.

5.2 Applications

The key application of this work is to develop adaptive online learning environments that respond to student SRL. As SRL detection continues to improve, systems like Betty's Brain might choose from wide range of intervention strategies that have already been shown to improve SRL (e.g., discussion in section 1). For example, once students who are not employing optimal strategies have been identified, additional scaffolding tasks might be used to encourage new behaviors. Similarly, the software could deliver interventions to increase motivation or interest.

It is important to note that the proposed intervention strategies rely on SRL detection, which is likely always to be imperfect. Self-regulation is highly internal [32], and as such, it is unlikely that we will ever be able to infer SRL perfectly. Any interventions should be designed to be "fail-soft" in that there are no damaging effects to student learning or future SRL if delivered incorrectly.

In situations where computer-based learning is being used to augment classroom instruction, a further application of this work would be in providing feedback to teachers. Such feedback could help them dynamically adapt their instruction, as outlined in [18] for example, providing real-time feedback or an early warning system, etc.

5.3 Limitations and Future Work

This work has limitations that should be addressed going forwards. Firstly, the SMART features only characterize student operations, and they do not give a complete SRL picture. Future work should look to combine the SMART framework with the broader COPES model [43]. The interview and survey measures used in this work may also capture aspects of the cognitive and task conditions referred to in the COPES model, but additional study would be required to confirm this hypothesis.

A further limitation is the slightly cyclic nature of using student activity features derived from log data, to predict SRL, also derived from log data. While we made every effort to ensure that our models were not confounded in some way, future work should consider an external measure of SRL for additional validation [44].

Finally, interview data is time-consuming to collect, limiting scalability. In the future, we will employ alternate measures for some of the interview codes measured in this work, such as student surveys. It is possible that voice recognition and natural language processing could be used in the future to support this type of data collection.

5.4 Conclusions

This paper investigates predicting student SRL behavior in a computer-based learning environment from a complex dataset of coarse-grained activity data, in-situ student interviews, and student surveys. Our analyses indicated that SRL was best predicted from a combination of the three feature sets. We found our predicted SRL operations were better at predicting future learning than their ground truth equivalents, suggesting the potential for a smoother latent encoding and better supporting students in future endeavors. We envision this paper contributing to future technologies that will track and respond to student SRL behaviors and create more positive learning experiences.

ABSTRACT

This study examines data from a field experiment investigating the effects of a personalized recommendation algorithm that proposes to students which videosto watch next, after they complete mini-assessments for algebra that available on the Math Nation intelligent virtual learning environment (IVLE). The end users of Math Nation are students enrolled in an Algebra 1 course in middle and high schools of the state of Florida, and the IVLE is used both during and out of school time. The objective of the developed recommendation algorithm is to increase student preparation to take the state-mandated End-of-Course (EoC) Algebra 1 assessment at the end of the school year. The algorithm is based on a Markov Decision Process framework that uses as input the students' responses to a series of mini-assessment tests. The current study randomly assigned 16,406 students to either treatment or control conditions, which were blind to both students and teachers. The results indicate that the effects of the recommendation algorithm depend on the level of usage of students, showing significant improvements on EoC test scores of students who have a moderate level of usage. However, there was no effect for low usage students. The study also shows that students practicing with the mini-assessments available on Math Nation, helps them improve by a small margin their performance on the End-of-Course test, irrespective of the usage level. Finally, the study provides insights on challenges posed for implementing personalized recommendation algorithms at a large scale, related both to student self-regulation and teacher orchestration of technology use in the classroom.

1. INTRODUCTION

There is a growing trend in employing intelligent virtual learning environments (IVLE) to aid students in improving their math performance in K-12 education [8, 26, 23]. While there is a robust body of literature that shows that students' preparedness together with various demographic and school characteristics are key factors for predicting students' performance in various math tests [15], IVLE have been viewed as an especially promising way of improving students' achievements in mathematics. Given the investment of resources into technology products and the time and effort needed to integrate them into the curriculum, there has been considerable interest in determining their effectiveness. A number of studies have reported positive effects based both on small scale randomized control trials and longer term interventions [14, 13, 19, 16, 15], as well as based on observational data [12]. There have also been a series of meta-analysis studies showing that IVLE have substantial effects on student outcomes [10, 11, 24, 27].

IVLE have the potential of offering personalized learning experiences. The latter refer to instruction "in which the pace of learning the instructional approach are optimized for the needs of each learner", according to the United States National Education Technology Plan 2017. IVLE that offer some degree of personalization include Khan Academy at the K-12 level and Newton at the higher education level. As discussed in [3], at the core of personalized learning strategies is a recommendation algorithm aiming to propose appropriate learning materials and topics to the student at the right time, leveraging the student's prior history of interactions with the IVLE.

Many personalized learning strategies leverage ideas and tools from the field of Reinforcement Learning [4, 5, 9, 20]. The key components of a reinforcement learning based algorithm are the triplet of *state, reward, action*. The state reflects information on the student's knowledge and skills set on the topic(s) under consideration, the reward relates to the goals of the strategy (e.g. performance on tests, engagement with the IVLE, etc.) and the action refers to an activity, (e.g. watch a video on a topic of interest, take an assessment test, etc.) that, based on the current state information, aims to maximize the expected reward.

This study reports the results of a large-scale randomized field experiment that focuses on the impact of a simple personalized strategy implemented on the Math Nation IVLE, on a high-stakes, state-mandated End-of-Course (EoC) algebra test. Although many evaluations of IVLE have been published, most of them rely on locally developed standardized tests, rather than high-stakes statewide tests [10]. Math Nation, is an online video-based tutoring program aiming to prepare students in the state of Florida for the EoC, which is required for high school graduation. The platform offers videos on various algebra topics recorded by different tutors, explaining the main concepts and walking the student through related examples, 3-question assessments for each topic and 10-question assessments for sets of related topics, with video explanations for each question. Therefore, students can assess their progress by taking both the short (3-question) and the long (10-question) tests. Further, the platform offers a monitored discussion area, wherein students can pose questions to peers and volunteer tutors. Hence, at launch time, it shared a number of characteristics with Khan Academy, both being self-guided and easy to use on an ad hoc basis, without the need for extensive professional development training for teachers. The content of the videos and assessments are aligned with the curriculum adopted by the state and also the content and format of the EoC test.

A new feature of Math Nation is the introduction of an algorithm to recommend videos to students, leveraging information on their performance on the mini-assessments associated with each video. Specifically, Math Nation divides the whole Algebra 1 course materials into 10 sections. Each section is further divided into several topics, thus resulting in a total of 93 topics for the entire course. For each topic, there is a tutorial video associated with it, recorded by different tutors. At the end of the video the student is presented with a 3-question assessment (henceforth called a mini-assessment) and based on the score obtained, a video recommendation (the action) is offered aiming to maximize the student's expected score (the reward) on these mini-assessments. The student can follow the recommendation or decide to ignore it and select another video of her/his own choice by the same or another tutor. To compare the effectiveness of the recommendation algorithm, a "business-as-usual" competitor is implemented, which recommends the next video in a predetermined sequence related to the structure of the algebra state curriculum, irrespective of the score achieved in the mini-assessment.

The objectives of the study are twofold: (i) estimate the average treatment effect of the recommendation algorithm vis-a-vis its competitor together with its interactions with previous achievement and level of usage of the algorithm, and (ii) understand the relationship between performance in the mini-assessments and the EoC test, after accounting for math preparedness and school characteristics of the students that participated in this randomized control study.

The remainder of the paper is structured as follows. Section 2 presents the developed personalized recommendation strategy. Section 3 describes in detail the data recorded from the algorithm, as well as other covariates used in the analysis. Section 4 presents the statistical methods used in the analysis and the main results of the study. Finally, Section 5 discusses the implications of our findings and suggestions to modify the recommendation algorithm.

2. PERSONALIZED RECOMMENDATION STRATEGY

Next, we describe the data-driven algorithm for recommending a suitable tutoring video to each individual student. As previously mentioned, the content of the course is divided into 93 topics, with each topic accompanied by a video recorded by 5 tutors in English and 1 tutor in Spanish. Students can freely select the tutor for each video.

To rigorously set the stage for the video recommendation algorithm, fix a single student, and let $s_k(t)$ be the corresponding "mini-score" for topic $k \in \{1, 2, \cdots, 93\}$, at time $t = 0, 1, \cdots$. These mini-scores, representing the knowledge level of the student, are obtained by assessing responses to the mini-assessments comprising of 4-choice questions, with a single correct choice. Thus, the set of possible outcomes consists of i correct answer(s), together with $3-i$ wrong answer(s), for $i = 0, 1, 2, 3$. Then, we center and normalize the corresponding scores (henceforth referred to as mini-scores), so that on average, simply guessing the answers lead to a zero score. Thus, we have $s_k(t) \in \{-3, 1, 5, 9\}$, and if the answers are selected completely at random, $\mathbb{E}[s_k(t)] = 0$.

With the above setting, the full state of the student at time t is given by $S(t) = [s_1(t), \cdots, s_{93}(t)]' \in \{-3, 1, 5, 9\}^{93}$, while $\|S(t)\| = \sum_{k=1}^{93} s_k(t)$ reflects the (total) score of the student under consideration at time t. The dynamical model for topic k consists of a Markov chain for which the state is $s_k(t)$. For the time being, suppose that the parameters of the Markov chain consisting of 4×4 tables of transition probabilities among the states $\{-3, 1, 5, 9\}$ are available. We will shortly discuss a statistical method leveraging transfer learning techniques, for estimating the Markov transition kernels according to the observed data.

The recommendation strategy is to propose to the student the tutoring video corresponding to the topic with the *largest predicted growth* in the mini-score. Formally, at time t, the IVLE recommends the student to watch the tutoring video of topic $k^\star$, wherein

$$k^\star = \arg\max_k \mathbb{E}\left[s_k(t+1) - s_k(t) \,\middle|\, S(t)\right],$$

where the notation " | " is used to indicate a conditional probability distribution. The student can either accept the recommendation, watch the video and take the mini-assessment, or can ignore the recommendation and select another video

to watch (by possibly another tutor).

Note that in order to compute the above expected values, for every topic $i \in \{1, \cdots, 93\}$ it suffices to have only the 4 probabilities corresponding to the transition of the Markov chain from the current state $s_i(t)$ to the next one $s_i(t+1)$. Intuitively, the difference quantity $s_k(t+1) - s_k(t)$ reflects the predicted growth of the student in topic k. Therefore, the high level idea of the recommendation strategy is to propose to the student to work on the topic (s)he is capable of improving her/his knowledge level the most. Therefore, the recommendation aligns with Vygotsky's theory [28] of zone of proximal development by providing a video that is neither too easy, nor too challenging. Further, the recommended topic is totally personalized to the student, since the state $S(t)$ at time t is unique to each student.

Finally, we describe the statistical learning procedure for estimating the Markov transition probabilities. For this purpose, the students are clustered in 12 different groups, based on their demographic and other background data, so that students of similar learning abilities will be assigned to the same group (cluster). The details of the clustering procedure are provided in Section 3. We assume that students in each group share the Markov transition probabilities reflecting their cognitive responses to watching the tutoring video of a specific topic. Thus, in order to estimate the transition probabilities for students in a fixed group, we divide the total number of transitions between every pair of the possible states $\{-3, 1, 5, 9\}$ in the group, with the total number of transitions in the group. We emphasize the following points. First, while the Markov transition probabilities are the same for all students in one demographic/background group, the states are uniquely personalized to each student. Second, the estimates of the transition probabilities change over time as the platform collects more data from the responses of the students to the mini-assessments. Further, when Math Nation starts being used by the students, the initial estimates of the transition probabilities are selected randomly, and are updated throughout the academic year as the students continue to use it. Finally, if there is more than one $k^\star$ maximizing the predicted growth, one will be selected at random.

Before the algorithm was deployed within Math Nation platform, it was extensively tested on synthetic data generated based on data collected in previous years from the platform. Specifically, students that have used the platform in previous years were clustered in 12 groups (see also Section 3) based on their demographic and background information. Note that the distributions of such data are very similar to those in the academic year that the recommendation algorithm was launched and evaluated in the current study. Subsequently, the response data to the mini-assessment tests of the students within each cluster were used to estimate the corresponding Markov transition probabilities. The latter were then used to initialize the recommendation algorithm and to generate synthetic data for students in different clusters. The upshot of this analysis was that the algorithm required adequate engagement ($t \geq 45$) to show significant improvement in performance in the mini-assessments. We revisit this point in the Discussion section.

Table 1: Distribution of the students across different Math Achievement Levels, School Grades and Student Grades

Achievement Level	No. of Students	School Grades	No. of Students	Student Grades	No. of Students
1	473	A	4,377	5	3
2	1,453	B	2,001	6	1463
3	3,487	C	4580	7	3599
4	2,711			8	5893
5	2,834				
Total	10,958	Total	10,958	Total	10,958

Note: Data based on previous school year performance

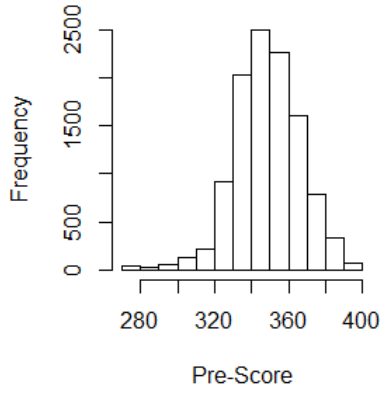

Figure 1: Distribution of Pre-Score

3. DATA DESCRIPTION

In this study, we randomly assign a sample of 16,406 middle and high school students enrolled in Algebra 1 in a large school district in the state of Florida, to a treatment (proposed recommendation strategy) or a control (business as usual recommendation strategy) group. The assignment was blind to students and teachers. The treatment group received video recommendations as described in the previous section, while the control group received a recommendation to watch the next video in the curriculum sequence. To initialize the recommendation, a randomized cluster design was employed. Specifically, students were first matched according to their grade, school characteristics and math preparedness test scores from the previous school year and then randomly assigned to the two groups. The variables used for matching purposes were the scores on the state standardized mathematics test, called the Mathematics Florida Standards Assessment[1](henceforth, referred to as Pre-Score and the corresponding test referred to as Pre-Test), as well as an achievement level assigned to them by their schools, while the quality of each school is reflected by a grade assigned to it by the state Department of Education[2]. The latter grades are based on several components and have five different levels ('A' being the highest level and 'F' being the lowest one). Due to lack of data for many of these variables, 5,448 students were removed from any further analysis and hence Table 1 that shows the distributions of the students across different Achievement Levels, School Grades and Student Grades and Figure 1 that depicts the distribution of the Pre-Score are based on the remaining 10,958 students.

[2]http://www.fldoe.org/accountability/accountability-reporting/school-grades/

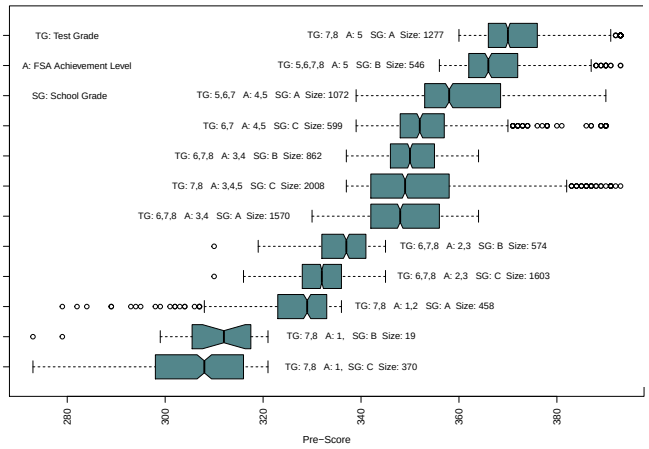

Figure 2: Boxplots of clusters hierarchically ordered based on Pre-score: For each cluster, School Grade, Achievement Level and Student Grade and Cluster Size are reported.

Using the above information, students were assigned to clusters/groups. This cluster assignment is used as a categorical variable in the analysis presented in Section 4. The clusters are designed in such a way that each of them corresponds to a group with a unique combination of math preparedness and school grade. In summary, the following four variables were considered by the clustering algorithm: Pre-Score, Math Achievement Level, School Grade and Student Grade. An agglomerative hierarchical clustering algorithm was employed for this task and using the dendrogram with Gower's distance metric, along with silhouette values [7], the number of clusters was chosen to be 12. Figure 2 provides a pictorial representation of the key features of the clusters. Specifically, for each cluster the Figure depicts the boxplot of the Pre-Score and also the corresponding Student Grade, Math Achievement Level, School Grade and Size of the cluster. For ease of comparison, the clusters are ordered according to the distribution of the Pre-Score. Hence, cluster 1 corresponds to the group of students having the lowest Pre-Score, while cluster 12 is the group with the highest Pre-Score. As Figure 2 shows, the size of cluster 2 was very small and hence it was merged with cluster 1 for the subsequent analyses.

The number of times a particular student takes the mini-assessment after watching a video, is defined as the usage by that student. Figure 3 depicts the average usage per student for each of the clusters for both the control and treatment groups. It can readily be seen that the overall average across the study population is 2.88, with many clusters exhibiting significantly lower usage. There are also a few clusters exhibiting high usage; e.g. cluster 5 for the control group and cluster 9 for the treatment group.

4. METHODS AND RESULTS

The analyses described below, aim to provide answers to the two objectives outlined in Section 1. In our first analysis, we estimate the average treatment effect of the recommendation algorithm on EoC scores, using a simple linear regression model, with the following two categorical variables and the interaction between them; (i) the first categorical variable TC, comprises of two levels: the first represents the Treatment group that watched the personalized recommended videos and took the corresponding mini-assessments, and the second level corresponds to the Control group; (ii) the second categorical variable Previous Achievement Level, comprises of five categories, each corresponding to a different level of achievement in the Pre-test. Level 1 stands for the lowest achievement, whereas the highest level is coded by level 5. Then, the linear regression model with the above two predictors and their interaction is given by:

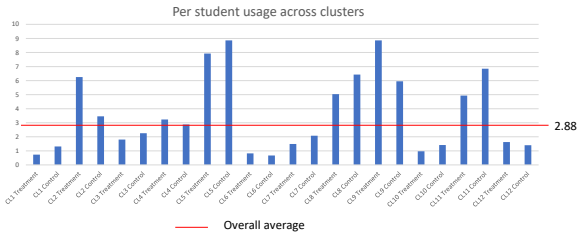

Figure 3: Average usage per student for different clusters, for both treatment and control groups

$$y = \mu + \beta_1\ TC + \beta_2\ Achievement + \beta_3\ (TC \times Achievement) + \epsilon \quad (1)$$

where y represents the EoC score and we further assume that $\epsilon \sim N(0, \sigma^2)$. Based on this model, the estimate of the average treatment effect of the personalized recommendation on EoC score, is the coefficient β_1 corresponding to the variable TC. Further, estimates of standard errors of the regression coefficients are based on cluster-robust estimators [2]. To answer the first research question discussed in Section 1, we test $H_0^{TC} : \beta_1 = 0$ vs. $H_1^{TC} : \beta_1 \neq 0$. The coefficient β_1 is the difference between the mean EoC score of the Treatment and the Control group, after accounting for the effect of all the other covariates. The estimated coefficients (scaled) and corresponding p-values are reported in Table 2. Table 2 shows that the achievement levels are statistically significant, while the treatment effect (i.e., the impact of the developed recommendation algorithm) is not. Further, there is a small positive significant effect for the interaction of the treatment with Achievement level 2. However, as shown in Figure 3, usage patterns vary widely across different groups (clusters) of students.

To that end, and in order to gain a deeper understanding of how the average treatment effect behaves across different IVLE usage levels, we fit model (1) separately on groups of students exhibiting different usage levels. After some initial exploratory analysis, we divided the students in approximately evenly distributed usage groups as shown in Table 3. The results are summarized in Table 3, whose first column specifies the usage levels of the group. As an example, students who have taken at least 10 mini-assessments tests, are categorized as a group with usage level 10 or higher.

Table 2: Estimated coefficients and corresponding p-values for Model (1)

Variable	Scaled Coefficient	p-value
Intercept	348.45	<0.001
Treatment	-0.99	0.32
Achievement level 2	11.28	<0.001
Achievement level 3	23.14	<0.001
Achievement level 4	35.31	<0.001
Achievement level 5	50.02	<0.001
TC*Achievement level 2	1.94	0.05
TC*Achievement level 3	0.94	0.34
TC*Achievement level 4	1.25	0.21
TC*Achievement level 5	1.09	0.27

Note: The scaled coefficients are obtained by dividing the estimated coefficients by their standard error.

The second and third columns contains= the p-values corresponding to the test $\beta_1 = 0$ and the scaled version of the estimated coefficients, respectively. As it is evident from Table 3, the first few rows that correspond to lower usage groups, have high p-values and thus the average treatment effect is not statistically significant. The treatment effect becomes significant for students who used the platform more extensively (≥ 48).

The model also controls for the level of achievement of students. Table 4 presents the results for the β_2 regression coefficient for different usage levels. The corresponding p-values are given in parentheses. It can be seen that the effect is statistically significant (marked in bold font) across almost all Previous Achievement levels and usage levels, as expected based on the overall results presented in Table 2. Further, this result is in accordance with a large body of literature that has found a positive association between level of math preparation and test scores (see, e.g.,[16, 15] and references therein). Further, the magnitude of the coefficient is larger for higher achievement levels.

Model (1) also estimates the interaction effect between the treatment and the Previous Achievement level. Table 5 summarizes the scaled estimates of the interaction effects and the p-values (given in parentheses). Since the Previous Achievement level has 5 categories, we obtain the estimates for all the levels except the baseline category, i.e., Previous Achievement level 1, which is absorbed in the intercept of the model. As usage increases, Table 5 displays more significant interaction effects (in bold font) between treatment and achievement level as compared to low usage groups. Note that due to lack of data in selected categories, some of the interaction effects could not be estimated and hence left blank.

Note that most of the interaction effects are not statistically significant. There are selected ones with a positive coefficient, corresponding to higher achievement levels (3 and above) for high usage groups (e.g., 33 and 65). Analogously, there are selected interaction effects with a negative coefficient corresponding to the lower achievement level 2, and relative high usage level.

To answer the second research question on the relationship between the performance of the students in mini-assessments and in the EoC test, we obtain the *Average Mini-Assessments*

Table 3: Usage-wise effect of the recommendation: p-values and scaled coefficients for different usage levels

Usage Level	p-value	Scaled Coefficient	Sample size
9	0.64	0.46	1097
13	0.40	0.85	932
27	0.29	1.07	515
33	0.17	1.39	411
48	0.02	2.41	254
52	0.01	2.56	230
55	0.05	1.93	207
59	0.06	1.91	183
65	0.02	2.31	140
74	0.08	1.78	92

Table 4: Usage-wise effect of the Previous Achievement level: p-values and scaled coefficients for different usage levels

Usage Level	Level 2	Level 3	Level 4	Level 5
9	4.65 (**<0.001**)	7.41 (**<0.001**)	10.67 (**<0.001**)	15.76 (**<0.001**)
13	4.94 (**<0.001**)	7.51 (**<0.001**)	- 10.74 (**<0.001**)	15.37 (**<0.001**)
27	1.87 (0.06)	2.64 (**0.008**)	4.61 (**<0.001**)	6.76 (**<0.001**)
33	2.45 (**0.01**)	3.02 (**0.002**)	4.72 (**<0.001**)	6.19 (**<0.001**)

48	-2.82 (**0.005**)	-1.21 (0.22)	-2.05 (**0.04**)	-
52	-2.85 (**0.004**)	-1.47 (0.14)	-2.13 (**0.03**)	-
55	-2.49 (**0.01**)	-1.18 (0.24)	-1.73 (0.08)	-
59	-2.40 (**0.02**)	-0.71 (0.48)	-1.68 (0.09)	-
65	-	2.56 (**0.01**)	2.01 (**0.04**)	2.85 (**0.005**)
74	-	-0.98 (0.32)	-1.28 (0.20)	-

Score for each of the $\sim$ 11,000 registered students, wherein the average is computed over the mini-scores for all the mini-assessments the student has completed.

Then, the following Analysis of Covariance model is fitted to the data. To control for the students math preparedness and school characteristics, we include the cluster information as a factor in the model.

$$y_{ij} = \mu + \alpha_i + \beta x_{ij} + \varepsilon_{ij}, \quad (2)$$

wherein y_{ij} is the EoC score and x_{ij} is the Average Mini-Assessments Score for the j^{th} student in the i^{th} cluster. Further, μ is the overall mean effect and α_i is the additional effect due to the assignment of the student to the $i-$th cluster that accounts for prior math knowledge, grade and school characteristics of the students.

Table 6 depicts the estimated regression coefficients, their standard errors, together with the value of the test statistic and the p-value corresponding to the significance test for each of the coefficients. All p-values are significantly smaller than the nominal 0.05 (or 0.01) level, thus indicating that the corresponding predictor has a significant effect on the EoC test score. The estimated coefficient for the mini-assessment is 1.15. This small, but statistically significant coefficient indicates that an increase of one point in the average student score on the mini-assessment corresponds to an expected improvement in the EoC score of 1.15 (the corresponding scaled regression coefficient is 7.46) points. At first glance, this relationship between the average mini-score performance and the EoC test seems of limited practical significance. However, when examining the distribution of EoC scores across all students ($\sim 90,000$) that used the Math Nation platform at some point in time (not necessarily participants in the current study), we find that about 1.9% are within 1 point of the passing threshold. Hence, in light of this information, it is reasonable to posit that the recommendation algorithm would have been beneficial for a good number of students, if it were adopted and used by all platform participants.

Table 6: Results of the Analysis of Covariance model: Response EoC Score; categorical predictor cluster and numerical predictor Average Mini-Assessments Score

Coefficients	Estimate	Std. Error	t-value	p-value
Intercept	464.29	2.61	178.18	<2e-16

Avg. Mini-Assessments	1.15	0.15	7.46	1.3e-13

5. DISCUSSION

The analysis of the data from the randomized control study provide a number of useful insights in designing recommendation strategies for IVLE. Firstly, the recommendation algorithm holds a lot of promise, but as it is well known in reinforcement learning, it requires adequate amount of usage to "explore" various possibilities in order to maximize expected reward. The adequate usage requirement is also discussed in the literature evaluating recommendation strategies for Massive Online Open Courses; see [6, 17, 18] and references therein. As mentioned in Section 3, an initial evaluation of the proposed algorithm during its development phase based on synthetic data indicated that it starts yielding satisfactory results, in terms of students improving their performance on the mini-assessments, once students follow its recommendations for over 45 times. The results of the analysis in Section 4 are in line with the aforementioned finding. As Table 3 indicates, the recommendation strategy shows significant impact starting from a usage level of 48. Further, note that in our study the primary outcome under consideration is the EoC test that takes place at the end of the academic year, as opposed to a more direct outcome related to the recommendation algorithm, such as performance over time on the mini-assessment tests. In many studies in the literature (e.g., [1, 22], assessment of a recommendation algorithm was based on more immediate outcomes (e.g., the mini-assessments in our setting), as opposed to a more distal outcome, such as the EoC. Nevertheless, the results of our experiment indicate that with stronger student engagement the developed algorithm could be more widely beneficial.

To address the issue of low usage, a new experiment has been designed, wherein the teachers are directly involved in the implementation of the recommendation system in the classroom, which is expected to yield higher levels of engagement of students with the IVLE platform. This experiment is under way at the time of this publication.

It is also worth mentioning that our first analysis was of "Intent-to-Treat" type, because it evaluated the effect of being randomly assigned to treatment or control groups without consideration of the extent that students used the recommendation strategy. On the contrary, traditional Complier Average Causal Effect analysis [21, 25] is based on "Treatment-on-the-Treated" principle, wherein one estimates the treatment effect for those who complied with the treatment. The latter constitutes a direction of future research.

Another issue of broader interest is that many IVLE recommendation algorithms are designed to assign test problems in an adaptive way, as opposed to assigning videos that Math Nation does. However, in the modified implementation of the algorithm currently under evaluation, the student can skip watching the recommended video and take the mini-assessment directly; in case, (s)he gets less than two of the questions correctly, the algorithm recommends to watch the segment of the video that covers the corresponding material and then retake the mini-assessment. This modification aims to enhance the emphasis of the recommendation algorithm on solving problems, but at the same time enable students to review relevant material to questions that they answered incorrectly.

Student Practice Sessions Modeled as ICAP Activity Silos

Adam M. Gaweda, Collin F. Lynch

agaweda,cflynch@ncsu.edu

ABSTRACT

There are a number of novel exercise types that students can utilize while learning Computer Science, each with its own level of complexity and interaction as outlined by the ICAP Framework [10]. Some are *Interactive*, like solving coding problems; *Constructive*, like explaining code; *Active*, like retyping source code; and *Passive*, like reviewing slides. To date, there has been little research on how students vary their study and engagement habits by exercise type and when they do so. In this paper, we present our findings on student activity sequences from an online professional development course. We isolated student activities into sessions and then produced activity transition visualizations to compare the behavior of students who complete the course to those who do not. We then used multiple factor analyses to examine how students transition from one type of activity to the next. From this analysis we identified *platform silos* in student's work. We further expand this concept to the presence of *activity silos* grouping by type. We find that this siloing behavior is consistent in both completers and non-completers but is weaker for the latter group. Finally, we discuss our findings and how instructors and researchers may use this information to ensure that students show persistence through practice.

Keywords

novel exercises, ICAP framework, study sessions, activity sequences, platform silos, activity silos, student modeling

1. INTRODUCTION

CS Education have introduced a number of novel exercise types to better scaffold students' experiences. These include retyping source code [14], arranging scrambled code fragments (Parsons Puzzles) [21], debugging provided code [8], predicting output [26], fill in the blanks [4], self-explanation [4], and small scale coding exercises [2, 12]. Each of these exercise types can also be mapped onto the ICAP framework [10]. This framework defines four categories of instructional activities based upon students' level of engagement: Interactive, Constructive, Active, and Passive. *Passive learning* includes reading static course materials or watching lecture videos. *Active learning* is described as rehearsing or copying solution steps. *Constructive learning* includes self-explanation of content or creation of novel externalized outputs like summaries. Finally, *Interactive learning* involves directly engaging with a peer, agent, or instructor to explore information and receive feedback which can be expanded upon.

While these exercise types have made their way into classrooms there is little evidence of how these types of engagement interact with one-another. Traditional intervention studies have focused on the overall impact of one or more exercise types [20, 19, 14, 8], or on the automated selection/recommendation of future excercises based upon a student model [27], but not on how students work with or across them in the absence of guidance. Nor has this recommendation work been extended to nontraditional learning contexts. Absent an understanding of how students orchestrate multiple interaction modes we face challenges in scaffolding effective learning opportunities and in evaluating the impact of novel learning environments. Providing students with ineffective, or overly complex learning opportunities risks trapping them in a fail/skip practice cycle that would inhibit any functional learning gains [17].

In this paper we report our investigation of how students direct their practice of CS concepts when presented with a set of options. Our study was conducted in the context of an online professional development course for Python programming. This course is part of a research study funded by the Department of Labor to create novel learning pathways for existing technical professionals to move into AI and Data-Science areas. We extracted students' practice/study sessions and analyzed the activity transitions within each session. We then analyzed these activity sequences to answer the following research questions (RQs):

RQ1 Can we replicate the existence of *platform silos* introduced in [1] with a new dataset?
RQ2 Are there common activity transitions between students?
RQ3 How do activity sequences connect with the ICAP Framework?
RQ4 How do the practice sessions of completers of the course differ from non-completers?

To answer these questions, we first produced and analyzed a set of activity transition diagrams for students in the course comparing those who completed the course to those who did not. Through this analysis, we confirmed the presence of *platform silos* which we extend this notion to include *activity silos*, where students primarily focus on a single mode of engagement (consistent with ICAP) during a given practice session. When students did transition between modes, it was only to move up the ICAP chain and never to 'downgrade' to a lower level of engagement. We support our findings through two different factor analyses, which help explain the 42-62% of variance between the sessions. From

our results, we found ICAP categories isolated into individual sessions, as well as LMS content consumption and quiz taking.

2. BACKGROUND

2.1 ICAP Framework

The ICAP Framework seeks to classify the modes of student engagement while engaging in learning activities [10]. These categories, *Interactive, Constructive, Active* and *Passive* respectivel. *Passive* engagement includes activities such as reading a text or observing a video. *Active* engagement includes rehearsing steps or copying solutions. *Constructive* engagement includes self-explanation or comparing and contrasting materials. Finally, *Interactive* engagement includes responding and interacting with an agent, system, or another person. Tthe framework is hierarchical, suggesting I > C > A > P, or that activities with higher levels of engagement promote the greatest levels of learning.

Chi and Wylie present a literature review of several empirical studies supporting their ICAP hypothesis [10]. The first study consisted of all four modes of engagement in materials science and showed learning improved significantly at a rate of 8-10% per mode. They then present two studies which used active, passive, and constructive modes in evolutionary biology and plate tectonics. Finally, Chi and Wylie present comparisons of two modes across note taking, concept mapping, and self-explanation. In each of these studies, the results again showed that higher modes of engagement had higher learning gains.

Chi and Wylie's work, as well as our own personal communications with Chi [9], note that identifying the mode of a particular activity can be a non-trivial task. For example, a toy example task could be presenting steps toward making a peanut butter and jelly sandwich given randomly shuffled segments of instructions. This task could be constructed as an *active* exercise if the student already knows the recipe and the task is simply picking the appropriate sequence from the list of steps. However, if the student had not learned the appropriate order, then the task of figuring out the right sequence would be construed as a *constructive* exercise. Computer Science has a similar task, known as Parsons Puzzles, that mirrors this toy example, discussed in more detail in the following section.

2.2 Novel Exercise Types

In this section, we describe eight different exercise type studied in Computer Science education, provide some research background on the exercise type, and justifications for which ICAP mode we will classify them as for of our study.

2.2.1 Typing Exercises

Typing Exercises (TE) require students to retype source code that has been presented to them [14]. Typing Exercises can be used as *active* learning activities under the ICAP Framework as they require students to retype verbatim the code presented to them. Previously, we presented images of source code and showed that self-selected students that completed optional typing exercises earned higher course grades and submitted less code with build failures. Leinonen et. al. also presented optional typing exercises to students before programming tasks [19], but were not able to find the same results as ours. However their study only lasted two weeks and many of their selected participants did not attempt the exercises at all.

2.2.2 Fill in the Blank

Fill in the Blank ($FitB$) exercises remove a small portion of code from a snippet and asks students to 'fill in' the blank. Students need to have an understanding of the snippet as a whole to deduce what needs to be included at a particular blank location. Reviewing incomplete worked examples reduces ineffective self-explanations and enhances the transfer of learned materials [4, 5]. Based on the results from Atkinson et. al., we consider FitB-style exercises to require lower levels of engagement than self-explanation, and thus classify them as an *active* ICAP mode.

2.2.3 Parsons Puzzles

Parsons Puzzles (PP) present snippets of code that have been separated into segments and then shuffled in order [21]. Students are then tasked with placing the segments back into the correct order. While Parsons Puzzles are helpful for learning how to structure code, performance on Parsons Puzzles has not been shown to correlate with students' ability to read or trace code [11, 20] and 'distractor' variants are not beneficial to young learners [13, 16]. These findings further support our research goals, as not every exercise type may be beneficial for learning all the technical skills necessary for Computer Science.

Chi and Wylie's definition of constructive modes of engagement include "learners generate or produce additional externalized outputs... beyond what is provided". As mentioned in the previous section, Parsons Puzzles are similar to our toy peanut butter and jelly exercise. While Parsons Puzzles could be construed as *active*, students may not fully comprehend the appropriate order of code syntax and must figure out the right sequence as part of the exercise. In our communications with Chi about Parsons Puzzles, Chi states that determining the particular ICAP mode for an activity can be non-trivial [9]. 'If a student already [knows] the recipe, then re-ordering it is just picking out the sequencing, guided by the sequence information [they] already know' then it is *active*. However, 'if the student [has] not learned the order from some other source, and you are asking her to figure out the right sequence', it is a *constructive* exercise. Since novices may not have proficiency at the time of the exercise, we elect to use the upper bound ICAP mode and consider Parsons Puzzles as a *constructive* learning activity.

2.2.4 Output Prediction

Output Prediction (OP), also known as variable tracing, exercises ask students to analyze code and then state the expected outputs of code execution or the expected value of a variable as the code progresses. Often, variable tracing is done during conditional and loop instruction to demonstrate how the values of the variables change after each iteration. Like Parsons Puzzles, OP-style exercises require students to process code snippets and externalize their expected outputs. Thus, we consider output prediction as another *constructive* learning activity.

2.2.5 Self-Explanation

Self-explanation (SE) exercises present students with source code and ask the student to explain how the code operates, describe the overall efficiency of the code, or create a documentation string to appear as a comment for the program or function. These are open-ended exercises that are subjective in nature and are considered to be *constructive* [10]. However, Chi and Wylie do note that students' may treat the self-explanation activity as *active* if "the student's self-explanation is verbatim to what was read". However, novices may struggle with reading and evaluating programming code in a linear fashion, focusing more on what each line of code did, rather than how each line interacted with each other, or in general produce poor explanations [25, 5]. While *constructive* SE activities may produce higher learning gains than lower-level modes, they may also not be the most appropriate activity for students who are struggling, Thus, similar to our

decisions for Parsons Puzzles, we use the upper bound to classify self-explanation as a *constructive* learning activity.

2.2.6 Find and Fix the Bug

Resolving errors, or debugging, is one of the first hurdles students encounter when learning to program [3]. Once they find that an error has occurred, it will be necessary for them to resolve it before addressing any remaining subgoals for their solution. For the purposes of our study, we separated debugging into two separate activities - Find the Bug (FnB) and Fix the Bug (FxB). Find the Bug exercises present students with code that contains a common misconception for novices. Instead of resolving the error, students are asked to highlight the area of code where this error exists. Though the ICAP framework considers highlighting text as an *active* learning activity, Chi and Wylie define *constructive* behaviors as requiring some level of "inference", or adding in additional detail or qualification. Since students must assess if a line of code is 'correct' or not, they are producing qualifications and therefore, we elect to label FnB exercises as *constructive*.

Fix the Bug exercises follow the natural progression of debugging tasks by requiring students to resolve broken code[8]. FxB activities could be considered *constructive* or *interactive* depending on the context. Similar to FnB exercises, Chi and Wylie include 'repairing' as a *constructive* behavior. However, FxB-style exercises can also be *interactive* because students often rely on the code interpreter's feedback during the debugging process. Fixing one error may produce new errors with new feedback, or the repair made by the student could be incorrect. Thus, we again choose use the upper bound to label FxB exercises as *interactive*.

2.2.7 Coding Exercises

The final exercise type we used in our study is the de facto standard of introductory CS courses - the Coding Exercise (CE). While Computer Science is more than programming, coding exercises are often used by instructors as graded course material for students to demonstrate their understanding of the current course topic. There has been work on the use of 'many-small programs' and 'simple syntax exercises', which simply require students to complete small-scale coding exercises to become familiar with the a particular implementation before utilizing it as part of larger-scale problems [2, 12]. In both cases, completing these smaller-scale programming exercises improved student performance and yielded happier students. Students often rely on feedback from the interpreter as they construct their solutions and more than likely need to debug their own work during this process. Thus, we consider Coding Exercises as an *interactive* learning activity.

2.3 Student Modeling and Activity Mining

Seshadri et. al. analyzed how student study sessions operated across multiple platforms for three separate courses [1]. Their results found that given multiple education platforms, students will often operate within *platform silos*, or only utilize one educational platform during an individual study session. Of the student sessions, more than 90% of them included only one platform. In a follow-up study, they compared the activities of higher performing students to the lower performing group and showed that both groups were most likely to stick within platform silos [15]. Their work serves as the motivation for our RQ1. Our hypothesis is that the presence of these 'platform silos' will continue to hold across other educational platforms not studied in their research.

3. STUDY

3.1 Design

We studied problem solving in the context of an online professional development course in Python programming. This is a preparatory course for a series in AI that is aimed at non-traditional students making a career transition. The course used the Moodle Learning Management System and TYPOS, a CS exercise platform [14], and is organized into 10 modules Each module includes a set of static reading material, lecture slides, prerecorded videos, optional practice exercises, and a module assessment. There were 24 optional exercises per module, 3 exercises for each of the 8 types previously described. Students were free to work on the practice exercises or assessments as much as they liked. The only requirement for progressing to the next module was to earn a passing grade (80% or higher) on the prior module's assessment. In order to complete the course, students needed to earn passing grades on all assessments.

We had 69 students consent to the study. Of those students, 37 successfully completed the course. Student interactions on both platforms were logged. We omitted some Moodle interactions such as like "file downloading" and "viewing the course" which did not pertain to the explicit learning actions we were foucused on.

The resulting dataset contained a total of 29,190 interactions from all the students. We then used a similar strategy as [1] to extract user sessions from these interactions based upon an exploratory analysis of the gaps between interactions. The time deltas between course interactions were measured. If a delta between interactions exceeded a predefined cutoff threshold, that session was considered over, and a new session was created. This was repeated for all interactions a student had for the course. While Seshadri et. al. used a 40 minute cutoff to establish the end and start of a new session, we chose a 60 minutes as it was our most frequently observed delta between interactions. We extracted 1,313 sessions in total. Students that completed the course accounted for 71%, or 20,748, of the course interactions, with 1,041 sessions total, at an average of 28.1 ($\pm$17.9) sessions per completer.

3.2 Activity Session Transition Probabilities

The route that students take through online materials can be modeled as discrete Markov processes, in which each state represents an activity within the session. For example, a student may transition from reviewing lecture slides to viewing lecture videos on Moodle, or $MS \rightarrow MV$. Jeffries et. al. [17] used a similar process to analyze success and help seeking behaviors with students in an introductory CS course.

Figure 1 visualizes the transition probabilities for completers: transitions within TYPOS appear as dashed blue lines, transitions within Moodle are solid red lines, and transitions between TYPOS and Moodle are solid black lines. For visibility, only transitions involving the start/end of a session or those with a frequency above 5% are presented. Module assessment (MA) accounted for 39% of starting session behavior, TYPOS practice accounted for 36%, and lecture slides and videos (Content Consumption) accounted for 26%. This figure shows students' practice was largely siloed by platform with each session taking place within a single mode of interaction. With the exception of the $MS \rightarrow TE$ transition, students either interacted with TYPOS or Moodle, but rarely together. Since MA showed the highest starting session probability, one assumption is that students enrolled in the course with prior coding experience may have reviewed the course material to become familiar with Python syntax before going on to complete the module assessment.

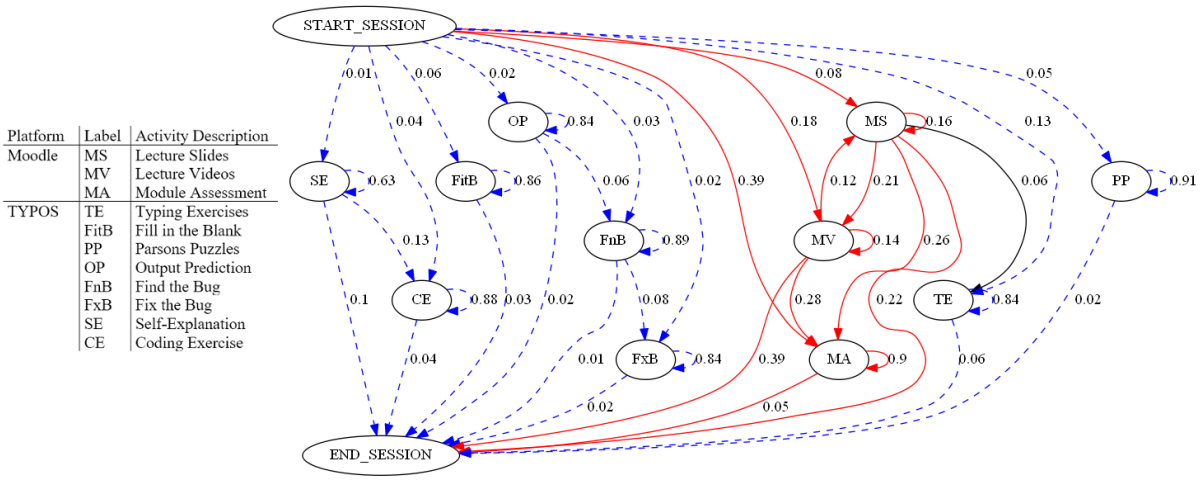

Figure 1: Completer activity transition probabilities during sessions.

One interesting observation from Figure 1 is that TYPOS practice sessions involved only one or a small subset of the exercise types available to the students. For example, the TE, PP, and $FitB$ exercises were typically completed alone. Among two exercise pairs, $SE \rightarrow CE$, $OP \rightarrow FnB$, and $FnB \rightarrow FxB$ showed higher probabilities than ending the session.

We can further classify the activities by their respective ICAP modes. For example, the $SE \rightarrow CE$ transition can also be viewed as a Constructive$\rightarrow$ Interactive transition, $MS \rightarrow TE$ can be viewed as Passive$\rightarrow$ Active, and so on. From this perspective, transitions between activities rarely 'downgraded' to a lower mode. With the exception of $MS \rightarrow MA$ and $MV \rightarrow MA$, mode changes primarily shifted by one level of engagement.

3.3 Activity Session Factor Analysis

The probabilities shown in Figure 1 raise new questions about students' practice behaviors. Not only were we able to confirm the existence of *platform silos* from our RQ1, but based on the observed transition probabilities, we found that students may also operate within what we term an *activity silo*, focusing primarily on one ICAP mode per session. In this section we report on two factor analyses which we use to identify the latent variables for each practice session in order to strengthen our claim.

Factor Analysis is a dimension reduction method to describe the variability of observed variables into, potentially, lower latent variables, or factors. To prepare our dataset for factor analysis, each activity was converted into a binary value, representing the presence or absence of the activity in the session. For example, if a session only involves passive content consumption, the resulting vector for the session would be [1,1,0,0,0,0,0,0,0,0,0], where the 1s represent the presence of lecture slides and videos and 0 represents the absence of all other activities.

In order to evaluate the appropriateness of our data for factor analysis, we use the Bartlett's and Kaiser-Meyer-Olkin tests. Bartlett's test compares our correlation matrix against an identify matrix to test whether our samples are from populations with equal variance. Our samples were statistically significant ($\chi^2 = 3360.05, p = 0.0$) and thus we can continue with our factor analysis. Kaiser-Meyer-Olkin checks the adequacy for our variables to determine the suitability of factor analysis. Our KMO score was 0.83, which again shows our dataset is adequate.

The next step for our analysis was to determine the appropriate number of factors. Table 1 shows the eigenvalues for each factor and their cumulative variance. Based on these results, we utilized two separate factor analyses. The first analysis uses 3-factors to correspond to the 3 eigenvalues greater than 1, as suggested by Kaiser [18]. The second analysis increases to 5-factors based on the variance extraction rule, which specifies a 0.7 threshold for eigenvalues [6, 24, 23].

Table 1: Eigenvalues for Factor Analysis of Completers

Factor	Eigenvalue	Cumulative Variance
1	3.860695	30.51%
2	1.390921	37.21%
3	1.170659	41.79%
4	0.916401	52.26%
5	0.810977	62.27%
6	0.665925	60.91%
7	0.649612	69.59%
8	0.486275	70.05%
9	0.446064	55.23%
10	0.391094	55.42%
11	0.211376	55.42%

Our next task was to identify load factor thresholds for our latent variables. While there is no universal standard for loading thresholds, the goal is to only observe variables that share a strong association with each other and is a non-trivial process [22]. For our paper, we will focus our attention to variables above a 0.50 (or 25% of the variable's variance) threshold, highlighting them in our tables as green. Since the difference between a 0.50 and 0.49 loading is minimal, we will also highlight values greater than 0.4 (or 16% variance) in yellow for additional reference.

Table 2 shows the factor load values for our 3-factor analysis. F1 has high loadings for OP, FnB, FxB, SE, and CE. If we consider the ICAP modes for this factor, this indicates a transition of *Constructive* $\rightarrow$ *Interactive* TYPOS Practice. F2 has high loadings for $FitB$ and PP, or *Active*$\rightarrow$ *Constructive* TYPOS Practice. Finally, F3 has high load for MS, or *Passive* Moodle Interaction. From Table 2, we once again can confirm the presence of *platform silos*, however we expand our factor analysis in order to see the presence of *activity silos*. Moreover, 3-factors only accounts for 41.79% of the cumulative variance and so using the 0.7 eigenvalue threshold will allow us to account for 62.27%.

And finally, Table 3 shows the factor load values for our 5-factor analysis. Similar to Table 2, we see a separation between

Table 2: Loadings for 3 Factor Analysis for Completers. Values greater than 0.4 are in yellow and greater than 0.5 are in green.

Activity	F1	F2	F3
MS	0.0306	-0.0294	0.5073
MV	-0.1006	-0.0999	0.3891
MA	-0.0269	-0.2862	0.2177
TE	0.0193	0.4336	-0.1345
FitB	0.4703	0.5471	-0.0286
PP	0.3300	0.6726	0.0392
OP	0.6257	0.3885	0.0216
FnB	0.8215	0.2149	0.0307
FxB	0.8399	0.1546	0.0059
SE	0.6802	0.1020	-0.0933
CE	0.5019	0.0135	-0.1306

TYPOS activity and Moodle activity. Further, the activities for each factor are confined to a single ICAP mode, or within one mode. F1 contains mostly *Constructive* activities (as well as FxB), F2 contains *Active*→ *Constructive* activities, F3 contains *Passive* activities, and F4 and F5 contain *Interactive* activities. In addition, F3 and F4 show a separation between *Passive* Moodle content consumption and *Interactive* assessment taking. Thus, from the results of our 5-factor analysis, we confirm the presence of *activity silos* within our students.

3.4 Comparing Completers to Non-Completers

Having shown the basic activity structures and identified relevant factors we then chose to explore was the difference between completer and non-completer students. We used the same methods for the non-completer group for comparison. There were 32 students that failed to complete our course. Non-completers made 8,442 course interactions across 341 sessions, with an average 10.7 (±7.8) sessions per non-completer.

We first produced the same transition probabilities diagram for non-completer activity sessions, seen in Figure 2. Similar to completers, module assessment accounted for 31% of starting session behavior, TYPOS practice accounted for 49%, and lecture slides and videos (Content Consumption) accounted for 22%. Non-completers primarily operated within a single platform, though there was more interactions between Moodle and TYPOS. For example, 12% of MV's transitions migrated to TYPOS exercises and 5% of SE transitions migrated to MA. While completer students separated $SE \rightarrow CE$ and $OP \rightarrow FnB \rightarrow FxB$ transitions, these two sequences were combined for non-completers. However, this could potentially be due to the size differences. Both populations had similar population sizes, but non-completers did not complete each module assessment and would not produce as many sessions.

We then carried out the same factor analyses for non-completers. The results of a Bartlett's test showed statistically significant differences ($\chi^2 = 997.8, p > 0.0001$) and our KMO score was also adequate for analysis (0.77). Similar to Table 1, we found support for 3- and 5-factor analysis, seen in Table 4. We note that a 6-factor analysis is also possible, but to mirror the factor analysis for completers, we elected not to pursue it.

Table 4: Eigenvalues for Factor Analysis of Non-completers

Factor	Eigenvalue	Cumulative Variance
1	3.480694	26.26%
2	1.503161	34.57%
3	1.286916	41.39%
4	0.888718	47.44%
5	0.821608	54.51%
6	0.719444	62.12%
7	0.657629	66.31%
8	0.520019	63.79%
9	0.499220	57.46%
10	0.375677	57.69%
11	0.246915	57.69%

Table 5 shows our 3-factor analysis for non-completers. The same activities having high loadings as F1 and F2 as the 3-factor analysis for completers (Table 2) and also show similar *platform silos*. Likewise, the ICAP mode considerations are similar for each factor. F1 shows *Constructive*→ *Interactive* behaviors, F2 shows *Active*→ *Constructive* behaviors, and F3 shows *Passive* Moodle interaction.

Table 5: Loadings for 3 Factor Analysis for Non-completers.

Activity	F1	F2	F3
MS	0.0362	0.0014	0.4167
MV	-0.0334	0.0106	0.6616
MA	-0.0136	-0.2524	0.2999
TE	0.0756	0.4637	-0.0719
FitB	0.3176	0.6024	-0.0202
PP	0.1082	0.7404	0.0221
OP	0.5310	0.3499	0.1105
FnB	0.5573	0.4837	-0.0910
FxB	0.6636	0.3369	-0.1218
SE	0.8012	0.0568	0.0573
CE	0.5900	0.0201	0.0056

Table 6 shows our 5-factor analysis for non-completers. Non-completers maintained the *Constructive*→ *Interactive* connection for F1 and F2 also maintains the *Active*→ *Constructive* connection. The remaining factors do differ, F3 separated the $FnB \rightarrow FxB$ exercises from F1 and F4 focuses primarily on TE. The absence of MA was expected since course progression requires passing module assessments. From our analysis, we conclude that non-completers still operated within *activity silos*.

Table 6: Loadings for 5 Factor Analysis for Non-completers.

Activity	F1	F2	F3	F4	F5

4. DISCUSSION

The results from our probability transition diagrams confirm the presence of both *platform silos* and *activity silos* in student work. They also serve to highlight areas where educators and researchers can tailor more appropriate learning paths for students and in particular those students that may be struggling with course material.

Our study allowed students to self-select which activities they wanted to focus their attentions on. While this style of course design could be adopted, it does still present limitations. However, students that primarily focus on lower-level ICAP mode activities may be reluctant to move into high-level modes. Instructors or systems that can identify this stagnate practice behavior could encourage students to move into high-level ICAP modes. There is growing interest in the concept of *nudge theory* to "alter behavior without incentives or banning alternatives" [7] to encourage progression.

Similarly, we presented students with a number of different activities, at different complexities, for their learning experience. Based on our results, students were more than willing to complete each type of exercise. Some students even asked for more activities in our post-course survey. While increasing the workload for students and learning material creators, many of the activities we used are not overly complex and required a minimal amount of time to create, or from the students' perspectives complete. Activities like typing exercises or Parsons puzzles can be created from existing course materials and offer little incentive for students to cheat. They simply allow students an opportunity to practice the concepts they learned rather passively given to them, refining their understanding, before needing to apply it to problem solving activities like coding exercises.

5. LIMITATIONS

We acknowledge some limitations with our study. First, our course ran during the COVID-19 pandemic, which has altered many individuals' habits. Our population also contained non-traditional students who were balancing their studies with working from home and supporting other family members. Thus, non-completion may have been driven by external constraints that are not reflected in our dataset, and the observed habits may change somewhat during non-COVID times.

Second, the exercise types were presented in a consistent manner for each module. Thus they were implicitly sequenced with lower-level ICAP modes appearing on the top. As we mentioned in our introduction, discerning the appropriate order for 11 different activities is a non-trivial matter and measuring the appropriate order of exercise types was not a part of our study. Thus, we presented exercises in an order that progressively increased the level of engagement. This may have influenced next practice selections by students.

Finally, we acknowledge that the ICAP modes associated with each exercise type are somewhat subjective and open for discussion. Moreover the exact evaluation of exercises like Parsons Puzzles or self-explanation may require additional research and context. For the purposes of this study, when faced with uncertainty we classified exercises according to a higher level mode of interaction.

6. CONCLUSIONS

In this work, we extracted the practice and study session behaviors from non-traditional students learning Python. Among completers and non-completers of the course, they primarily focused on a single platform. The activities within these platforms were mapped to the ICAP framework. Further, we used factor analyses to identify the presence of *activity silos* within practice sessions. Completers and non-completers shared similar behaviors during these practice sessions, primarily focusing on one or two modes of engagement and rarely 'downgraded' to lower level modes.

We can utilize these activity sequences to help shape our overall course designs for ensuring student learning. Lower-level activities can provide students with the foundational knowledge necessary as a part of the technical skills for the content, while higher-level activities can refine and encourage additional learning gains. As the research in this area expands, we hope the information presented in this study encourages educators and researchers alike to provide practice in both levels and can serve as a guide for recommendations on how to best build long-term proficiencies.

ABSTRACT

In educational applications, *Knowledge Tracing* (KT) has been widely studied for decades as it is considered a fundamental task towards adaptive online learning. Among proposed KT methods, Deep Knowledge Tracing (DKT) and its variants are by far the most effective ones due to the high flexibility of the neural network. However, DKT often ignores the inherent differences between students (e.g. memory skills, reasoning skills, ...), averaging the performances of all students, leading to the lack of personalization, and therefore was considered insufficient for adaptive learning. To alleviate this problem, in this paper, we proposed **L**eveled **A**ttentive K**N**owledge Tr**A**cing (LANA), which firstly uses a novel student-related features extractor (SRFE) and pivot modules to distill and distinguish students' unique inherent properties from their respective interactive sequences. Moreover, inspired by Item Response Theory (IRT), the interpretable Rasch model was used to cluster students by their ability levels, and thereby utilizing leveled learning to assign different encoders to different groups of students. With pivot module reconstructed the decoder for individual students and leveled learning specialized encoders for groups, personalized DKT was achieved. Extensive experiments conducted on two real-world large-scale datasets demonstrated that our proposed LANA improves the AUC score by at least 1.00% (i.e. EdNet ↑ 1.46% and RAIEd2020 ↑ 1.00%), substantially surpassing the other State-Of-The-Art KT methods.

1. INTRODUCTION

Knowledge Tracing (KT) aims to accurately retrieve students' knowledge states at a certain time by his past sequential exercising interactions. To evaluate KT's performance, it is asked to predict the correctness of students' future exercises with the retrieved knowledge states as Equation 1 represented.

$$P(r^{s_i}_{t+1}|I^{s_i}_1, I^{s_i}_2, I^{s_i}_3, ..., I^{s_i}_t, \{I^{s_i}_{t+1} - r^{s_i}_{t+1}\}),\ I^{s_i}_t = (e^{s_i,q_j}_t, c^{q_j}, r^{s_i}_t) \tag{1}$$

Where e^{s_i,q_j}_t is referred as student $s_i \in \mathbb{N}^+$ answering question $q_j \in \mathbb{N}^+$ at discrete time step $t \in \mathbb{N}^+$, c^{q_j} represents the contextual information of question q_j (e.g. related concepts, part, etc.) [23, 14, 10, 4], and $r^{s_i}_t \in \{0, 1\}$ represents the correctness of student s_i's answer to q_j at time t. Additionally, the student's interaction sequence is defined as $S^{s_i}_{t_0,t_1} = \{I^{s_i}_t | t_0 < t < t_1\}$ and κ is defined as $\kappa^{s_i}_t = \{s_i, q_j, c^{q_j}, r^{s_i}_t\}$, referring to all features that participated in one interaction $I^{s_i}_t$ for latter explanation.

Traditionally, KT was regarded as a sequential behavior mining task [8, 17], and therefore various methods established models with the theory of bayesian probability (BKT [3]) and psycho-statistics (IRT [5]), providing excellent interpretability and good performance. Nevertheless, recently proposed Deep Knowledge Tracing (DKT) [16] and its variants [13, 4, 14, 1, 18] significantly outperform other KT methods in metrics using Recurrent Neural Network (RNN) and Long Short Term Memory (LSTM [6]). However, DKT distinctly lacks personalization for students compared to BKT and IRT [15, 25], which are capable of separately training unique models for each student, while DKT only trains a unified model for all students due to massive training data and abundant computing resources required by deep learning. Hence, DKT weakly reflects the large inherent property (i.e. memory skills, reasoning skills, or even guessing skills) gaps between students.

ASSUMPTION 1. *For any interactive sequences satisfying* $\left|\left|S^{s_i}_{t_0,t_1}\right|\right| > \Theta >> 1$, $||\kappa|| > \Psi$ *and* $t_2 - t_1 > \mathcal{E}$, $S^{s_i}_{t_0,t_1}$ *can be distinguished from* $S^{s_j}_{t_0,t_1}$ *and* $S^{s_i}_{t_2,t_3}$ *respectively.*

Is it possible to bring personalization back to DKT? To answer this question, we observed that the proactive behavior

sequence (i.e. interactive sequences) of each individual is unique and changeable over time. Hence, we argue that the minimal personalized unit in KT is "a student at a certain time t_i" instead of just "a student", and **student's inherent properties at time t_i can be represented by his interactive sequences around time t_i (Assumption 1)**. In such a way, these student-related features could tremendously help personalize the KT process since they could be used to identify different students at different stages. Consequently, in our proposed **L**eveled **A**ttentive K**N**owledge Tr**A**cing (LANA), unique student-related features are distilled from students' interactive sequence by a Student-Related Features Extractor (SRFE). Moreover, inspired by BKT and IRT that assign completely different models to different students, LANA, as a DKT model, successfully achieves the same goal in a different manner. Detailedly, instead of separately training each student a model like BKT and IRT, **LANA learns to learn correlations between inputs and outputs on attention of the extracted student-related features**, and thus becomes transformable for different students at different stages. More specifically, the transformation was accomplished using pivot module and leveled learning, where the former one is a model component that seriously relies on the SRFE, and the latter one is a training mechanism that specializes encoders for groups with interpretable Rasch model defined ability levels. Formally, the LANA can be represented by:

$$\overbrace{r_t^{s_i} \sim (f(p_t^{s_i}))(h_t^{s_i})}^{Adaptive\ by\ Pivot\ Module} \quad , \quad \underbrace{p_t^{s_i} \sim k(h_t^{s_i}), \quad h_t^{s_i} \sim g(h_{<t}^{s_i}, S_{0,t}^{s_1})}_{Adaptive\ by\ Leveled\ Learning}, \tag{2}$$

where $h_t^{s_i}$ is referred as student s_i's knowledge state at time t respectively, $f(\cdot)$ (decoder), $g(\cdot)$ (encoder) and $k(\cdot)$ (SRFE) are three main modules that LANA seeks to learn.

2. METHODOLOGY

2.1 Base Modifications

There are mainly two base modifications in the LANA model (Figure 1) that were made to the basic transformer. Firstly, in the LANA model, the positional information (e.g. positional encoding, positional embedding) was directly fed into the attention module with a private linear projection, instead of being added to the input embedding and shared the same linear projection matrix with other features in the input layer. Although experiments in [22] suggested that blending input embedding with positional information is effective, recently some work [19] debated that when the model becomes deeper, it tends to "forget" the positional information fed into the first layer. Moreover, some other work [9] believed that adding positional information to the input embedding and offering them to the attention module, is essentially making them share the same linear projection matrix, which is not reasonable since the effects of the input embedding and the positional information are clearly distinctive. For exactly the same reason, in the LANA model, multiple input embeddings (i.e. question ID embedding, student ID embedding, etc.) are concatenated instead of added, leading to the second base modification. Specifically, assumes there are m input embeddings in total, each with a dimension of D^f. Then after concatenating, the input embedding would have a total dimension of D^{mf}. Hence, a $D^{mf} \to D^f$ linear projection layer was used to map the concatenated input embedding of dimension D^{mf} to dimension D^f.

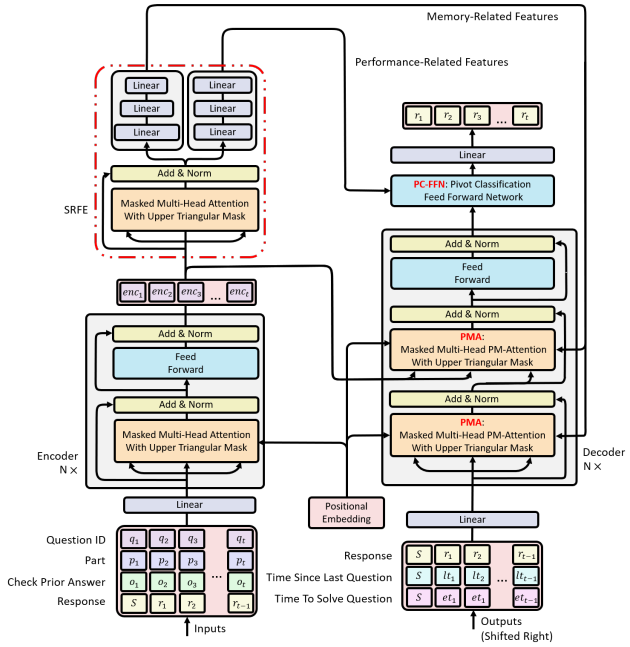

Figure 1: The overall model architecture of LANA. There are mainly three differences compared to vanilla transformer-based KT method [1, 18]: I. Modifications to the basic transformer model. II. Introduced SRFE and III. Introduced PMA Module and PC-FFN Module, which collectively referred to as pivot module.

2.2 Student-Related Features Extractor (SRFE)

Student-Related Features Extractor (SRFE) summaries students' inherent properties from their interactive sequences with Assumption 1 for the pivot module to personalize the parameters of the decoder. Specifically, SRFE contains an attention layer and several linear layers, where the attention layer was used to distill student-related features from the provided information by the encoder, and the linear layers were leveraged to refine and reshape these features. It is notable that in the LANA model there were primarily two SRFEs: memory-SRFE and performance-SRFE, where the former one was utilized to derive students' memory-related features for the PMA module (be introduced later) and the latter one was dedicated to distill students' performance-related features (i.e. Logical thinking skill, Reasoning skill, Integration skill, etc.) for PC-FFN module (introduced later either). The reshaping process was drawn in Figure 3 for better illustration, where bs, n_{heads}, seq and d_{piv} are referred to as the model's batch size, the number of attention heads [22], the length of the input sequence and the dimension of performance-related features. The intuition that memory-related features have a second dimension of n_{head} comes from the theory that each attention head only pays attention to one perspective of the features. Thus it is reasonable that each student has different memory skills for different attention heads (e.g. for different concepts).

2.3 Pivot Module

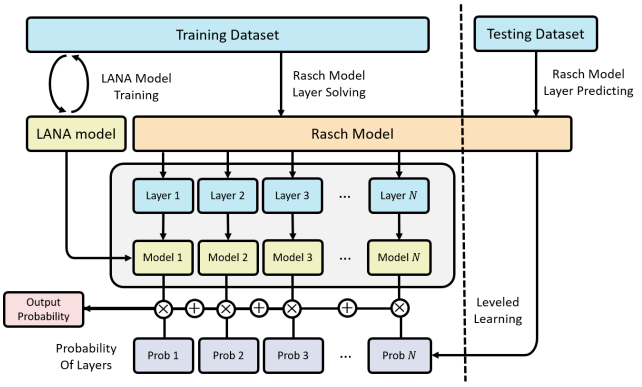

Figure 2: The workflow of leveled learning: interpretable Rasch model was leveraged to analyze students' overall ability levels, and then cluster students into multiple layers, where each layer would respectively fine-tune the LANA model by its own training data.

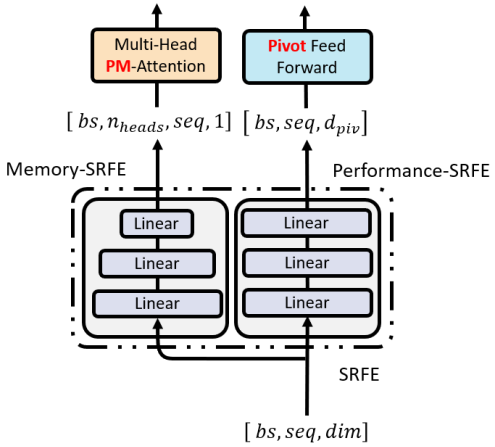

Figure 3: The data shape transformation of two SRFE: Memory-SRFE and Performance-SRFE.

Provided an ordinary input x, a student-related features p and a target output y, pivot module learns the process of learning how to project x to y based on p, instead of simply learning to project x to y (i.e. Pivot module learns to learn) as Equation 3 shown.

$$y = (f(p))(x), \tag{3}$$

where $f(\cdot)$ here is the function that pivot module learns to learn. That is, the projection matrix of x is adapted to p instead of being fixed. To accomplish this dynamic mapping, the weight and bias of x need to be a projection from p. Assumes $p \in \mathbb{R}^{D_p}$, $x \in \mathbb{R}^{D_x}$ and $y \in \mathbb{R}^{D_y}$, Equation 3 could be formally presented in Equation 4:

$$y = W^x x + b^x, \tag{4}$$

where $W^x \in \mathbb{R}^{D_y \times D_x}$ and $b^x \in \mathbb{R}^{D_y}$. Since W^x and b^x is derived from p, the detailed transformation could be revealed in Equation 5, which was also depicted in Figure 4 for better illustration.

$$W^x = W_1^p p + b_1^p, \quad b^x = W_2^p p + b_2^p, \tag{5}$$

where $W_1^p \in \mathbb{R}^{(D_y \times D_x) \times D_p}$, $b_1^p \in \mathbb{R}^{(D_y \times D_x)}$, $W_2^p \in \mathbb{R}^{D_y \times D_p}$ and $b_2^p \in \mathbb{R}^{D_y}$.

By simplification, Equation 3 can be defined as Equation 6, being named as $PivotLinear(x, p)$.

$$y = (Wp)x + b = PivotLinear(x, p), \tag{6}$$

where $W \in \mathbb{R}^{D_y \times D_x \times D_p}$ and $b \in \mathbb{R}^{D_y}$.

In the LANA model, there are primarily two modules that pertain to the pivot module: Pivot Memory Attention (PMA) Module and Pivot Classification Feed Forward Network (PC-FFN) Module. In many methods [4, 14], Vanilla Memory Attention (VMA) Module was employed to consider the "forgetting" behavior of students, which is pivotal in KT's context since students are very likely to have done similar exercises to the one he is going to do, and if the student could remember the answers to previous similar exercises, the probability of him correctly answering the future related exercises will be increased greatly. Inspired by the Ebbinghaus Forgetting Curve [12] and much previous work [14, 4], "forgetting" behavior of students are defined as exponentially decaying weights of corresponding interactions in the timeline. Detailedly, in the original attention module, the weight of item j on item k, i.e. $\alpha_{j,k}$, is determined by the `sigmoid` result of the similarity between item j and item k:

$$\alpha_{j,k} = \frac{sim(j,k)}{\sum_{k'} sim(j,k')}, \tag{7}$$

where $sim(\cdot)$ is a function to calculate the similarity between item i and item j by dot production. In order to take "forgetting" behavior into $\alpha_{j,k}$'s account (e.g. The further away from j, the lower the weight $\alpha_{j,k}$ would be), we replaced Equation 7 with Equation 8:

$$\alpha_{j,k,m} = \frac{e^{-(\theta+m)\cdot dis(j,k)} \cdot sim(j,k)}{\sum_{k'} sim(j,k')}, \tag{8}$$

where m is the student's memory-related features extracted in memory-SRFE, θ is a private learnable constant that describes all students' average memory skill in the PMA module, and $dis(\cdot)$ calculates the time distance between item j and item k (e.g. item j is done $dis(j,k)$ minutes after item k is done). The reason for representing the memory skill with two learnable parameters is to reduce the difficulty for model converging since m has a much longer back-propagation path compared to θ. When θ is introduced to fit

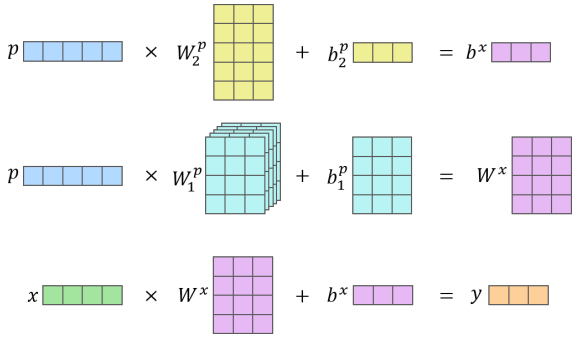

Figure 4: An illustration of the data transformation in the pivot module.

the average memory skill of all students, the distribution of m becomes a Gaussian distribution, which makes the model much easier to learn.

On the other hand, PC-FFN was utilized to make the final prediction in reference to the performance-related features, which essentially is a PivotLinear module with a dropout and activation. The idea of this module comes from many investigations that the early layers in a deep neural network are often used as a feature extractor while the latter layers are often used as a decision-maker to decide which feature is useful to the output of the model. As a result, these investigations point out that many models are actually having similar early layers, and it is the latter layers that make these models distinctive in usage. Consequently, PC-FFN in the LANA model was utilized as a personalized decision-maker to adaptively make the final prediction based on students' distinctive inherent properties:

$$PC{-}FFN(x,\, p) = x + PivotLinear(PivotLinear(x,\, p),\, p), \tag{9}$$

where p is the students' performance-related features extracted in the performance-SRFE.

2.4 Leveled Learning

While the pivot module enables the decoder to be transformable for different students, the encoder and the SRFE of the LANA model that provides necessary information for the pivot module remains the same for all students. This is not problematic if the length of the input sequence is large enough since Assumption 1 assures long sequences are always distinguishable, unless they both belong to the same student at the same time period. However, DKT, especially transformer-based DKT, can only be inputted with the latest n (commonly $n = 100$) interactions at once due to the limited memory size and high computational complexity. Consequently, it is possible for the encoder and SRFE to output similar results for two different students, resulting in a failure for the decoder to adapt. To alleviate this problem, it is natural to think of assigning different students with different encoders and SRFEs that are highly specialized (sensitive) to their assigned students' patterns. However, in practice, it is not feasible to train a unique encoder for each individual student considering both the limited training time and the limited training data. As a result, a novel leveled learning (Figure 2) method was proposed to address this problem, which was initially inspired by the fine-tuning mechanism in transfer learning [20], where we consider each student a unique task, and we want to transfer a model that fits well on all students to one student s_i efficiently.

Leveled learning holds the view that the earlier layers of a model are similar for similar tasks. Thus, to save training time and enlarge the training set, instead of training each student a unique encoder and SRFE by his private training data, students with similar ability levels are considered to be grouped together, sharing their private training data and having the same encoder and SRFE. Therefore, LANA firstly utilizes an interpretable Rasch model to analyze the ability level a^{s_i} for each student s_i, then groups students into different independent layers l_i. Assuming the ability distribution of all students and students at the level l_i are Gaussian distribution $N(\mu_a, \sigma_a^2)$ and $N(\mu_i, \sigma_i^2)$ respectively, we have the Equation 10:

$$\mu_a = \frac{\sum_i \mu_i}{L}, \quad \sigma_a^2 = \sum_i \sigma_i^2. \tag{10}$$

In LANA, for simplicity, we consider all layers share the same variance σ^2 [1], and the difference of mean μ_i between consecutive layers is a constant τ. Hence, μ_i and σ_i^2 are given by:

$$\mu_i = \mu_a - \frac{L-1}{2} \times \tau + i \times \tau, \quad \sigma_i^2 = \frac{\sigma_a^2}{L}. \tag{11}$$

where $L = ||l_i||$ is the number of layers. With both μ_i and σ_i^2 retrieved for every layer l_i, given a student's ability constant a^{s_i}, we can now calculate the probability of s_i been grouped into different layers by Equation 12:

$$p_i^{s_i} = \frac{\phi_i(a^{s_i})}{\sum_{i'} \phi_{i'}(a^{s_{i'}})}, \quad \phi_i(a^{s_i}) = \frac{1}{\sigma_i\sqrt{2\pi}} e^{-\frac{(a^{s_i} - \mu_i)^2}{2\sigma_i^2}} \tag{12}$$

where $p_i^{s_i}$ is referred as the probability of student s_i being grouped into layer l_i. As it can be seen from Equation 12, students that have high ability levels are not necessarily grouped into layers with high expected ability levels μ_i. Contrarily, these high ability students only have a higher probability of been grouped into high ability layers in comparison with those low ability students, which obeys rules in reality (e.g. high ability students may also come from normal schools).

Then, the LANA model that has been pre-trained on all students was duplicated L times, each cloned model m_i would be assigned to a layer l_i to be dedicatedly fine-tuned with l_i's private training data by weighted back-propagation:

$$loss_i = p_i \times loss(predict_i, target), \tag{13}$$

where $predict_i$ is the prediction of the model m_i.

While the training phase of leveled learning seems promising, the inference phase of it suffers problems. The first problem is how to make the prediction using multiple specialized models. In LANA, the prediction was made by $top-k$ models fusion. Detailedly, when student s_i's future responses are needed to be predicted, LANA firstly computes p_i, then feed s_i's interactive sequence to all models m_i that satisfies $p_i \in top-k(p)$, where k needs to be manually set up to control the predicting time. Then, the outputs of these models would be multiplied by $sigmoid(p_i)$ to form the final prediction. The workflow of leveled learning's inference step could be described in Equation 14:

$$r_i = \sum_{i'} (m_i(x) \times \sum_{h \in i'} \frac{p_h}{\sum_{h'} p_{h'}}), \quad i' \in \{\, i \mid p_i \in top-k(p) \,\}, \tag{14}$$

where r_i is the leveled learning's final prediction and x is the input of the model. This workflow seems similar to the ensemble where multiple models are unitized to generate the final answer. Nonetheless, weights of models in LANA are probabilities that come from an interpretable Rasch model

[1] In practice, if the number of layers is small, their variances then need to be manually measured and tuned based on the targets. If the number of layers is large, then multiple layers can be regarded as one layer and therefore sharing the same variance for all layers should be fine.

so that it is clear which model is dominant to x. Moreover, unlike in ensemble, where the role of each model is ambiguous, in LANA, every model has its explainable effect (e.g. l_L is committed to high ability students, and therefore a student with large p_L indicates he must be similar to those high ability students in l_L), suggesting that leveled learning significantly outperforms ensemble in interpretability. Detailed comparison was shown in Table 1. On the other hand, the

Table 1:
Comparison Between Leveled Learning And Ensemble

	Leveled Learning	Ensemble
Sub-set Select	Psycho-statistics	Random
Interpretability	Good	Bad
Predicting Time	Controllable (top-k)	Uncontrollable

second problem of the leveled learning is how to compute p_i for students that LANA has never met in training, namely the "cold start" problem [24]. In vanilla KT context, we can only initiate newly arrived students' ability levels to the average ability level of all students. However, in practice, we can estimate their ability levels more accurately by asking them to do a couple of sample exercises or using ranking at school.

3. EXPERIMENTS

3.1 Experimental Setup

In order to evaluate the effectiveness of the proposed LANA[2], we applied it to two real-world large-scale datasets in comparison with many other State-Of-The-Art (SOTA) KT methods. Specifically, EdNet [2] and RAIEd2020 [7] are employed in our experiments, where EdNet is currently the largest publicly available benchmark dataset in education domain, consisting of over 90,000,000 interactions and nearly 800,000 students. On the other hand, RAIEd2020 is a recently published real-world dataset that has approximately the same size as EdNet with nearly 100,000,000 interactions and 400,000 students. Particularly, the average number of exercising interactions per student in RAIEd2020 is double to EdNet's. Moreover, 6 KT methods that had previously achieved SOTA performance have participated in the comparison: DKT [16], DKVMN [26], SAKT [13], SAINT [1], SAINT+ [18], AKT [4]. In terms of the basic experimental environment, all experiments were conducted with Pytorch[3] 1.6 on a Linux server that is equipped with an Nvidia V100 GPU. For hyper-parameters setup, the learning rate was set to $5e-4$ with *AdamW* [11] optimizer, the length of the input sequence was set to 100, the batch size was set to 256, and other detailed configurations were listed in our source code. The input features κ in EdNet contains *Question ID*, *Question part*, *Students' responses*, *Time interval between two consecutive interactions* and *Elapsed time of an interaction*, whereas in RAIEd2020, a new feature is additionally added to κ, which indicates *Whether or not the student check the correct answer to the previous question.* Finally, The Area Under the receiver operating characteristic Curve (AUC) was leveraged in our experiments as the performance metric, which has been widely used in many other KT-related proposals.

For the ease of explanation, hereinafter Base Modification (Section 2.1), Pivot Module (Section 2.3) and Leveled Learning (Section 2.4) would be abbreviated as *BM*, *PM* and *LL* respectively.

3.2 Results And Analysis

The overall experimental results of different KT methods on different datasets were illustrated in Table 2. Because we had successfully reproduced the performance of SAINT and SAINT+ that was previously reported in SAINT+'s paper [18] (with considerable precision), AUCs of other models are therefore directly cited from the paper (labeled with subscript r).

From the comparison table, it can be seen that in both Ed-

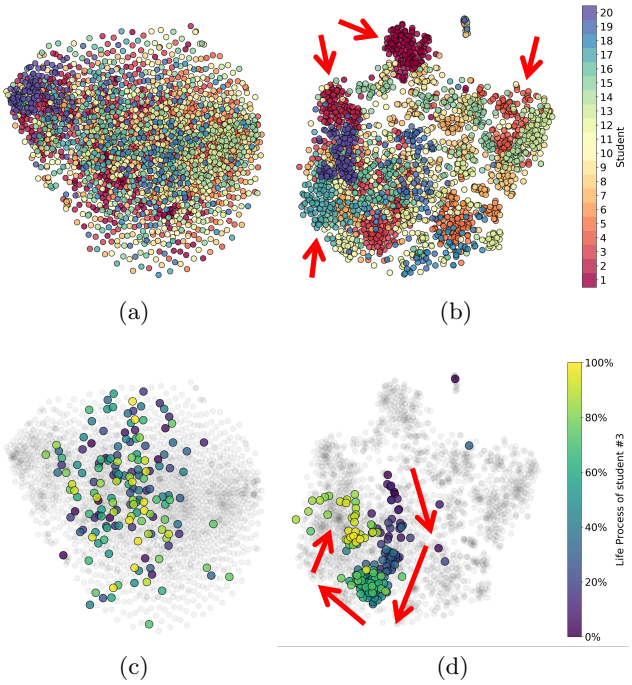

Figure 5: The visualization of intermediate features in SAINT+ (a) and in LANA (b). Compared to (a), students in (b) (different colors) are notably clustered (marked arrows). The learning process of student #3 overtime in SAINT+ (c) and in LANA (d). compared to (c), a clear learning path appeared in (d).

Net and RAIEd2020 datasets, LANA (marked bold) outperforms the previous SOTA method (marked italic) by 1.46% and 1.00% respectively, readily verifying the effectiveness of our proposed improvements. Moreover, LANA also surpasses SAINT+ & *BM* by 1.24% and 0.65% respectively, suggesting adaptability contributes most to LANA's AUC increment. Considering experimented datasets are by far the two largest knowledge tracing datasets in the world, these results undoubtedly provide strong evidence of the validity of the proposed LANA method.

3.3 Ablation Studies

In this section, we investigated the effectiveness of each of our proposed improvements: *BM* that customizes the basic transformer architecture, *PM* that enables the decoder to be adaptive to the students' personal characteristics, and *LL* that interpretably specializes encoders and SRFEs for better predicting performance. The results of the ablation study were shown in Table 3.

The table shows in EdNet, applying *BM* alone was already capable of improving the predicting AUC by approximately 0.2% averagely, verifying the importance of both the action of positional embedding and the personalized linear projection for each input feature in KT's context. Meanwhile, applying *LL* solely can benefit the model performance as well, by generally 0.2% compared to 0.1% with the vanilla ensemble. Considering without *PM*, *LL* would just perform fitting on students with different ability levels, the performance gain from sole *LL* could be interpreted as reductions in students' inherent properties gaps. Moreover, *BM* + *PM* drastically boosts the model performance by nearly 1.25%, suggesting *PM* makes proper use of extracted student-related features from SRFE to adaptively reparameterize the model's decoder for different students at different stages, and therefore contributes most to the final performance gain. Finally, by combining all improvements together, *BM* + *PM* + *LL* (i.e. LANA) achieves a final AUC of 0.8059, substantially outperforms previous SOTA by at least 1.46%.

3.4 Features Visualization

For vividly illustrating the validity of student-related features distilling in LANA, 20 students' intermediate features from PC-FFN module was sampled to generate Figure 5 by t-SNE[21]. In figure 5 (a) and (b), each sample represents intermediate features of different students with different colors in SAINT+ and LANA respectively. It can be seen that in SAINT+, samples are almost randomly distributed, indicating the correlation between samples of the same student is not more significant compared to samples of the others due to the ignorance of students' personalities. On the other hand, in LANA, clusters (marked arrows) of samples have notably appeared in comparison to (a). Thus, we concluded that LANA is capable of successfully extracting student-related features from their interactive sequences, summarizing the similarities and differences, which eventually results in more distinguishable features for the final classifier.

Furthermore, we individually visualized student #3's (randomly picked) samples along the time axis to investigate the transitioning pattern of features in Figure 5 (c)(SAINT) and (d)(LANA). In (c), there is no clear pattern in the change of features over time, while in (d), a clear transitioning path could be noticed. Since many other students are sharing the same pattern in LANA, we argue that it represents the trajectory of the student's ability changes with more and more exercising. Namely, it is the learning path of the student. Consequently, we contended that it is potentially helpful for other applications, such as learning stages transfer and learning path recommendation.

4. CONCLUSION

In this paper, we proposed a novel **L**eveled **A**ttentive K**N**owledge Tr**A**cing (LANA) method that was committed to bringing adaptability back to DKT. Instead of directly learning the model parameters of different students, LANA distills students' inherent properties from their respective interactive sequences by a novel SRFE, and learns the function to reparameterize the model with these extracted student-related features. Consequently, innovative pivot module was proposed to produce an adaptive decoder. Besides, a novel leveled learning training mechanism was introduced to cluster students by interpretable Rasch model defined ability level, which not only specializes the encoder and therefore enhances the significance of students' latent features, but also saves much training time. Extensive experiments on the two largest public benchmark datasets in the education domain strongly evaluate the feasibility and effectiveness of the proposed LANA, features visualization also suggests extra impacts of LANA, be it learning stages transfer or learning path recommendation.

Recommendation System for Engineering Programs Candidates

Bruno Mota da Silva
Instituto Superior Técnico
brunomotadasilva@tecnico.ulisboa.pt

Cláudia Antunes
Instituto Superior Técnico
claudia.antunes@tecnico.ulisboa.pt

ABSTRACT

Automatic discovery of information in educational data has been broadening its horizons, opening new opportunities to its application. An open wide area to explore is the recommendation of undergraduate programs to high school students. However, traditional recommendation systems, based on collaborative filtering, require the existence of both a large number of items and users, which in this context are too small to guarantee reasonable levels of performance.

In this paper, we propose a hybrid approach, combining collaborative filtering and a content-based architecture, while exploring the hierarchical information about programs organization. This information is extracted from courses programs, through natural language processing, and since programs share some courses, we are able to present recommendations, not just based on the performance of students, but also on their interests and results in each of the courses that compose each program.

Keywords

Recommendation systems, higher education programs, educational data mining

1. INTRODUCTION

Nowadays, it is common to have teenagers applying to a higher education program after finishing their high school. Every year, new programs appear and thousands of candidates must choose which one is the best for them.

This type of problem is very well-known in Educational Data Mining and in Recommendation Systems community [3, 11]. This past decade, many studies were made on creating engines that help students in choosing the courses that are suited for them, using different approaches, like content-based or collaborative filtering recommendation systems. The last type is the most used due to the large amount of data community can give.

Bruno Mota da Silva and Claudia Antunes "Recommendation System for Engineering Programs Candidates". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 609-613. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Despite courses recommendation being a more studied problem, we want to apply these systems to programs recommendation that is not very researched yet. This brings an important challenge, since courses recommenders have already the target user inside the system rating previous courses among the others students, and in our problem candidates did not rate anything to be compared to other users in first hand.

Considering all of these aspects, our work aims for creating a recommendation system that will receive candidates personal data and high-school academic records, with the proper consent given by them considering general data protection regulations (GDPR), and will output the programs that most fit to their profile, comparing to the current student community. The system will consider the personal characteristics of the students as a matching measure and the programs' courses, objectives and description to find keywords that define the corresponding programs. These keywords will allow to compute ratings for every program considering the academic marks of the students on their own program.

This paper is divided in four more sections. Literature review covers the basic aspects of recommendation systems, with special focus on their use for educational purposes. After this, we present the architecture of our system that can be applied at a common university structure. After system architecture, current results are shown, followed by the reached conclusions at this time.

2. LITERATURE REVIEW

Recommendation Systems (RS) are software tools and techniques that provide suggestions for items to be of use to a user [10]. A RS can be exploited for different purposes, such as, to increase the number of items sold, to better understand what the user wants or, in another point of view, to recommend a specific item to that user.

There are two main types of recommendation engines, Content-based and Collaborative Filtering. The first one is focused on item similarities, and the second one use past behaviors of users to recommend items to the active user [1].

There is also a third type of recommendation systems, knowledge-based approaches where recommendations are given based on explicit specification of the kind of content the user wants. These systems are very similar to content-based ones, but with domain knowledge input. Finally, a hybrid recommen-

dation system is constructed if there is a combination of two or more RS philosophies in order to improve the global performance.

Over the years, a large amount of educational data is being generated and there are being applied more collaborative filtering approaches than content-based methods in this area.

Morsomme and Alferez proposed a collaborative recommendation system that outputs courses to the target users, by exploiting courses that other similar students had taken, through k-means clustering and K-nearest neighbors techniques [2].

A recommendation system for course selection was developed in Liberal Arts bachelor of the University College Maastricht [6], using two types of data, students and courses. Student data consisted of anonymized students' course enrollments, and course data consisted of catalogues with descriptions of all courses, which allowed to find the topics of each one, using the Latent Dirichlet Allocation statistical model. Recurring to regression models of student data, the authors could predict his grade for each course. In the end, the system outputs 20 courses whose content best matches the user's academic interest in terms of Kullback-Leibler distance.

This content-based approach was applied as well in Dublin [8], where the authors used an information retrieval algorithm to compute course-course similarities, based on the text description and learning outcomes of each one.

In Faculty of Engineering of the University of Porto, it was created an engine to help students choosing an adequate higher education program to access a specific job in the future [5]. Therefore, it was implemented a recommendation system that uses the data from alumni and job offers and outputs a ranking of programs that could lead to the candidates' desired careers. The collaborative filtering approach can match the skills needed for that job and the skills given to the students of a specific degree.

Fábio Carballo made an engine that predicts students masters courses marks, using collaborative filtering methods, singular value decomposition (SVD) and as-soon-as-possible (ASAP) classifiers. With his work, he could recommend the more suitable program for students skills [4].

The topic around course and programs recommendations gained even more attention recently, with several published studies in the last years, following a variety of approaches [13, 14, 7, 9, 12].

3. RECOMMENDATION SYSTEM

The proposed system shall enlighten candidates about the degrees that are more compatible with their interests and that were successfully concluded by similar students, using a hybrid approach.

Our system must recommend higher education programs to a specific high-school student who wants to enroll at university. Usually, the candidate searches information about each program at universities web pages, such as courses or professional careers, or talks with students who are already enrolled at the programs he or she likes. The process of choosing a degree is very important to a high school student and it must be done analysing all the information available. Therefore, the main use case of our system focuses on candidates point of view.

As we can see on Figure 1, when the candidate uses our system, he or she must be able to give personal data that will be considered during the recommendation process. After that, the system must output a ranking of the programs that are most suitable to the candidate. Candidate's personal data can be academic interests, high school grades, personal data, such age or gender, among others. Since we are collecting data, it must be made according to the GDPR, applying anonymization techniques when necessary.

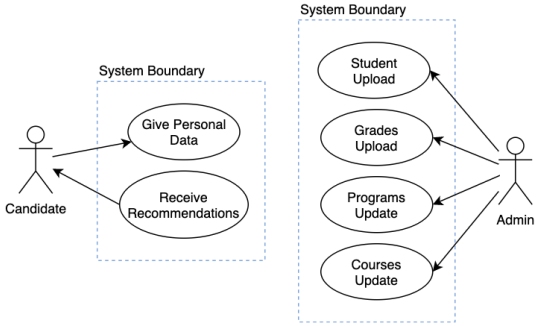

Figure 1: Use cases of the system.

Looking at the system from Admin point of view, there are several tasks he or she must be able to do, as we can see on Figure 1. System Administrator is the one responsible for system updates: upload new students data every year, upload students grades at the end of each semester, and update programs and courses when necessary. All the essential data to relate the candidate to current students and to make proper recommendations must be inputted before the system launching.

Finally, analysts staff can use this system when useful, to get a summary of student community and a characterization of new students.

3.1 Architecture

The overview of our system architecture can be seen on Figure 2, where we can distinguish two main modules: Students Profiler and Programs Recommender.

Candidates start using our system by inputting their personal data that will be used to find their profile. Current students data allow us to compute candidate profiles that will feed the second module. Programs Recommender uses the previous output to estimate a program success measure considering estimated grades, returning in the end a ranking of the most suitable programs to the candidates.

Figure 2: Proposed architecture.

3.1.1 Students Profiler

There is a major difference between our recommendation system and the common ones, where the target user is inside the system among the others. Here, the target user candidate is not in the system, since he or she is not enrolled at a higher education degree yet, and therefore can not rate programs or take courses. Hence, it must be developed a strategy where we can compare users.

Students Profiler computes the candidate profile as if he or she was inside the system, by comparing him with current students using shares personal variables. Therefore, the first step was to collect these data and to build a students profiling model, where we performed a feature engineering study.

A simple choice to implement Students Profiler is to apply the K Nearest Neighbors (KNN) method, after choosing the best similarity measure and number of neighbors, K. To compute the similarity, we used five different measures which results were studied. We also tuned the KNN process as well by trying to find the optimal value for K, that was the one having the minimum error rate.

In the end, Students Profiler returned candidate profile that will be fed to the next module.

3.1.2 Programs Recommender

Programs Recommender module is a more complex one which aims at finding the ranking of the best programs to the candidates, considering their profile **and interests**.

In order to reach its goal, this module has to create two models. The first one, called Grades Model, for estimating the candidate performance in each possible academic units, and the second one, the Ranking Model, for mapping students to programs.

As usual, the Grades Model is constructed by following a collaborative filtering approach, meaning that it uses a singular value decomposition (SVD) matrix factorization. This factorization performs a feature extraction step, reducing the number of elements to the minimum required for estimating students grades. When in the presence of the candidate profile, the Grades Model is applied to estimate the candidate grades. Using the candidate profile, instead of its original data, is the first difference in our approach, but there is more, achieved through the use of a content-based approach.

RS usually deal with a very large number of items, but the number of programs available in any university is just a few, when compared. Additionally, each student is enrolled on just one program, which means that our grades matrix would be very sparse, not contributing for a good recommendation. A third aspect is that programs share some courses (for example all engineering students study Physics and Maths, while all art students study Drawing and Geometry). But we can go a step further, and understand that courses cover some topics present in different areas. For example, several engineering courses study systems, their architecture and their dynamics.

The third proposal is the possibility of dealing with the academic units at different levels of granularity: we can aggregate everything to recommend programs, or we can simply identify a ranking of topics that are recommend for the candidate. This ability is very important to reach a new level of explainability, so needed in the field.

4. PRELIMINARY RESULTS

A recommendation system validation is a hard task to take. In contexts, like education, where these systems can not be made available before being proved 'correct', this task is even harder.

In our case, we made use of students data collected at the time of their enrollment in the university, to mimetize candidates surveys. Then, we used students data from 2014 to 2018 for training and data from 2019 for evaluation purposes. Moreover, every model of the system has to be validated independently, in order to better estimate each component performance, and only after tuning each of them evaluate its global quality.

We started by evaluating the Students Module, which has the use of KNN to estimate candidate profile on its basis. As data sources for this phase, we had personal data from 7918 students and grades from 7302 students, that resulted in a dataset of 7300 instances by intersecting the first ones. This dataset is composed by 101 variables, where enrolled program is the only categorical one, all of the others are numeric. Note that, we had no missing values on the dataset.

In this module, we wanted to find the K students that are most similar to the candidate. Therefore, we made a study to find the best pair (K, similarity measure) mimetizing a KNN performance study, but without focusing on the classification task. First, we needed to define which condition must students achieve to have success on their program, based on their Grade Point Average (GPA), from a 0-20 scale. Hence, a histogram was made and it is shown at Figure 3.

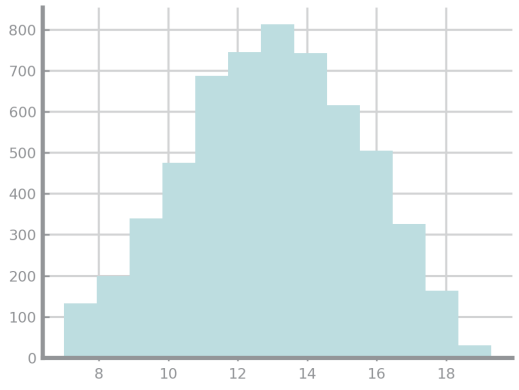

Figure 3: Number of students by each GPA class.

Since the average of students GPA is 12.99, we labeled as having success students which GPA was equal to 13 or more, and not having success otherwise. This way we guaranteed a balanced dataset. After the labelling, we computed ten trials

of data train-test split for five similarity measures (chebyshev, correlation, cosine, euclidean, and manhattan) and for K between 5 and 155 in multiples of 5. For each pair (K, similarity measure), we computed the average of KNN model accuracies, since 70% train and 30% test datasets are random in each trial. The results are shown in Figure 4, and zoomed in Figure 5.

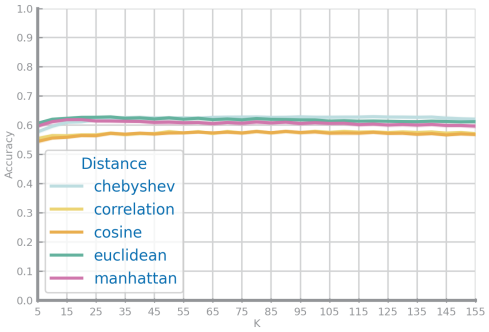

Figure 4: K and similarity measure study.

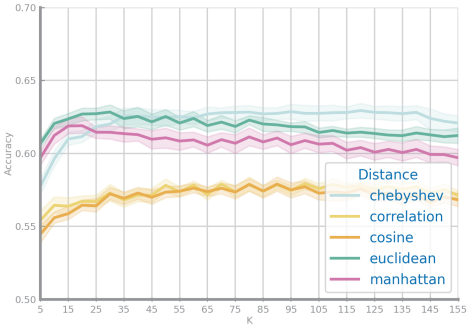

Figure 5: Zoom of K and similarity measure study.

Students Profiler module has five conditions that will be tested in the global system: (120, chebyshev); (100, correlation); (90, cosine); (30, euclidean) and (20, manhattan).

We implemented as well a simple recommendation system where we used the candidate profile, composed by the average grades of all neighbors for all courses taken by them, to predict the candidate grades for all available courses. In this component, four conditions were used for testing the system behaviour for all similarity measures: A) using SVD as matrix factorization technique with the K values mentioned above and considering all the variables from students data; B) same as A), but using K equals to 5; C) using SVD with the best K values predicted using a reduced students dataset with only academic records; and D) same as C) but using the Slope One prediction method.

After that, we used 1509 candidates to test the system, where we computed the GPA that each of them would have in each one of the available programs using their predicted course grades and ranked them by GPAs. Then, we computed the mean absolute error for those which first recommended program coincides with their current program in terms of GPA, and results are showed in Table 1.

Table 1: Mean Absolute Errors for each prediction method and for each similarity measure

Similarity Measure	A	B	C	D
chebyshev	2.065	2.378	2.139	2.289
correlation	2.149	2.580	2.359	2.325
cosine	2.153	2.583	2.430	2.451
euclidean	2.538	2.497	2.153	2.289
manhattan	2.313	2.488	2.376	2.451

The next steps will consist of improving the way we recommend the programs and its ranking model, considering different ensembles, namely random forests and gradient boosting. At this time, we are predicting GPA with almost 90% accuracy.

5. CONCLUSIONS

The current educational context, even more after the beginning of the pandemic situation, demands new educational systems. Systems able to address the difficulties inherent to distance learning contexts, where students are far from educators, and plenty of times try to follow their path without any guidance. Most of the times, online education tools deal with students in a 'one-fit-all' approach, that ignore each students preferences.

In this paper, we propose a new architecture for a recommendation system, designed for suggesting programs to university candidates. Our system benefits from an hybrid architecture, that combines collaborative filtering with a content-based philosophy, exploring the full documentation of programs and courses available. Additionally, we explored the notion of feature stores to easily update the data repositories to support our system.

The proposed architecture is adaptable to smaller contexts, for example for suggesting learning resources at any abstraction levels, such as exercises.

ABSTRACT

Essays test student knowledge on a deeper level than short-answer and multiple-choice questions but are more laborious to evaluate. Automatic clustering of essays, or their fragments, prior to evaluation may reduce the manual effort required. Such clustering presents numerous challenges due to the variability and ambiguity of natural language. In this paper, we introduce two datasets of undergraduate student essays in Finnish, manually annotated for salient arguments on the sentence level. Using these datasets, we evaluate several deep-learning embedding methods for their suitability to sentence clustering in support of essay grading. We find the suitable method choice to depend on the nature of the exam question and the answers, with deep-learning methods being capable of, but not guaranteeing better performance over simpler methods based on lexical overlap.

Keywords

deep learning, essay clustering, text similarity, paraphrase, grading support

1. INTRODUCTION

Essay-type questions have been shown to help with the retention of learned material [10] but are time- and labour-consuming to evaluate. Computational methods can be used to grade essays, or to assist in their evaluation. Examples of the latter approach include pre-processing to show statistics of student answers such as average answer length and keywords [11], comparing student answers to a given text [11], generating word clouds of student answers [6], and grouping student answers into clusters of similar answers [2]. Most of these systems target the pre-processing and analysis of short answers, and less effort has been dedicated to computer-aided assessment of longer essays. One approach to reducing human effort in fact-based student essay assessment computationally would be to identify similar arguments in student essays. This approach draws inspiration from qualitative research methods where interviews are first transcribed verbatim, and categories are then formed and themes are created [5]. By identifying recurring arguments across a cohort of essays, it is expected that human grading effort could be reduced, much like the analysis of interviews is made simpler after forming categories.

In this paper, we evaluate the applicability of several representative deep learning methods to the task of identifying distinctly-phrased, but semantically near-equivalent segments of student essays[1]. We approach the task from two angles. As an *information retrieval* (IR) problem, whereby given a query text, e.g. a reference answer or an essay, the task is to retrieve the matching essays from the cohort, and establish their mutual correspondence down to sentence level. The other approach is that of *clustering*, where the objective is to discover groups of sentence-long segments with same meaning in the essay cohort. We test several algorithms, including TF-IDF [7], LASER [1], BERT [4], and Sentence-BERT [13]. To evaluate these algorithms, we gather and annotate two sets of factual essays written in exams by Finnish university students.

2. DATASETS

We collected Finnish essays written by bachelor's level students as answers to exam questions. Two sets of essays replying to questions from two courses were selected for manual annotation. The annotator was a PhD student from a different discipline than the domain of the essays. The goal of the annotation was to identify similar arguments in separate essays. The data were annotated by cross-referencing the arguments found in every essay, and assigning textual labels to recurring arguments or concepts on a sentence level. Specifically, all essays were first segmented into sentences, and each sentence was then assigned zero or more textual labels representing its content. If an argument appears more than once, it is given a distinct label which is assigned to all sentences containing that argument. For an argument to be considered recurring, the two sentences are required to clearly aim to communicate the same information about a common subject matter. An example of two sentences that are considered to have the same argument (on the pros and cons of group interviews in research): "It is not the quieter and more timid individuals that come out, but the loudest ones come to the fore." and "In a group interview, there is a danger that some will talk too much and some will not have a turn to speak at all." Both of these sentences describe

Table 1: Dataset statistics

	Research methods	Accounting standards
No. of essays	47	10
Total no. of sentences	486	158
No. of labels	59	34
Avg. no. of labels per sentence	1.29	0.82

the imbalance of expression of opinions in group interviews. In the next example, however, the two sentences are considered to have different arguments, despite both of them being related to the role of trust in interviews. "In interviews, a trusting relationship must be established between the interviewee and the interviewer, which can be challenging." and "If the interviewee remains anonymous, one can also openly discuss more sensitive topics, especially when one is alone with the interviewer." This is because the two sentences make opposing arguments: the former takes a positive perspective towards the role of trust in interviews, while the latter views it as a challenge. Clearly, these communicate different information. For each dataset, the number of labels thus depends on the number of recurring arguments in the essays, and the annotation scheme differs. We estimate that the development of the annotation scheme and the annotation effort required about two person-weeks in total. We note that we do not expect to annotated all sets of essays that are to be evaluated. Instead, these two sets of annotations serve as benchmarks for testing ideas on automatically assisting essay evaluation. The two resulting datasets are introduced below. The key statistics of the two datasets are summarized in Table 1 and the distribution of the labels in the two datasets is illustrated in Figure 1 in the Appendix.

2.1 Research methods dataset

The first dataset is created from student essays from the course "Research process and qualitative research methods" (henceforth *Research methods*). The essays answer the question, "Consider the positive and negative aspects of interviews". Several main points are frequently mentioned by students: for example, almost all students discussed how time consuming interviews can be (label `time_consuming`). 93% of the dataset sentences have at least one label, indicating that the great majority of sentences involve at least one argument repeated in other essays.

2.2 Accounting standards dataset

The second dataset consists of student essays from the course titled "IAS/IFRS accounting standards" (henceforth *Accounting standards*). The essay prompt is "What are the components of IFRS financial statements? Consider the significance of the various components in the light of the qualitative criteria for the financial statement information". The label distribution of this dataset is more even, and almost a third of the sentences do not have a label. This may be due to the fact that there are fewer essays in this dataset. This implies that given one main argument, it is less likely that the argument is also mentioned by somebody else.

3. SENTENCE REPRESENTATIONS

To identify sentences with similar arguments, we consider a set of methods for representing each sentence with a vector, which allows efficient computation of sentence similarity via the similarity of their vectors. As baselines, TF-IDF vectors and average of word embeddings are used for sentence representation. For deep learning methods, the encoders LASER, BERT, and Sentence-BERT are tested. The distance measure used is the cosine similarity between two sentence vectors, a standard metric applied also in previous studies.

3.1 TF-IDF

Term frequency–inverse document frequency (TF-IDF) is a family of popular IR metrics that estimate the importance of a given word in a document from a document collection based on the number of times the word appears in the document (term frequency) and the inverse of the number of documents the word appears in (document frequency) [7]. TF-IDF can be applied with words or character sequences. For this baseline, all the tokens in a sentence are first lemmatized using the Universal Lemmatizer [8]. Character ngrams, specifically bigrams, trigrams, 4-grams and 5-grams, are created out of text inside word boundaries. We note that the TF-IDF encoding generates sparse high-dimensional vectors where there is no inherent similarity between words.

3.2 Average of word embeddings

This baseline represents each sentence using the average of the vector representations of the words in the sentence. We use the Finnish word embeddings created by Kanerva et al. [9] and refer readers to this paper for further details of the embeddings. These embedding were induced using the implementation of the skip-gram algorithm [12] in the `word2vec` software package on Finnish Common Crawl data. The average of word embeddings produces dense, comparatively low-dimensional representations that can capture the similarity between words, but the representation of words is independent of the context they appear in.

3.3 LASER

The Language-Agnostic SEntence Representations (LASER) released by Facebook is a sentence embedding method that aims to achieve universality with respect to language and NLP task. The encoder can encode 93 languages, all of which share a byte-pair encoding [14] vocabulary. The encoder consists of a BiLSTM with max-pooling operation, coupled with an LSTM layer during training on parallel corpora [1]. LASER produces dense, low-dimensional representations that can capture the contextual meaning of words.

3.4 BERT

Bidirectional Encoder Representations from Transformers (BERT) introduced by Google is a deep contextual language representation model [4]. The training objectives of BERT make them cross-encoders, i.e. the model takes in a pair of sentences at a time. However, we encode one sentence at a time and use the mean-pooling of the resulting outputs as the sentence representation. We use the uncased variant of FinBERT, a monolingual Finnish BERT Base model that has been demonstrated to provide better performance in Finnish text processing tasks than multilingual BERT [16]. Like LASER, BERT produces dense, low-dimensional representations that account for context.

Table 2: Results of the IR evaluation

Accounting standards	**Avg First**	**Avg Med**	**Avg Mean**	**Avg Last**	**MRR**	**MAP**
TF-IDF	**4%**	**9%**	**11%**	**24%**	0.47	**0.48**
word2vec	6%	17%	20%	40%	0.47	0.34
LASER	**4%**	13%	15%	33%	**0.53**	0.42
BERT	5%	15%	17%	37%	**0.53**	0.41
SBERT	5%	11%	14%	31%	0.46	0.42
Research methods	**Avg First**	**Avg Med**	**Avg Mean**	**Avg Last**	**MRR**	**MAP**
TF-IDF	**1%**	18%	24%	72%	0.46	**0.28**
word2vec	2%	26%	31%	79%	0.34	0.19
LASER	2%	19%	26%	73%	0.42	0.23
BERT	**1%**	**17%**	23%	70%	**0.49**	**0.28**
SBERT	2%	**17%**	**22%**	**65%**	0.43	**0.28**

3.5 Sentence-BERT

Sentence-BERT (SBERT) trains BERT models using Siamese and/or triplet networks to induce a single-sentence encoder specialized for cosine-similarity comparison [13]. We obtain machine translated versions of the SNLI [3] and MNLI [17] corpora using the English to Finnish Opus-MT model [15]. Finnish SBERT is subsequently trained from FinBERT-base-uncased using these two natural language inference corpora. Specifically, the model is fine-tuned for an epoch with learning rate 2e-5 and batch size of 16, with mean pooling as the pooling method. The representations produced by SBERT are dense, low-dimensional, and context-sensitive, like those of LASER and BERT.

4. EVALUATION

The sentence representations are evaluated from IR and clustering perspectives. Six evaluation metrics are used for the IR approach: two well-known metrics **mean reciprocal rank (MRR)** and **mean average precision (MAP)**, and four metrics tailored to our specific task setting. **average of highest rank (Avg first)**, **average of median rank (Avg med)**, **average of mean rank (Avg mean)**, and **average of lowest rank (Avg last)** measure the rank of the highest, median, mean, and lowest rank of the relevant items respectively, as percentage of the whole (0% first rank, 100% last rank), averaged over all items. These four metrics give more insight into the distribution of the relevant retrievals by measuring where, on average, the first, median, mean, and last relevant items are ranked. Since some sentences have more than one label, sentences with at least one overlapping label are considered relevant retrievals for all metrics.

The clustering evaluation measures how well the clustering induced by the vector embeddings corresponds to the clustering induced by the sentence labels. **Cluster accuracy** is based on the most frequent label of a cluster: for each cluster, the majority label is obtained from the ground truth annotations of the sentences in the cluster. A sentence is considered to be correctly clustered if it has the majority label of its cluster as one of its labels. The number of correctly and incorrectly clustered sentences can then be interpreted as an accuracy percentage. We note that random baseline performance varies drastically between different datasets with this metric, so accuracy values are not directly comparable between datasets. **Adjusted Rand index** and **adjusted mutual information** are established clustering metrics. We use sampling to work around the multi-label nature of the annotations: For each sentence with multiple labels, one label is randomly chosen. Then the clusters are evaluated against these labels with the two metrics. This process is repeated 50 times and the values of the metrics are subsequently averaged. The resulting scores are between -1 and 1, and they are adjusted for chance, so that a random clustering has a score close to zero. We use the agglomerative clustering algorithm with ward linkage. Sentences that have no labels, i.e. containing a unique argument, are each given a unique label for the purposes of the clustering evaluation, effectively each forming one singleton cluster. The resulting true number of clusters (60 for the research methods dataset and 95 for the accounting standards dataset) is the clustering model input.

Table 3: Results of the two clustering evaluation methods. Average adjusted Rand (Avg adj. Rand), Average adjusted mutual information (Avg adj. mutual info.), Cluster accuracy (Clus. acc.), Standard deviation (Std dev).

Accounting standards	**Avg adj. Rand**	**Std dev**	**Avg adj. mutual info.**	**Std dev**	**Clus. acc.**
TF-IDF	**0.31**	0.02	**0.33**	0.02	**73%**
word2vec	0.18	0.02	0.23	0.02	69%
LASER	0.21	0.01	0.27	0.01	72%
BERT	0.21	0.01	0.27	0.02	72%
SBERT	0.28	0.01	**0.33**	0.02	**73%**
Research methods	**Avg adj. Rand**	**Std dev**	**Avg adj. mutual info.**	**Std dev**	**Clus. acc.**
TF-IDF	**0.12**	0.01	0.22	0.01	**55%**
word2vec	0.05	0.00	0.13	0.01	41%
LASER	0.08	0.00	0.17	0.01	46%
BERT	0.11	0.01	**0.23**	0.01	50%
SBERT	0.11	0.01	0.22	0.01	51%

5. RESULTS

The IR evaluation results are shown in Table 2. We find that there is no single method that systematically outperforms the others. Surprisingly, for the accounting standards dataset, the advanced methods fail to outperform the TF-IDF baseline, which achieves the highest results for all metrics except MRR. This indicates that while TF-IDF is not the most competitive in consistently ranking relevant items at the highest ranks, it is able to concentrate relevant items towards higher ranks in general. This is particularly evident for the average of the lasts metric, where TF-IDF scores 7% points higher than the second best performer, SBERT. Here the number 24% indicates that, for the accounting standards dataset, TF-IDF on average ranks all the relevant items within rank 24 out of 100. The high performance of TF-IDF on this dataset may be attributed partly to the essay prompt requiring students to list the correct keywords. The elements of the IFRS financial statements are only so many, and these items cannot be paraphrased. Methods that compare strings directly thus outperform methods that use dense vector representations that approximate their meaning.

The research methods dataset, however, does not have such a strong emphasis on exact keyword matching: there are no fixed numbers of keywords that have to be mentioned in the answers. Rather, the pros and cons of interviews as a research method are described, and thus sentences that

describe the same concept using different words are more likely to occur. On this dataset, considering the retrieval of the first relevant item, both TF-IDF and BERT perform best on the average of the firsts metric, while BERT performs best on the mean reciprocal rank. Since the average of the firsts metric is more lenient on lower rankings of first relevant items, we can infer that BERT performs more consistently on the retrieval of the first relevant item. Overall, BERT-based methods obtain better results, with SBERT in particular outperforming the other methods by 5% points on the retrieval of the last relevant items. BERT and SBERT both obtain the highest results on four out of six metrics.

The results of the clustering evaluation are summarized in Table 3. These results clearly tend towards the TF-IDF baseline, while the word2vec-based approach is the weakest, tallying with the IR evaluation. Of the neural methods, SBERT is particularly strong in the accounting standards dataset, while being in line with BERT in the research methods dataset. Of the two sentence embedding methods, SBERT outperforms LASER in all tests. We are surprised to find that the TF-IDF model seems to be better suited to the clustering objective than the neural methods, and will examine this in future work.

Overall, we find that the comparative ranking of the methods varies strikingly depending on the dataset, evaluation setting, and metric. The dataset dependence may partly be explained by the nature of the arguments made: if the argument is required to contain certain specific terms, TF-IDF can be a very strong method. On the other hand, if the argument involves more abstract concepts that can be expressed in many ways, neural methods may have an advantage over methods that are based on exact string matching. While deep neural methods have led to breakthroughs in many NLP tasks, the gain they show here over the simple TF-IDF baseline is quite small even in the cases where they outperform it. This may indicate challenges specific to the task and domain beyond those we have identified here, and calls for further research into the topic. This includes searching for more suitable encoding methods, improved evaluation methods, and also study of how data should best be annotated to develop methods serving the needs of essay graders.

6. DISCUSSION

Our annotation makes at least two assumptions that call for further investigation: the sentence is the unit of annotation, and the labels are categorical and non-overlapping. Figure 1 shows that approximately 57% and 64% of the sentences in the Accounting standards and Research methods datasets (respectively) have exactly one label. Another 33% and 7% (resp.) of sentences do not have any labels. Since labels are only assigned if a main argument appears more than once, these sentences can be seen as singleton clusters with a label that occurs exactly once. With the current annotation granularity, the annotation is best applicable to cases where each sentence conveys a single main argument. However, the annotation statistics indicate that sentence may not always be the most suitable unit of annotation. These include cases where an argument is made across several sentences, and where a sentence makes several arguments.

In addition to issues related to the sentence as a unit of annotation, there is also a degree of subjectivity to their labeling. For example, in the Research methods dataset, the two labels `workload` and `time_consuming`, which state that interviews are labor-intensive and time-consuming respectively, could arguably be merged. For such boundary decisions to be helpful for essay graders, the marking criteria play a central role and there is no universal cut-off. As an alternative to disjoint categorical labels, one could consider that the arguments (and the labels that represent them) can be organized hierarchically. For instance, in the research methods dataset, the label `interviewer_influence` represents the argument that the stance of the interviewer may affect the research results, and the label `unnatural_performance` describes the affect of the interview situation on the performance of interviewees. On a higher level, both of the labels convey the research results being negatively affected by artificial factors. For these two datasets, the boundary decisions also depend on the sample size: if there are more essays, chances are that a small number of students make the exact same argument, in which case the boundary is unambiguous, or could be seen as a subcluster of a bigger cluster. We hope to address these and related challenges in future work.

One focus of our ongoing work is the practical use of the clusters. An approach to capitalizing on these clusters would be to make them manually adjustable, i.e. examiners can adjust the contents of the clusters, create new clusters, and delete clusters. These clusters can then be color-coded or annotated with text, indicating whether the presence of a certain cluster is desirable in an essay. In addition, if reference answers are available, essays with more overlapping clusters with the reference answers can be automatically identified.

7. CONCLUSIONS AND FUTURE WORK

We focused on the task of computer-assisted assessment of comparatively long essays through the perspectives of IR and clustering. We have created two datasets based on two exam questions from different fields, on which we tested several deep-learning methods with respect to their ability to retrieve and cluster sentences containing the same arguments paraphrased. We found no method to be universally best; rather, the results depend on the nature of the essays under assessment. Overall, the difference between the state-of-the-art deep learning methods and the much simpler TF-IDF baseline is not numerically large, leaving clear room for further development and application of more advanced methods for embedding meaning. Developing such methods, as well as further practical testing of the approach constitute our future work.

ABSTRACT

The extraction of sentiment from text requires many methodological decisions to make inferences about mood, opinion, and engagement in informal learning contexts. This study compares sentiment software (SentiStrength, LIWC, tidytext, VADER) on $N = 1{,}382{,}493$ tweets in the context of the Next Generation Science Standards reform ($N = 546{,}267$) and U.S. State Educational Twitter Hashtags ($N = 836{,}226$). Automated sentiment classifications were validated on $N = 300$ hand-coded tweets. Additionally, we developed a discrepancy measure to identify tweet features associated with scale inconsistency. Results indicated that binary sentiment classifications (positive/neutral vs. negative) were more accurate than trinary classifications (positive, neutral, negative). Combined tidytext dictionaries and VADER outperformed LIWC for negative sentiment, which was overall difficult to classify reliably while positive sentiment was classified with high accuracy across all four dictionaries. Thus, researchers are encouraged to (a) consider employing overall sentiment scales or positive/neutral to negative ratios based on binary classification to characterize their sample, (b) aggregate multiple dictionaries or use domain-specific sentiment dictionaries, and (c) be aware of the current limitations of detecting negativity through dictionary-based sentiment analysis in educational contexts.

Keywords

Social media data, sentiment analysis, online communities

1. INTRODUCTION

Sentiment analysis extracts positive and negative emotions from text. Its many applications include stock market prediction [22], marketing research [29], and, recently, investigating public sentiment on educational reforms on Twitter [32, 38]. Sentiment analysis typically requires numerous methodological decisions, such as deciding whether to use a dictionary-based or a supervised machine learning approach and determining how sentiment measures are suited to the investigation of a particular domain (e.g., VADER for social media data) [13, 30].

User-defined sentiment dictionaries (UDDs) rely on matches of word occurrences with a value in their dictionary, with little overlap often yielding less valid results. Whereas many sentiment measure validation studies investigate binary (i.e., positive and negative) sentiment classifications [1, 25, 28], less research has systematically compared trinary classifications (i.e., positive, neutral, negative) and sentiment scales. Furthermore, as sentiment classifiers do not generalize well across domains [2], sentiment validation studies are needed to inform educational researchers utilizing the increased availability of big data in education [7]. This study examines the performance of popular sentiment analysis methods in the context of a particular, social media-based data source: large education-related Twitter communities.

The motivation of this study is two-fold. First, sentiment measures can give insight into how and why teachers engage in online communities on Twitter, a potentially novel form of informal teacher learning [6, 33]. Second, public opinion and sentiment can be viewed as a proxy for successful reform implementation [4, 27]. Wang and Fikis applied SentiStrength on more than 660,000 tweets related to the Common Core State Standards, finding sentiment, including that expressed by teachers, to be largely negative [38]. In contrast, Rosenberg et al. found largely positive sentiment in 570,000 NGSS-related tweets through the same SentiStrength algorithm [32]. However, the validity of the utilized sentiment methods was not examined.

2. RESEARCH BACKGROUND

2.1 Sentiment Analysis Methods and Tools

Sentiment analysis is frequently carried out through *user-defined dictionaries* (UDDs) [9]. UDDs contain sets of labeled words that are rated on affect dimensions (e.g., valence, potency, activity) and matched to word occurrences in texts [23]. Researchers can either use pre-defined dictionaries or create their own dictionaries [9]. UDD methods

Conrad Borchers, Joshua Rosenberg, Ben Gibbons, Macy Alana Burchfield and Christian Fischer "To Scale or Not to Scale: Comparing Popular Sentiment Analysis Dictionaries on Educational Twitter Data". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 619-624. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

examine words individually, potentially neglecting figurative language and ambiguous phrases [36]. This study examines four popular examples of UDD software: (a) SentiStrength, (b) Linguistic Inquiry and Word Count (LIWC), (c) the R-package tidytext, and (d) the social-media attuned software VADER.

SentiStrength outputs two truncated five-point scales [37] which is different from many other UDD implementations. It offers feature selection options and measures sentiment weight, which is the intensity or strength of positivity or negativity in a text, as opposed to simply comparing the frequency of sentiments in a text [14].

LIWC is possibly the most popular text analysis software [17]. It uses a well-validated default dictionary [16] and contains around eighty subdictionaries of topics for which it outputs individual scales [26]. LIWC has been used to infer psychological processes and constructs (e.g., emotional expressions) from text [36].

Tidytext [34] does not provide its own default dictionary. At its core, it strives to pre-process input text which is then analyzed through any input dictionary [35]. Tidytext provides functions for converting text into a "one-token-per-document-per-row" format which may ease text analysis.

VADER (Valence Aware Dictionary for Sentiment Reasoning) features multiple subdictionaries and considers word order and degree modifiers (e.g., "very", "slightly", "somewhat") [5]. It performs well in sentiment analyses of social media content (including from Twitter) while remaining applicable to other contexts [5, 13]. That said, we found the R implementation of VADER to take around 80 times longer to compute compared to the other methods.

2.2 Research Questions

This study examined the validity of SentiStrength, LIWC, tidytext, and VADER in the context of educational Twitter data with the following research questions (RQs):

RQ1: How valid are the employed sentiment measures with respect to human coding of sentiment?

RQ2: How discrepant are sentiment scales and are correlations among scales consistent with these discrepancies?

RQ3: Which features of texts (i.e., the number of words, likes, retweets, and context) account for scale discrepancy?

3. METHOD

3.1 Sample

The study utilized tweets related to the Next Generation Science Standards reform and large educational state-wide hashtags (1,382,493 tweets, 156,446 users) posted between July 2008 and October 2020. Search terms included the #NGSSchat hashtag (N = 175,094 tweets, N = 67,060 of which being inside of designated chat-sessions), the terms "ngss" (without #NGSSchat, N = 312,167 tweets) or "next gen[eration] science standard[s]" (N = 59,006 tweets). In addition, we included tweets from 47 State Educational Twitter Hashtags (N = 836,226). Tweets not recognized as of English language by the Twitter API were omitted (5.0%).

3.2 Sentiment Measures

To investigate the validity of different sentiment measures, we used SentiStrength [37], LIWC [26], tidytext [34], and VADER [13] to obtain (a) binary and trinary classifications, (b) unidimensional (positive and negative) sentiment scales, and (c) a bidimensional sentiment scale rating for all tweets. While SentiStrength has binary and trinary classification methods, we subtracted negativity ratings from positivity ratings to obtain overall scores and defined a tweet as neutral if that overall rating was 0 (over 0 as positive, under 0 as negative) for LIWC and tidytext. For tidytext, we used the NRC [24], Loughran-McDonald [20], AFINN [10], and Bing [12] dictionaries, standardizing ratings by the number of words in each tweet and averaging across available ratings. The remaining non-matches were assigned a 0. For VADER, we used its internal compound score as overall scale and classified tweets as neutral if that score was between -0.05 and 0.05 (instead of 0) [13]. Binary classification combined positive and neutral tweets, such that neutral tweets were coded as positive, as done in previous validation studies [8] and since we observed that SentiStrength always classified tweets rated neutral in its trinary method positive in its binary method. Additionally, we defined ambiguity measures for all sentiment dictionaries as the sum of the absolute values of their positivity and negativity ratings.

3.3 Additional Variables

Continuous predictor variables included the number of likes, retweets, and words (excluding links and user mentions) of each tweet. To account for some features of the specific data sets we analyzed, we created a *categorical predictor variable* indicating whether a tweet was from the NGSS or SETHs data set (and, for the NGSS data set, whether the tweet was posted inside of #NGSSchat, designated chat-sessions of #NGSSchat, or included the term "ngss").

3.4 Data Analysis

3.4.1 Hand-coding and validation

To provide a validation set of tweets to investigate how UDDs compare to human-evaluated sentiment (RQ1), two raters hand-coded 300 randomly sampled tweets on two 1-5 scales for positivity and negativity, similar to SentiStrength. Our two raters reached a consensus of $\kappa = 0.728$ for positivity and $\kappa = 0.689$ for negativity after coding 70 tweets independently, fulfilling common thresholds for satisfactory agreement [21]. After discussing and resolving any disagreements, an additional 230 tweets were coded independently. The binary and trinary sentiment classifications of human coders were assigned analogously to how they were created for the other UDDs. We calculated accuracy, precision, recall, and F-score for each category in each classification method (binary and trinary).

3.4.2 Scale consistency and discrepancy index

To quantify scale discrepancy for RQ2, we normalized the sentiment scales to $M = 0$ and $SD = 1$, accounting for SentiStrength's truncation of scales at |5| (contrasting LIWC, tidytext and VADER). As a discrepancy index, we calculated the absolute difference between normalized scales for positivity, negativity, and overall scales for all six pairs of sentiment measures. For each tweet and scale type, the total scale discrepancy was summed up and divided by the

number of comparisons. As a robustness check for our discrepancy measure, we calculated pairwise scale correlations between methods.

3.4.3 Predictive modeling of scale discrepancy

To examine RQ3, we conducted three ordinary least square linear regression models to predict discrepancy in the (a) positivity, (b) negativity, and (c) overall scales through various tweet properties. Model assumptions (normal distribution of residuals, homoscedasticity, linearity assumptions and leverage) were investigated through graphical model tests in R. Robust standard errors (HC3 estimator [19]) were used to address residual heteroscedasticity for discrepancy in the positivity scales. Independent variables included tweet context and the number of words, likes, and retweets of a tweet. We also included binary classifications (0: negative, 1: positive or neutral) to investigate whether scale discrepancies varied with sentiment polarity and ambiguity ratings to estimate whether tweets being high in positivity and negativity were less consistently rated than tweets with less emotional valence. All independent variables had a generalized variance inflation factor (GVIF) of less than 5 [3].

4. RESULTS

4.1 Validation of Sentiment Measures (RQ1)

4.1.1 Dictionary coverage

Coverage characterizes the fit of user-defined dictionaries with the data. Coverage is the relative frequency of texts that had a least one match inside a specific dictionary. We observed a coverage of 58.91% for SentiStrength, 55.7% for LIWC, and 67.7% for VADER. The combined tidytext dictionaries had a coverage of 84.9%. As subdictionaries, coverage was 70.5% for NRC, 62.0% for AFINN, 56.9% for Bing, and 34.9% for the Loughran-McDonald dictionary.

4.1.2 Hand-coded tweets and validation

Comparing human coders with SentiStrength's scale ratings (LIWC, tidytext and VADER do not output 1-5 scales; we describe these later in this section), we found a moderate two-way random effects ICC for absolute agreement [18] for both the positivity scale, $ICC2k = 0.690$ [0.57, 0.77] and the combined, overall scale, $ICC2k = 0.683$ [0.59, 0.75]. The negativity scale exhibited worse agreement, $ICC2k = 0.448$ [0.31, 0.56]. Notably, Cohen's kappa ratings were not satisfactory with $\kappa = 0.301$ for positivity, $\kappa = 0.270$ for the overall scale, and $\kappa = 0.183$ for negativity [21].

Tables 1 and 2 describe the validity of the binary and trinary classifications for SentiStrength, LIWC, tidytext, and VADER. We found trinary classifications to have higher accuracy scores than binary classification (ranging from 85.00% to 88.33% and 56.33% to 67.00%, respectively). Notably, we found classifications of negative tweets to be less accurate than for positive tweets, with F-scores of tidytext and VADER (0.45 and 0.44, respectively) being higher compared to SentiStrength and LIWC (0.38 and 0.29, respectively). To test whether these differences were significant or random, we ran permutation tests with 250,000 simulations [39]. Tidytext and VADER improved compared to LIWC, but not to SentiStrength, (albeit marginally) significantly ($p = .058$ and $p = .047$, respectively), although only 11.67% of tweets were rated as negative by human coders.

4.2 Consistency of Sentiment (RQ2)

4.2.1 Positivity scale

For positivity scales, LIWC and VADER were the most consistent with each other based on scale correlation ($r = .83$) and mean discrepancy (0.41 *SDs*) followed by tidytext and VADER ($r = .71$, 0.53 *SDs*) and LIWC and tidytext ($r = .63$, 0.61 *SDs*). On average, positivity scales yielded pairwise correlations of $r = .63$ and scale discrepancies of 0.60 *SDs* (Table 3).

4.2.2 Negativity scale

For negativity scales, LIWC and VADER were the most consistent with each other based on scale correlation ($r = .68$) and mean discrepancy (0.33 *SDs*) followed by SentiStrength and LIWC if based on scale correlation ($r = .61$, 1.14 *SDs*) and LIWC and tidytext if based on scale discrepancy ($r = .09$, 0.59 *SDs*). On average, negativity scales yielded pairwise correlations of $r = .35$ and scale discrepancies of 0.83 *SDs* (Table 3).

4.2.3 Overall scale

For overall scales, LIWC and VADER appeared to be closest based on scale correlation ($r = .69$) and mean discrepancy (0.54 *SDs*) followed by LIWC and tidytext ($r = .65$, 0.59 *SDs*), SentiStrength and VADER ($r = .64$, 0.65 *SDs*), and SentiStrength and LIWC ($r = .56$, 0.64 *SDs*), respectively. On average, overall scales yielded pair-wise correlations of $r = .61$ and scale discrepancies of 0.64 *SDs* (Table 3).

Table 3: Pairwise scale correlations (Corr) and discrepancy (Disc) for positivity, negativity, and overall scales of SentiStrength (SS), LIWC (LI), tidytext (TT), and VADER (VA)

	Pos		Neg		Scale	
	Corr	Disc	Corr	Disc	Corr	Disc
SS, LI	0.54	0.64	0.61	1.14	0.56	0.64
LI, TT	0.63	0.61	0.09	0.59	0.65	0.59

4.3 Understanding Scale Discrepancies (RQ3)

Linear models for evaluating scale discrepancies included four notable associations between tweet properties and scale discrepancies (Table 4). First, all four ambiguity measures were positively associated with scale discrepancy measures across all three models, most notably SentiStrength's ambiguity measure with negativity scale discrepancy, $\beta = 0.21$, $t(1382478) = 229.30$, $p < .001$. Second, for binary classifications (i.e., positive/neutral vs. negative), negative tweets tended to have higher negativity discrepancy and vice versa. For example, discrepancy in negativity scales was negatively associated with tweets classified as positive/neutral by SentiStrength, β = -0.64, $t(1382478)$ = -281.13, $p < .001$. Meanwhile, tidytext classifying tweets as positive was associated with increased positivity discrepancy, $\beta = 0.30$, $t(1382478) = 129.71$, $p < .001$. Third, text- and tweet-specific variables (e.g., number of words, likes, and retweets) did not seem to be associated with scale discrepancy, while tweet context had a small effect size. For instance, tweets from State Educational Twitter Hashtags were positively associated with negativity scale discrepancy, $\beta = 0.05$, $t(1382478) = 52.86$, $p < .001$. Fourth, the explained variance in scale discrepancy was highest for negativity scales at 75.3%, followed by overall scales (23.5%) and positivity scales (22.4%).

5. DISCUSSION

5.1 Key Findings

This study evaluates sentiment analysis methods on educational Twitter data. Our three main findings are as follows:

First, negative sentiment is difficult to reliably detect with dictionary approaches. This could be due to nuanced linguistic markers (e.g., sarcasm) that require advanced algorithms to be detected [31]. While this finding aligns with previous work [30], it contrasts initial validations of SentiStrength [37] on a set of around 1,000 MySpace comments [37]. Nonetheless, this highlights the importance of validating commonly used sentiment analysis tools across multiple contexts. Thus, we encourage researchers to carefully examine how negativity may be expressed in their study context.

Second, in the context of educational Twitter data, binary sentiment classifications that combine positive and neutral sentiment are substantially more robust than trinary classifications. Thus, researchers may consider computing the ratio of negative to positive/neutral tweets, similar to a recent Twitter study on the Common Core State Standards [38]. For a continuous variable, our findings suggest using an overall scale, as discrepancy in negativity was substantially associated with ambiguity and binary classifications.

Third, in the context of educational Twitter data, tidytext and VADER produce more accurate classifications of negative sentiment than LIWC. Notably, tidytext also has the highest dictionary coverage. Thus, educational researchers are encouraged to aggregate multiple dictionaries or to create domain-specific sentiment dictionaries for more reliable measures of negative sentiment, for instance, similar to a previous study investigating political expression [11].

5.2 Limitations

This study has two notable limitations. First, the sample size of the training data is relatively small ($N = 300$). That said, it is comparable to sample sizes of previous sentiment measure validation studies [28]. Similarly, the lack of negative tweets in our training data (11.67%) may limit inferences about that particular type of sentiment. The number of negative tweets is considerably smaller compared to previous validation studies utilizing text data from sources such as MySpace, Twitter, BBC forums, and YouTube that include up to 86.84% negative sentiment [8]. Therefore, future validation studies should deliberately sample more negative tweets [13] or sample from contexts with higher expected negativity, such as Common Core State Standards hashtags [38]. Second, this study focuses on dictionary-based sentiment analysis, while future studies might also consider feature extraction and word co-occurrence methods [15].

5.3 Implications

This study highlights the importance of coverage, validity, and scale discrepancy in sentiment analysis, specifically for negative sentiment. For educational Twitter data, this study recommends using binary classifications or overall scales, preferably derived from tidytext or VADER, and encourages replication studies[1] across more educational contexts.

Knowledge Tracing Models' Predictive Performance when a Student Starts a Skill

ABSTRACT

Previous studies on the accuracy of knowledge tracing models have typically considered the performance of all student actions. However, this practice ignores the difference between students' initial and later attempts on the same skill. To be effective for uses such as mastery learning, a knowledge tracing model should be able to infer student knowledge and performance on a skill after the student has practiced that skill a few times. However, a model's initial performance prediction – on the first attempt at a new skill – has a different meaning. It indicates how successful a model is at inferring student performance on a skill from both their performance on other skills and from the difficulty and other properties of the first item the student encounters. As such, it may be relevant to differentiate prediction in these two contexts when evaluating a knowledge tracing model. In this paper, we describe model performance at a more granular level and examine the consistency of model performance across the number of student instances on a given skill. Results from our research show that much of the difference in performance between classic algorithms such as BKT (Bayesian Knowledge Tracing) and PFA (Performance Factors Analysis), as compared to a modern algorithm such as DKVMN (Dynamic Key-Value Memory Networks), comes down to the first attempts of a skill. Model performance is much more comparable by the time the student reaches their third attempt at a skill. Thus, while there are many benefits to using contemporary knowledge tracing algorithms, they may not be as different as previously thought in terms of mastery learning.

Keywords

Knowledge Tracing, Cold Start, Deep Knowledge Tracing, Bayesian Knowledge Tracing, Performance Factors Analysis, Dynamic Key-Value Memory Networks

1. INTRODUCTION

Knowledge Tracing (KT), attempting to measure student knowledge through performance during learning, is a critical component in modern intelligent tutoring systems and adaptive learning systems [18]. These models use students' previous performance to predict their proficiency on latent knowledge and infer their likelihood of success in future attempts within the learning system.

For well over a decade, Bayesian Knowledge Tracing (BKT; [5]) was the dominant algorithm in research on knowledge tracing – it remains the dominant algorithm in use in systems used at scale by students today. Later on, two waves of competing algorithms emerged – a first wave around 2010, including many psychometrically-influenced algorithms such as Performance Factor Analysis (PFA; [17]) and a second wave in the mid-to-late 2010s based on neural networks, including Deep Knowledge Tracing (DKT; [19]) and Dynamic Key-Value Memory Networks (DKVMN; [26]). Work over the last decade has shown that variants of BKT and PFA that take individual differences and timing into account perform better [9, 15, 25]. The current wave of algorithms based on neural networks, such as DKT and DKVMN, have reported further improvements to model fit [12, 26].

The comparisons between these algorithms have generally focused on metrics comparing overall success at predicting on later items, within the learning system applied to held-out students. In these comparisons, multiple large data sets are typically used, but performance is considered evenly across the data set. However, there are some reasons to think this may be a concerning practice. For one thing, even though the data sets used are typically large, these papers generally do not report if samples are large for all skills. Coetzee [4] notes that BKT parameter estimation is more precise for larger data sets than smaller data sets. Furthermore, Gervet [10] concluded that algorithms based on logistic regression, such as PFA, tend to underfit large datasets, while deep learning based algorithms, like DKT, tend to overfit larger datasets.

More concerningly, many data sets used in student modeling have skills which have only been encountered once or twice by many students, either due to stop-out [3] or rarely-tagged secondary skills. Slater and Baker [22] suggest that BKT models cannot be reliably fit unless there is sufficiently large pool of students who have at least three opportunities to practice each skill. As such, large proportions of existing data sets may reflect a seeming special case. Indeed, accurate prediction on these items likely reflects something different than accurate prediction after a student has had more practice. When a student has not yet worked on a skill, predicting their performance at this point represents what is referred to as a "cold start problem" – needing to perform well before having sufficient data for the current student [24]. It is possible that some more recent algorithms may perform better in these situations than earlier algorithms, either by using information from the student's performance on other skills or information on the difficulty or other properties of specific items. However, this better performance may reflect something different than the student's knowledge of the current skill being studied. As such, it may be meaningful to separate out cold start situations (for a given student and skill) from situations where the model has sufficient data to estimate the current skill by itself, when comparing KT algorithms.

In this paper, we study how the performance of three KT algorithms changes, depending on how much data the algorithms have on the current student's performance on the current skill. We compare the classic algorithms BKT and PFA to a more recent neural network-based algorithm, DKVMN, using the ASSISTments 2009-2010 Skill Builder data [7]. Within each model, the predictive performance, determined by AUC ROC (Area Under the Receiver-Operating Characteristic Curve) and RMSE (Root Mean Square Error) was analyzed at students' first through eighth encounter on a skill, reflecting the changes in model performance as students practice a skill more. We conclude with a discussion of the implications of our finding, for both the evaluation and use of knowledge tracing models.

2. METHODS

2.1 Data

In this study, we utilized the ASSISTments Skill Builder 2009-2010 dataset [7], using the updated version which represents an item requiring multiple skills as a single data point [23]. This specific dataset was chosen because it has clearly defined skills and because this dataset had frequently been used to compare KT models in previous research [11, 13, 14, 23, 27].

In the data preprocessing stage, we removed items not linked to any skill. Each student attempt was annotated with how many opportunities to practice the relevant skill(s) the student had encountered so far – i.e., the first instance means the learner is encountering a skill for the first time, the eighth instance indicates that the learner is encountering the skill for the eighth time. The resultant data set consisted of 4,151 students who attempted 16,891 unique problems on 101 skills, resulting in 274,590 responses. While all the skills were included in model training, only the four most common skills are discussed below (see Table 1).

While using the ASSISTments platform, students have to correctly answer *n* problems in a row to achieve mastery of a skill (where *n* is set by the teacher, but is usually three) and can only then move on to another skill. Given the design of the platform's three-in-a-row mastery learning approach, there is a drop in sample size as the number of instances increases (a common pattern in adaptive learning systems). There is also attrition due to stop-out, where students stop working on a problem set without mastering it [3]. Table 1 shows that across all four skills, the number of students encountering a specific skill *n* times decreased with instance. Of the four skills, an average 20% and 45% attrition rate is observed on the third and eighth instances, respectively.

Table 1: Number of students per instance in each skill

Skill Name	1	2	3	4	5	6	7	8
Addition and Subtraction Fractions	1353	1066	978	920	836	756	692	625
Addition and Subtraction Integers	1226	1021	790	693	640	579	510	460
Conversion of Fractions Decimals & Percents	1225	1145	1121	1034	982	928	852	781
Equation Solving Two or Fewer Steps	961	877	857	821	795	745	722	690

2.2 Model Construction

We constructed the following three knowledge tracing models with the preprocessed ASSISTments 2009 dataset: BKT, PFA and DKVMN. Each model was implemented with 5-fold student-level cross-validation. For the cross-validation, the dataset was split into five folds at the student level. Four folds were used to train the model and the trained model predicted student's performance in the 5th fold. Each part acted as the test set once. Predictions in the test sets were combined and used to compute AUC and RMSE for each opportunity to practice, within each skill. For comparability, the original skills were used to calculate opportunities to practice rather than the new skills derived by DKVMN. The folds were kept the same across models, reducing the likelihood of randomly favoring one algorithm over another. The metrics were averaged across the four skills in each instance for each model.

BKT and PFA predict students' success at each attempt based on their previous performance on the skill. When predicting a student's success on the first attempt of a new skill, without having any prior data, the initial prediction made by BKT and PFA reflect the overall student performance across the entire (training) data set on that skill, instead of the individual student's knowledge level on the skill. By contrast, the deep learning model DKVMN utilizes all of a student's historical data and exploits the underlying relationships between concepts. This transferability of prediction across skills can be expected to give the algorithm an advantage of making the initial predictions on a newly-encountered skill. In fact, [14] studied the effect of interaction among skills in DKT, a closely-related deep learning model, and compared it to BKT. By comparing different approaches to leverage skill data, they concluded that DKT's better performance may be largely due to their use of a student's performance on one skill to predict performance on another skill, whereas skills are strictly separated in BKT. PFA occupies a middle ground, as skills do not directly influence each other, but their combinations in the training set may influence the model parameters found during fitting.

The two widely studied deep learning algorithms DKT and DKVMN utilize neural networks to discover underlying relationships among skills and items when predicting student performance. Because of this, both algorithms have shown significant improvements in model fit compared to traditional algorithms. However, DKT maps the relationships on item level while DKVMN fits a skill model from scratch by considering the relationship among skills and items. Given the purpose of the study is to understand whether transferring information between skills influences a model's accuracy during the first few opportunities, DKVMN is a closer comparison to BKT and PFA within the class of deep learning-based KT algorithms.

2.2.1 Bayesian Knowledge Tracing

Bayesian Knowledge Tracing (BKT; [5]) inputs performance into a simple Markov model that is also a Bayesian Network [20]. To fit BKT, we applied BKT-Brute Force [1] to the data set with a floor of 0.01 for all probabilities and a ceiling of 0.3 for guess and slip to avoid model degeneracy [2]. The algorithm produced estimations for guessing, slipping, initial knowledge, and learning transition probabilities for each of the skills, which were then used to predict the probability of success for each student on each opportunity to practice each skill.

2.2.2 Performance Factors Analysis

Performance Factors Analysis (PFA; [17]) is a model that predicts learner performance using a logistic function that models changes in performance through learners' success and failures within a skill. In this study, following the formulas in [17], the basin hopping algorithm was used to fit the model to obtain the optimal parameters. A set of parameters for success, failure and skill difficulty was derived for each skill, which were then used to compute the

probability P(m) that the student would perform correctly, for each student at each opportunity to practice each skill.

2.2.3 Dynamic Key-Value Memory Networks

Developed based on neural networks, Dynamic Key-Value Memory Networks (DKVMN; [26]) employs two matrices that capture states and the relationships between skill and student mastery to predict performance on items and estimate mastery on a set of automatically-derived skills. We utilized code from Zhang et al. [26] to implement the DKVMN model and used the set of parameters that produced the optimal outcome for the ASSISTments 2009 dataset in the study. The model outputs a probability of success for each student at each problem.

3. RESULTS

3.1 AUC Results

Table 2 summarizes the average AUC results for each of the eight opportunities to practice each skill and the combined AUC for opportunities three through eight in the BKT, PFA, and DKVMN models. Additionally, the overall AUC across the first eight opportunities is also reported for the four skills. Note that the overall AUC only includes the targeted four skills in the first eight attempts and therefore, should not be considered to be the overall AUC of the algorithm across the entire data set.

For the first eight instances, a general upward trend is observed in AUC for all three models. Starting at the first instance, the AUC value for BKT is 0.49, PFA is 0.52, and DKVMN is 0.65. At this point, the AUC value for the DKVMN model is much greater than that of other two models, by approximately 0.15. Compared to BKT and PFA, DKVMN is better at making the initial prediction on the very first time a student sees a skill. In fact, at this point, both BKT and PFA are performing at or below chance.

In the following instances, the values of BKT and PFA became closer to the performance of DKVMN. In fact, by the fourth instance, the models' AUC values were fairly similar, having a range of 0.65-0.70. From the fourth opportunity to the eighth, the AUC values increased by 0.02 to 0.06 across skills. Performance stayed similar between algorithms at this point, but DKVMN still tended to achieve slightly higher performance. Across the 3rd-8th opportunities, DKVMN averaged AUC 0.02-0.05 higher than the other two algorithms (0.70 versus 0.68 for BKT and 0.65 for PFA). These trends can be seen in Figures 1-3.

Table 2: Average AUC values in each instance

Model Type	1	2	3	4	5	6	7	8	3-8	All (1-8)
BKT	0.49	0.63	0.68	0.68	0.68	0.68	0.66	0.70	0.68	0.66
PFA	0.52	0.59	0.63	0.65	0.65	0.65	0.66	0.71	0.65	0.63
DKVMN	0.65	0.68	0.70	0.70	0.70	0.69	0.69	0.72	0.70	0.69

Figure 1: AUC results for BKT model across instances

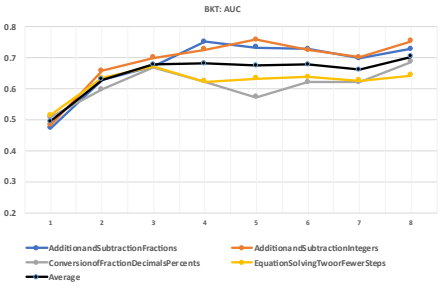

Figure 2: AUC results for PFA model across instances

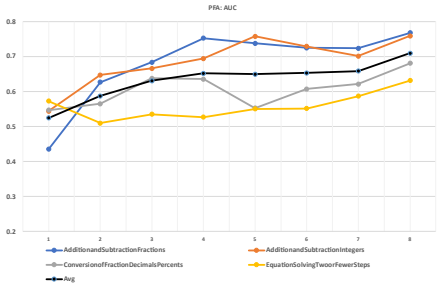

Figure 3: AUC results for DKVMN model across instances

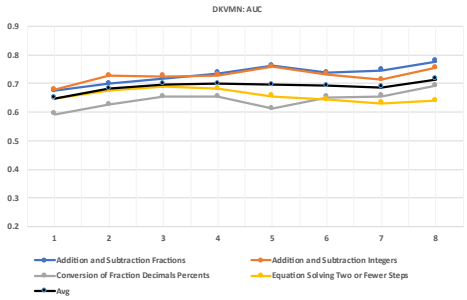

3.2 RMSE Results

Table 3 summarizes the average RMSE results for each opportunity to practice the skills and the combined RMSE for the 3rd-8th opportunities and the 1st-8th opportunities in the BKT, PFA, and DKVMN models. Again, the RMSE reported in the table only considers the targeted four skills in the first eight opportunities.

The RMSE demonstrates a downward trend across the first eight opportunities in all three models. As RMSE measures the difference between actual and predicted values, lower RMSE values indicate more accurate predictions. In the first instance, the RMSE value for BKT is 0.49, PFA is 0.51, and DKVMN is 0.47. As the RMSE value for DKVMN is better than that of BKT and PFA, similar to the AUC value, DKVMN is better able to predict student knowledge at the first attempt (0.02 better than BKT and 0.04 better than PFA).

In the following instances, the values of BKT and PFA became closer to the performance of DKVMN. In fact, by the fourth instance, the models' RMSE values were fairly similar, having a range of 0.43-0.46. From the fourth opportunity to the eighth, the RMSE values in all three models roughly remained the same across skills. Across the 3rd-8th opportunities, DKVMN's average RMSE was similar to BKT and 0.02 lower than PFA (0.44 versus 0.44 and 0.46). These trends can be seen in Figures 4-6.

Table 3: Average RMSE values for all models in each instance

Model Type	1	2	3	4	5	6	7	8	3-8	All (1-8)
BKT	0.49	0.46	0.44	0.44	0.44	0.44	0.45	0.44	0.44	0.45
PFA	0.51	0.48	0.46	0.46	0.47	0.46	0.48	0.46	0.46	0.47
DKVMN	0.47	0.45	0.44	0.43	0.44	0.44	0.45	0.43	0.44	0.45

Figure 4: RMSE results for BKT model in each instance

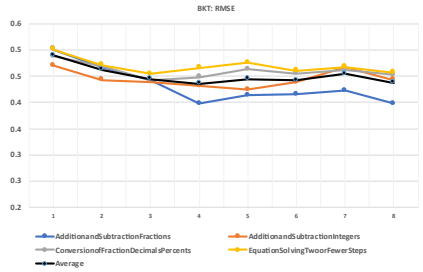

Figure 5: RMSE results for PFA model in each instance

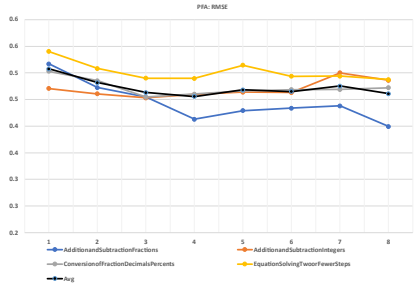

Figure 6: RMSE results for DKVMN model in each instance

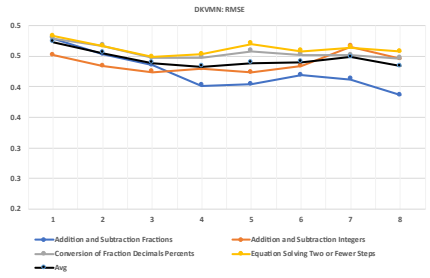

4. CONCLUSION AND DISCUSSION

In the last few years, there has been an explosion of interest in new variants to knowledge tracing that achieve higher predictive performance using neural networks. However, this work has generally not yet explored *where* and *when* these algorithms perform better, and what the implications are for using these models in practice. More specifically, previous practices have averaged predictions across students' entire learning history, ignoring the difference between the earliest work and later work on a skill.

In this study, we examined the performance of three KT models, BKT, PFA and DKVMN, across students' history of work on specific skills, and compared how the three models differ in predictive accuracy during the earliest and later opportunities to practice each skill. With all eight opportunities considered together, DKVMN outperformed BKT and PFA in both AUC and RMSE. However, DKVMN's better performance appears to be largely due to its initial prediction on the first attempt on a skill, in which DKVMN 's AUC was 0.16 higher than BKT and 0.13 higher than PFA, and RMSE was 0.02-0.04 better. After the first attempt, BKT and PFA's predictive performance improved substantially, and model performance became closer across the three algorithms after the third attempt, though DKVMN remained slightly better.

The results suggest that much of the difference in performance between these algorithms is due to DKVMN's ability to make more accurate initial predictions by using factors other than mastery of the current skill, such as past performance on other skills and other students' performance on the same item. In other words, a substantial amount of the difference between algorithms appears to be due to factors other than estimating mastery of the current skill the student is working on, from their performance on that skill. This may be especially true in datasets where students stop-out on specific skills [3], or where the skill model is added to or modified after the system is built. In these cases, many student/skill combinations may only occur once or twice, and having relatively higher performance on the first attempt will inflate AUC and RMSE values for models such as DKVMN. This raises the question of what the application is for having better knowledge prediction at the first time when a student sees a new skill. This type of improvement in prediction may be useful to systems that decide which skill a student should work on next (i.e., [6, 28]) but may be less useful in systems that have a predefined order of skills for the student to work on (i.e. [5, 8]) and the student does not move on until they have demonstrated mastery on the current skill.

Given the difference in predictive performance between situations, it may be appropriate to separate out cold start situations (for a given student and skill) from situations where the model has sufficient data to estimate the current skill by itself, when comparing KT algorithms. Specifically, we propose that the calculation of predictive metrics should separate out the predictions on the initial two opportunities to practice each skill from the rest. Adopting this approach will increase our ability to interpret the difference between algorithms and understand how much better a specific algorithm will be for specific use cases.

Two limitations to the current analyses can be addressed in future work. First, our recommendations may not be meaningful for all learning systems where contemporary KT is used. In specific, some systems may not have skill models at all, and may never intend to make inference at the level of interpretable skills. Although these systems typically use an entirely different family of KT models (i.e. [16, 21]), our recommendations would not be relevant in these cases. Second, we have only investigated these issues in the context of a single system and a set of skills for which there is extensive data, and for three algorithms; the generalizability of the findings presented here should be further investigated, using data from other learning systems where, for instance, the granularity of the skills differs. However, only limited effort is needed to separate out practice on early learning opportunities from later learning opportunities when calculating model AUC/RMSE. Therefore, it may be warranted to adopt this approach and see whether practical differences are also found for other contexts and algorithms as well.

Overall, we find initial evidence that one key factor leading to better performance for DKVMN compared to earlier algorithms is its performance in situations, before a student has had significant opportunity to work on a skill. This result leads to recommendations in how to better evaluate KT algorithms and suggests that the benefits of this algorithm may be greater for some applications (deciding which skill a student should work on next) than others (deciding if a student has reached mastery in the current skill they are working on). From the results of this study, future studies conducting research involving KT models may find it useful to calculate performance separately for a student's initial performance and their later performance on a skill; this would provide researchers with more information on how their models are working, and where their greatest benefits and potential are.

ABSTRACT

Computer-based learning environments offer the potential for automatic adaptive assessments of student knowledge and personalized instructional policies. In prior work, we introduced an individualized Bayesian model to dynamically assess student's knowledge, based on observed response times and response accuracy. In this paper, we leverage that model as a stopping instructional policy to determine when to stop the assessment. We evaluate several criteria based on the change of performance measures as questions are presented. These include the mean assessment level and the Kullback-Leibler divergence. Student performances are simulated considering their sensitivity to the prior belief for mastery over different educational cases. Our results indicate which criteria offer an efficient assessment, a confident assessment, and which can effectively handle wheel-spinning students.

Keywords

Bayesian Adaptive Mastery Assessment; stopping policy; individualization; empirical analysis; performance model; mastery criteria

1. INTRODUCTION

In adaptive learning systems, mastery is measured as a student performs a skill and demonstrates knowledge by solving a sequence of questions that tap that skill. Learner models that rely on the mastery learning theory are widely used in various personalized adaptive learning systems to infer student mastery sequentially.

In a mastery learning framework, 'under-practicing' and 'over-practicing' are two common pitfalls that cause students to face a practicing or testing burden rather than focus on the skill of their level [1, 2]. This might cause demotivation and low engagement [3, 4, 2, 1, 5, 6]. Particularly, students trapped in a mastery assessment cycle are referred to as wheel-spinning students [7, 3, 8, 9]. They are consistently unable to reach the mastery-success criterion set for the skill, which triggers the system to present even more items. In our previous paper, we proposed,Bayesian Adaptive Mastery Assessment(BAMA), a framework we created to assess a student individually on a single skill given an explicit mean success criterion. From an educational perspective, it can be used as a criterion-referenced assessment to assure mastery [10, 6, 11, 12, 13]. We evaluated the utility function of BAMA as a when-mastery-is-attained policy and show that it accurately recovers the true mastery efficiently, i.e., with few responses. However, this strategy is not sufficient as it assumes that all students at some point will reach that criterion [7, 2, 3, 4, 14, 9].

In this paper, we thereby evaluate the impact of the utility function of BAMA as a stopping policy. We design implicit stopping criteria and we provide an empirical analysis considering the variance of length practice across simulated student performances. We demonstrate that the developed policy delivers meaningful results and identifies any student profile, including wheel-spinners.

2. RELATED WORK

Student profiles aim to portray the individual performance of each learner. Based on the response time of student performances, learning sciences distinguish between struggling fluent from fluent as the latter provide correct responses with short response times [15]. An individual who has not yet acquired the skill and will not demonstrate successful performance is commonly modeled as having a low probability of a correct response [8, 2, 7, 9, 16]. These students are termed as wheel-spinning students [7, 3, 8, 9] and have been linked with long response times [8].

An instructional policy, also known as a stopping policy, refers to the total length of the assessment when a prespecified stopping criterion accompanies the model. The criteria are divided into two categories: (i) an explicit threshold

set to a statistic of the mastery estimator, known as a mastery success criterion, and (ii) an implicit threshold set to the size of change of a statistic of the mastery estimator. The former framework is typically referred to as when-mastery-is-attained policy, and the latter as a when-to-stop policy, as it stops, independent of whether the student has mastered the skill [7].

Substantial research efforts have focused on the impact of a learner model concerning the total number of questions it administers. Machine learning models were designed to detect wheel spinner performance [9]. Frameworks of instructional policies [7, 14] and metrics [5] were proposed for an evaluation of well-known prediction models on the final proposed length. Other work specified a framework for a conceptual interpretation over the stopping criterion [3]. Typically, these models assume a homogeneous class of students and they consider solely response accuracy. Previous research has shown that individualized models lead to significantly different policies [4] and highlighted the importance of response times in stopping policies [9, 12, 17, 18, 13, 10, 19, 2].

3. MODEL AND STOPPING POLICY

Below we briefly discuss the assessment model, the stopping criteria we consider, and the steps of our experiment.

3.1 Bayesian Adaptive Mastery Assessment

In the BAMA model, a student has a constant mastery level Z on a single skill which is the product of two independent random variables, the response time $T \sim \text{Exponential}(\lambda)$ and the accuracy $P \sim \text{Bernoulli}(\theta)$. We denote with τ the maximum response time. The score Z is close to 1 when a student answers correctly and relatively fast with respect to τ. The value of Z becomes zero when a student answers incorrectly, or when the response time exceeds τ. That is operationalized as follows: $Z = P \cdot \left(1 - \frac{T}{\tau}\right)^{+}$.

To keep the formulation tractable, we adopt a Bayesian approach to estimate the true unknown parameters θ and λ of a student. We model θ by a Beta(α, β) distribution, and λ by a Gamma(n, γ) distribution. This represents the prior distribution over the unknown parameters (θ, λ), denoted as p_0, as an initial belief over a student's mastery. The model updates the belief on a posterior distribution p over these parameters under the Bayes rule. As more responses become available, the posterior distributions of the accuracy (the Beta distribution) and the response time (the Gamma distribution) become more centered and peaked around the true values of θ and λ. However, this information is not known in practice and needs to be estimated from the observations received over the assessment.

3.2 Stopping Criteria

A respective policy is concerned with the nature of the estimated Z-score and adopts a different stopping rule. We employ the change of a point estimate, and the change of the distribution. These are computed according to the change observed between consecutive pairs of responses over the sequence. For the analysis and the evaluation of a policy, the following four properties are typically considered [20, 7]: 1) number of administered items, 2) number of non-stopping situations, 3) accuracy with regard to the true value, 4) uncertainty of the experiment and of the model.

The derivative-based stopping rule considers the reduction of changes observed between consecutive pairs of responses as measured with a pre-specified sample statistic of the Z distribution. To put this formally, let $\Delta f_i = f_{i-1} - f_i$ for any function f. Then, our policy proposes to stop after response i when the following decision rule holds.

$$|\Delta h_{i-1}| < \epsilon \wedge |\Delta h_i| < \epsilon, \tag{1}$$

where h_i denotes the value of a sample statistic of the distribution Z after the i-th observation, such as the mean, variance, or any other function. The rule indicates that in a sequence of three responses so far, two values for that rule are computed. Similar to all implicit-based stopping rules, the threshold value denoted as ϵ will also inevitably affect the length of the assessment, i.e., as ϵ gets smaller, the longer the assessment becomes. That is a special case of the probabilistic stopping rule proposed in [7] which doesn't directly generalize to our model.

In our first experiment, we leverage the derivative-based rule by considering the change of the posterior mean from the prior mean. Point-based estimates from sample statistics are all informative metrics that can be employed. However, other estimated statistics may exist to describe the information of a distributional score that may better accommodate a balanced length assessment. Thereby, a more elegant solution would be to calculate a metric that considers the whole distributional information obtained for Z at once.

We compute the second rule based on the reduction of divergence between two consecutive distributions of responses, the starting prior Z_{i-1} and the updating posterior Z_i, after item i has been administered. We formulate this with the Kullback-Leibler (KL) divergence D_{KL} as follows:

$$D_{\text{KL}}(Z_{i-1} \parallel Z_i) = \int_0^1 z_{i-1}(x) \log\left(\frac{z_{i-1}(x)}{z_i(x)}\right) \mathrm{d}x. \tag{2}$$

The quantity $z_i(x)$ describes the density of the distribution Z_i at response i evaluated at x.

3.3 Simulated performance profiles

A student is characterized by the pair (θ, λ) for their performance. For the exposition of our purpose, we take four equidistant intervals of Z defined as: mastered or fluent ($Z \in [0.75-0.95]$), accurate or struggling fluent ($Z \in [0.5-0.74]$), undetermined or average ($Z \in [0.2-0.49]$), wheel-spinning ($Z \in [0-0.19]$). Then, we arbitrarily draw a specific pair of (θ, λ) corresponding to the Z score from each interval. Particularly, we illustrate the following levels: mastered with high accuracy and short response times ($\theta = 0.9, \lambda = 1$) $\rightarrow$ $Z = 0.85$, accurate with high accuracy and long response times ($\theta = 0.9, \lambda = 0.1$) $\rightarrow$ $Z = 0.50$, undetermined with ($\theta = 0.5, \lambda = 0.5$) $\rightarrow$ $Z = 0.46$, and wheel-spinning with ($\theta = 0.1, \lambda = 0.1$) $\rightarrow$ $Z = 0.08$.

4. RESULTS

We evaluate our stopping criteria through simulated student performances. In practice, this translates to n observations of responses $x_1, \ldots, x_n$ according to the student profile (θ, λ)

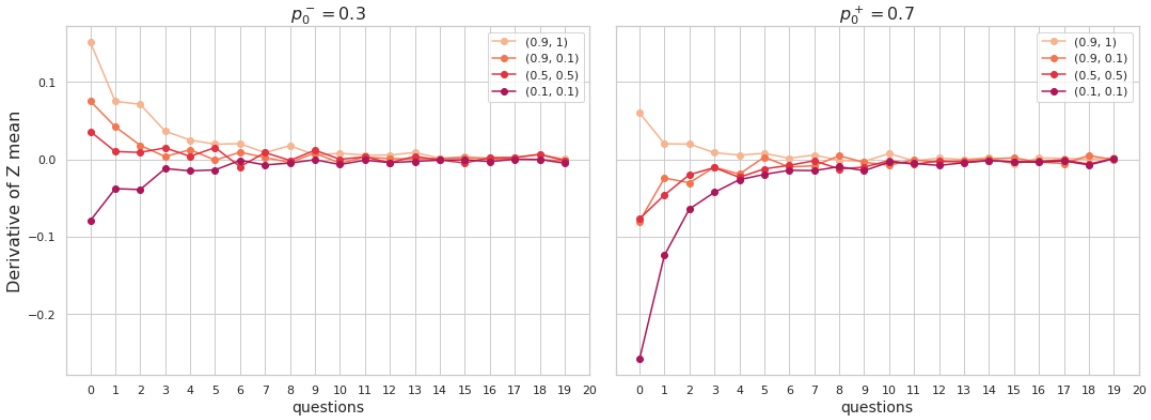

Figure 1: The size of the change between consecutive estimated expected values of Z for a prior $p_0^- = 0.3$ and a prior $p_0^+ = 0.7$.

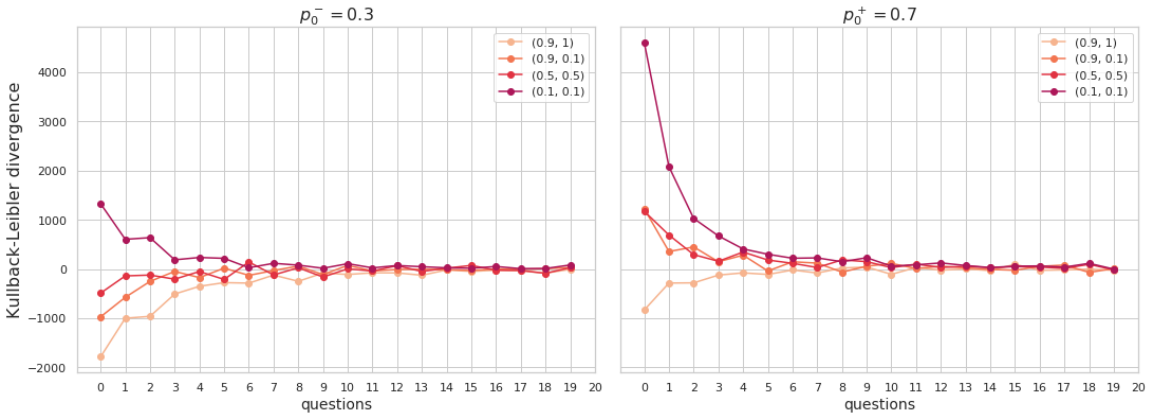

Figure 2: The KL divergence between consecutive estimated distributional scores for a prior $p_0^- = 0.3$ and a prior $p_0^+ = 0.7$.

and prior p_0. We update the prior distribution as observations arrive, i.e., p_i based on p_{i-1} and x_{i-1}. This allows us to collect statistics on the Z-score for each administered question. We repeat this 1,000 times to get accurate results for the statistics. To ensure that the practice length is not highly sensitive to the choice of the prior belief p_0, we simultaneously consider two priors. An optimistic view, denoted as p_0^+, assuming a student who has mastered the skill, and a pessimistic view denoted as p_0^-, assuming a student who has not yet mastered the skill. Considering a fixed maximum number of responses n and updating simultaneously p_0^+ and p_0^- additionally balances the efficiency and certainty of the assessment.

We perform our experiments according to the above procedure for each student profile (θ, λ) and prior p_0 for a sequence of length $n = 20$, similarly to previous research [7, 3, 9]. We set symmetric values of priors as $p_0^+ = 0.7$ and $p_0^- = 0.3$. The value of the maximum permitted response time is arbitrarily set to $\tau = 20$, and the fastest answer to $\lambda = 1$.

4.1 Change of the posterior predictive mean

Figure 1 shows the derivative rule described in Equation (1) implemented for the posterior mean $\hat{\mu}$. Particularly, the magnitude of change $\Delta\hat{\mu}_i$ is depicted over consecutive responses i across the student profiles (θ, λ). The response interval at which $\Delta\hat{\mu}_i$ does not change anymore is observed by the converging lines.

Intuitively, one would expect that the algorithm would propose more questions to wheel-spinning and undetermined students compared to mastered students. However, that is not the case when our starting belief, $p_0^- = 0.3$, is closer to the true posterior. Instead, the mastered students will be proposed to provide more responses. The situation is reversed when we start with an optimistic prior p_0^+.

Second, the algorithm adjusts quickly to the student's practice despite the presence of a non-representative prior. To illustrate this, take the mastered student. Also, take the same length of items, e.g., the first three questions. When we start with a representative prior for the student, in this case p_0^+, the reduction of the change will be twice smaller compared to the reduction of the change observed when we start with the non-representative prior, p_0^-.

4.2 Statistical divergence between consecutive distributional scores

Figure 2 shows the divergence of the estimated distribution $D_{\mathrm{KL}}(i)$ described in (2). Wheel-spinners have $D_{\mathrm{KL}}(i) \geq 0$,

Table 1: Analysis and evaluation of stopping policies per profile, criterion, prior and threshold.

Assessment length: (SE, $\hat{\sigma}$, $\lvert\frac{\mu-\hat{\mu}}{\mu}\rvert$%)				
Stopping rule	Mastered	Accurate	Undetermined	Wheel-spin
$\Delta\hat{\mu}_{.01}^{p_0^+}$	5: (0.0, 0.2, 2.84)	7: (0.0, 0.33, 8.67)	8: (0.01, 0.4, 16.76)	12: (0.0, 0.27, 135.04)
$\boldsymbol{\Delta\hat{\mu}_{.02}^{\mathbf{p_0^+}}}$	4: (0.0, 0.19, 3.49)	5: (0.0, 0.32, 9.99)	4:(0.01, 0.36, 26.62)	7: (0.0, 0.3, 217.43)
$\Delta\hat{\mu}_{.01}^{p_0^-}$	11: (0.0, 0.31, 11.04)	7: (0.0, 0.35, 5.43)	8: (0.01, 0.4, 6.93)	8:(0.0, 0.23, 81.34)
$\Delta\hat{\mu}_{.02}^{p_0}$	9: (0.0, 032, 12.66)	4: (0.01, 0.35, 9.55)	3: (0.01, 0.36, 14.4)	5:(0.0, 0.25, 119.89)
$\Delta D_{\mathrm{KL}}{}_{.02}^{p_0^+}$	6: (0.0, 0.2, 1.92)	12: (0.0, 0.34, 5.76)	8: (0.01, 0.4, 16.76)	7: (0, 0.3, 217.43)
$\boldsymbol{\Delta D_{\mathrm{KL}}}_{\mathbf{.05}}^{\mathbf{p_0^+}}$	4: (0.0, 0.19, 3.49)	8: (0.0, 0.33, 7.11)	5: (0.01, 0.38, 21.53)	6: (0.0, 0.31, 242.25)
$\Delta D_{\mathrm{KL}}{}_{.02}^{p_0^-}$	12: (0.0, 0.31, 10.39)	14: (0.0, 0.35, 4.1)	*19: (0.0, 0.43, 2.56)*	6: (0.0, 0.24, 95.95)
$\boldsymbol{\Delta D_{\mathrm{KL}}}_{\mathbf{.05}}^{\mathbf{p_0^-}}$	7: (0.0, 0.32, 15.77)	8: (0.0, 0.35, 4.94)	4: (0.01, 0.38, 11.09)	6: (0.0, 0.24, 95.95)

in contrast to the mastered students, who have $D_{\mathrm{KL}}(i) \leq 0$. This can be attributed to the prior under- or overestimating the Z score.

The results of $D_{\mathrm{KL}}(i)$ are consistent to the posterior mean $\hat{\mu}$. We observe a shorter length between two responses when the prior is representative for the posterior.

4.3 Analysis and evaluation of the policies

Table 1 reports the results of the implemented stopping policies. For each student profile and stopping rule, as presented by the columns and rows, we find the number of items at which each rule proposes to stop and the variance of the assessment length for different profiles. For each stopping criterion, the prior distribution p_0 is depicted as a superscript and the threshold ϵ as a subscript.

For $\Delta\hat{\mu}$ and the optimistic prior, the simulated students need to solve at most 5-12 questions; whereas for $\Delta\hat{\mu}$ and the pessimistic prior, the simulated students need to solve at most 3-11 questions, depending on the chosen threshold. Considering a single prior, the optimistic one performs better across all students compared to the pessimistic one. Those policies are depicted in bold letters.

For ΔD_{KL} and the optimistic prior, the simulated students need to solve at most 4-12 questions, depending on the threshold value. For ΔD_{KL} and the pessimistic prior, there is a chance of a non-convergent policy. That holds for the undetermined student as the policy converges only at the end. This is depicted with the italic letters in the table.

The assessment length is short when the prior is close to reality. This is depicted for the lenient threshold, e.g., in the case of p_0^+ for a mastered student and p_0^- for an undetermined student. Therefore, we satisfy both priors simultaneously. In that case, the maximum number of questions is 9 for $\Delta\hat{\mu}$. We get the same estimate of items with almost the same uncertainty for both thresholds. Hence, we argue that a shorter assessment length is preferred. It also shows that the policy is less dependent on the value of ϵ.

The results of the lenient threshold stopping policies of ΔD_{KL} and the $\Delta D_{\hat{\mu}}$ show that we achieve an efficient assessment for both priors across all student performances. The satisfaction of both priors is an efficient length considering that in criterion-referenced assessments, at least $n = 4$ responses are required to estimate the mastery of a single skill. Furthermore, we observe that using both priors results in more efficient assessment of wheel-spinning students. In the environment we have simulated, we see that one metric is preferred towards the other under a certain objective. To achieve efficiency for mastered and wheel-spinners, the KL can be used. When the objective is shifted towards efficiency among the average profiles, then the mean could be a more appropriate metric. That doesn't generalize to other settings.

5. CONCLUSIONS

To conclude, we analyzed the performance of different stopping policy rules for the utility function of the BAMA framework. The stopping policy is constructed using both the pessimistic and the optimistic prior for the assessment with a maximum length of $n = 20$. This has several advantages: fluent students will be picked up by the optimistic prior, wheel-spinners by the pessimistic prior, and the other two profiles by either one of the prior distributions. Consistent behavior was found between the two criteria. Furthermore, the lenient threshold is favored in both criteria. The mean assessed mastery level (i.e., $\Delta\hat{\mu}$) stopping criterion slightly outperformed the divergence of assessed mastery level (i.e., ΔD_{KL}). The evaluation of the stopping policies is based on these properties – fewer items, none non-convergent performance case, and relative percentage approximation error is low with high certainty. The simulated data has features that we modelled explicitly. As future work, we plan to evaluate the stopping policies in real-world scenarios with real data and provide a way to represent the average response time and the average response accuracy of the student performance.

Detecting Careless Responding to Assessment Items in a Virtual Learning Environment Using Person-fit Indices and Random Forest

Sanaz Nazari, Walter L. Leite, and A. Corinne Huggins-Manley
University of Florida
sanaznazari@ufl.edu

ABSTRACT

Careless responding and keeping students motivated for different tests have been common problems in many areas, especially in education. This study's objective was to demonstrate a novel approach to detect careless responding using person-fit indices developed within the field of psychometrics combined with a random forest. The data used was obtained from various tests in the Math Nation virtual learning platform. The result of person-fit indices as previously used measures of careless responding as well as the result of a random forest classifier to capture careless responding were compared by Receiver Operating characteristic (ROC) analysis and the area under the curve (AUC). The result showed that random forest combined with person-fit indices outperformed person-fit indices directly in detecting careless responding. Some important applications of this method for applied researchers are discussed in the conclusion section.

Careless responding, Person-fit index, Random forest classifier, Virtual learning environment

1. INTRODUCTION

Paulhus (1991) defined response bias as "a systematic tendency to respond to a range of questionnaire items on some basis other than the specific item content." Response biases are particularly important as they become a threat to the validity of conclusions and lead to measurement error (e.g., Meade & Craig, 2012). Three forms of biases frequently addressed in psychological and educational studies are acquiescence, careless responding, and social desirability bias (e.g., Cheung & Rensvold, 2000; Leite & Nazari, 2020; Wise, 2015). In formative assessments administered within virtual learning environments (VLE; Weller, 2007), it is hard to keep students motivated across different tests. Lack of motivation to complete formative assessments may result in careless responding, which in turn may produce biased estimates of student ability. This study focuses on careless responding, which occurs when students do not put much effort and thought into answering an assessment item (Voss & Vangsness, 2020). Wise and Kong (2005) have shown that careless responding can be associated with disengagement in an assessment. Other common names frequently used for this type of responding are non-effortful responding, inattentive responding, rapid guessing behavior, and examinee motivation (e.g., Rios & Soland, 2020; van Barneveld, 2007; Wise & DeMars, 2010; Wise, 2015; Wise and Kong, 2005). Throughout this paper, we use the "careless responding" label.

Researchers have proposed several different methods to identify careless responding. Attention check items including directed response items (e.g., "Please answer 'disagree' when responding to this item"), bogus items (e.g., "I do not understand a word of English," Meade & Craig, 2012), maximum longstring index, even-odd consistency, and Mahalanobis distance have been utilized to capture carelessness (e.g., Voss & Vangsness, 2020; Niessen et al. 2016). Self-report surveys have also been administered after the main test (e.g., Voss & Vangsness, 2020; Niessen et al. 2016; Wise, 2015), and response time effort and different types of time thresholds (Wise, 2017; Wise, 2015; Rios & Soland, 2020) are computed. Other researchers (e.g., Niessen et al., 2016; Patton et al., 2019) have used person-fit indices such as the number of Guttman errors and the standardized loglikelihood to detect careless responding. Since there is a wide range of available person-fit indices in the literature and each index captures misfitting persons from a different perspective, we opted for investigating person-fit indices.

Several nonparametric and parametric person-fit statistics (see Table 1) detect response biases that can be employed to detect carelessness (e.g., Karabatsos, 2003). Most of these indices were developed to target dichotomous items, and some of them have been extended to test polytomous items. Under the item response theory (IRT) framework, parametric person-fit indices assess the model fit at the individual level to examine the meaningfulness of obtained test scores (Embretson & Reise, 2013). In a way, the consistency of individuals' item response vectors is examined based on an IRT model by these indices (Embretson & Reise, 2013), which is the main concern when attempting to flag particular individual responses that may have been careless.

Although previous research on using person-fit indices to detect careless responding has provided promising results (Karabatsos, 2003), the current study attempted to improve the performance of person-fit indices by using multiple indices simultaneously. This is similar to considering multiple predictors in the model, which is possible by machine learning classifiers. Therefore, the present study sought to enhance capturing careless responding by using random forest (Breiman, 2001; Fernández-Delgado et al., 2014).). The study's research question is: Does the use of person-fit indices as features in a random forest to detect careless responding to items in formative assessments of a VLE outperform the use of person-fit indices by themselves? This

Sanaz Nazari, Walter Leite and Anne Huggins-Manley "Detecting Careless Responding to Assessment Items in a Virtual Learning Environment Using Person-fit Indices and Random Forest". 2021. Corrected lz	lzstar	Snijders (2001)

1.1 Theoretical Framework

A comparison of 36 person-fit indices was performed by Karabatsos (2003) to examine the strength of fit indices to detect five types of aberrant responding (cheating, careless responding, lucky guessing, creative responding, and random responding). Results showed that Ht (Sijtsma, 1986) and then U3 (Van Der Flier, 1982) person-fit indices produced the highest area under the curve (AUC) to detect all types of aberrant responding, and other indices such as Guttman errors (Meijer, 1994) and lz (Drasgow, Levine, & Williams, 1985) indicated acceptable AUC. Additionally, in a simulation study, Artner (2016) investigated five well-known indices to detect guessing, cheating, careless behavior, distorting, and fatigue in responses and found that Ht, Cstar, and U3 performed better than OUTFIT and INFIT. Recently, another comparative study (Beck, Albano & Smith, 2018) measured response time and mentioned person-fit statistics to detect inattentive responding. Again, Ht was found to have the highest AUC. However, a major limitation of using person-fit indices for detecting careless responding to formative assessment items is that they only classify the entire response vector for a quiz as careless or not. However, it may be that only part of the responses to an assessment was careless, such as the last few items due to respondent fatigue. To overcome this limitation, we propose the random forest approach that utilizes person-fit indices as predictors of careless responding.

Over the last decade, as educational datasets have become larger, alongside substantial increases in computation speed, researchers have shown interest in using more complex machine learning classifiers. The random forest was first introduced by Breiman (2001) to overcome the problems of boosting (i.e., fitting trees to bootstrap-resampled data, e.g., Shapire et al., 1998) and bagging (i.e., bootstrap aggregating: fitting trees to reweighted data; Breiman, 1996) by adding another layer of randomness to bagging. The advantage of the random forest is that it chooses the best predictor among a subset of randomly selected predictors for splitting a node, while in a standard tree, the best predictor is chosen among all variables (Liaw & Wiener, 2002). By using this strategy, the random forest is robust against overfitting, and it outperforms other classifiers, such as discriminant analysis, support vector machines, and neural networks in some situations (Breiman, 2001).

One major advantage of combining the random forest with person-fit indices to detect careless responding is that classification of responses as careless or not can be done at the item response level rather than the person-level. Therefore, for the vector of responses a student provides for a formative assessment, only some responses may be classified as careless. In other words, carelessness can be viewed less as a static person feature on a test and more as a feature of the interaction between a particular person and a particular assessment item. Another advantage of the proposed method is that it can simultaneously use multiple person-fit indices, allowing optimal use of each index's unique sensitivity to careless responding.

2. METHODS

2.1 Participants

The sample for this study consisted of item responses from 14474 students obtained from the Algebra 1 section of Math Nation during the time that face-to-face instruction in schools in the state of Florida was canceled due to the threat of COVID-19 infection and replaced by online instruction. More specifically, the period that responses were collected was from March 18 to May 31, 2020. Math Nation focuses on preparing students for taking the high-stakes Algebra 1 End-of-Course exam required for high school graduation, usually administered in May by the Florida Department of Education. Because of COVID-19, the Algebra 1 End-of-Course exam was canceled, removing an important motivator for students to use Math Nation. However, Math Nation usage spiked during this period because teachers could use it as a resource to teach algebra while students were attending classes virtually. Therefore, this sample is well-suited for studying careless responding because students were making heavy use of a VLE and its assessment features, and yet they did not have the pressure of practicing for the high-stakes achievement test at the end of the school year, and they were engaging in schooling from home, which may expose them to many distractions.

2.2 Measures

There are a total of 10 sections in Math Nation, which corresponds to major concepts in Algebra, such as linear functions and quadratic functions. Each section has between 6 and 12 formative assessments with 3 items and one formative assessment with 10 items randomly drawn uniquely for each student from an item pool. The students can take these assessments as many times as they like. This study's data included responses to 40 items of the item pool of the 10-item formative assessment of "Section 9: One-Variable Statistics" of Math Nation. We chose this section because it had the highest number of responses to items during the time period of interest. We chose to focus on the 10-item assessment rather than the 3-item ones because teachers frequently ask students to complete the 10-item assessment before moving forward to the next section of Math Nation. Once completed, students have the option to review their answers and watch solution videos for each item.

The items used in this study had multiple formats (e.g., single choice, multiple-choice, constructed response) but were scored dichotomously (i.e., correct, or incorrect). The items were written to mimic the content and format of items on the statewide Algebra 1 End-of-Course exam and have been found in our research project to correlate strongly to scores on that exam. Difficulty and discrimination parameters for the items in the study were taken from the estimates reported in a previous study (Xue et al., 2020), which used the 2-parameter logistic (2PL) item response theory model (IRT; Birnbaum, 1968).

2.3 Analysis

In the current study, we compared the effectiveness of 14 nonparametric and parametric person-fit statistics (see Table 1) as well as the performance of the random forest classifier to capture carelessly answered responses. These person-fit indices are available in the PerFit (Tendeiro, Meijer, & Niessen, 2016) package of R statistical software (R Core Team, 2018). To obtain nonparametric person-fit indices, no IRT model is required. However, for the parametric lz and lzstar, the item parameters (i.e., difficulty and discrimination) for a 2PL IRT model were obtained from Xue et al. (2020) and used to estimate the student ability parameters. The 2-PL model formula is

$$P(Y_{is} = 1|\theta_s) = \frac{exp^{1.7a_i(\theta_s - b_i)}}{1 + exp^{1.7a_i(\theta_s - b_i)}},$$

where P indicates probability, θ is a latent trait of ability, the subscript i indicates an item, Y is an item response, b is item difficulty, a is item discrimination, the subscript s indicates a student, and 1.7 is a scaling constant. This formula gives us the probability of correct response (Y=1) for item i and person s conditional on the individual's ability.

All 14 person-fit indices were computed using the *PerFit* (Tendeiro, Meijer, & Niessen, 2016) package for all selected individuals in the sample and the result of the person-fit indices (person-fit scores) was saved to be used as part of the predictors for the random forest. Additional predictors were item difficulty and discrimination estimated parameters, the number of items answered by each student, ranging from 10 to 40 items, and the number of correct items answered (from zero to 10). Within "Section 9: One-Variable Statistics", students could respond to all available 40 items by taking section tests multiple times. Only the responses for students who answered at least 10 items were retained for the analysis. The total number of answered items out of 40 were available in the dataset and used as a predictor of carelessness in the random forest.

Random forest was implemented with the *randomForest* (Liaw & Wiener, 2002) package in R. To identify carelessness in responses for the model training, the time taken by each student to answer each item was recorded, and by comparing the graph of the frequency of correct responses versus incorrect responses across time for each item, empirical cutoffs were determined. In most cases, the point in time where the frequency of incorrect responses was decreasing, and the frequency of correct responses started to increase, was chosen as a cutoff for carelessness. For example, for item two, a cutoff of eight seconds was determined (see blue dashed line in Figure 1). Therefore, student responses to item two that were recorded in less than eight seconds were coded as careless.

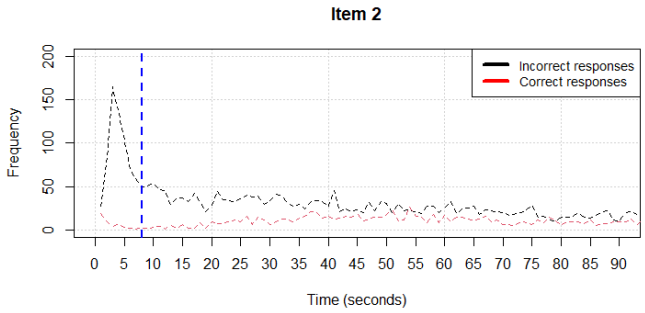

Figure 1: Frequency graph of correct responses versus incorrect responses across time for item 2.

To evaluate predictions by person-fit indices and random forest, we obtained the Receiver Operating Characteristic (ROC) curve. The ROC curve compares sensitivity against the specificity of a predictor for dichotomous data (Hanley, & McNeil, 1982). Sensitivity is the ability to identify true careless responding (true positive rate), and specificity is correctly identifying those items not careless (true negative rate). Usually, on ROC curves, "1-specificity" is demonstrated, which identifies the Type I Error rate (false positive rate; Hanley, & McNeil, 1982). The AUC of a ROC curve ranges from 0.5 to 1 from the identification line (i.e., the diagonal on the ROC) and represents the accuracy of the predictor or the feature, and different values of it can be interpreted to show the strength of a test. Generally, AUC that is 0.90-1 indicates an outstanding test, 0.80-0.90 is considered excellent, 0.70-0.80 is an acceptable one, and the AUC of about 0.5 suggests no discrimination (Hosmer, Lemeshow, & Sturdivant, 2013).

Creating ROC plots for person-fit indices requires the "true" careless responses (see above for flagging careless responses with time cutoffs) to compare them with estimated careless/non-careless responses by person-fit indices and calculate AUC. For person-fit indices, we defined a person as careless if he/she has responded to at least one item out of 10 carelessly based on the specified cutoffs. Regarding random forest ROC, true labels for carelessness were calculated per item response, and each student received 10 true labels of careless/non-careless for 10 answered items.

3. PRELIMINARY RESULT

Person-fit indices have been used as a measure to detect careless responding in previous studies (e.g., Niessen et al., 2016; Patton et al., 2019). In this study, all 14 available person-fit indices in the PerFit package were calculated for all students in the data, and the result are shown in Table 2. Most of these person-fit indices indicated a very poor AUC around 50%, which suggests no discrimination between careless/non-careless students. Therefore, only indices with the three best AUC were retained for later comparisons: 1) Guttman errors with 54.7%, 2) agreement statistic with 69.1%, and 3) dependability statistic with 63.5%. It is noteworthy that even the best performing index of agreement statistic with 69.1% AUC is not discriminating enough to be considered as an acceptable classifier of careless/non-careless students based on Hosmer, Lemeshow, and Sturdivant (2013) proposed cutoff of 70% AUC.

Table 2: AUC of 14 person-fit indices

Person-fit index	PerFit function	AUC (%)
Nonparametric		
Personal point-biserial correlation	r.pbis	50.2
Caution statistic	C.Sato	50.3
Modified caution statistic	Cstar	52.4
Number of Guttman errors	G	54.7
Normalized Guttman errors	Gnormed	49.9
Agreement statistic	A.KB	69.1
Disagreement statistic	D.KB	51.6
Dependability statistic	E.KB	63.5
U3 statistic	U3	52.4
Standardized normal U3	ZU3	50.1
Norm conformity index	NCI	50.1
HT statistic	Ht	50.4
Parametric		
Standardized normal loglikelihood	lz	50.1
Corrected lz	lzstar	50.1

The random forest has the advantage over person-fit indices in that it can use multiple person-fit indices as predictors but also include other predictors. The random forest included the three person-fit indices with the highest AUC and four additional predictors: estimated item difficulty and item discrimination parameters, number of correct responses, and number of items taken within the section. AUC of ROC illustrated that random forest with the set of specified predictors improved the classification and achieved the AUC of 77.2%, which is an acceptable test to distinguish between careless/non-careless responses (see Figure 2). The random forest also outperformed the best person-fit agreement statistic by about 8%.

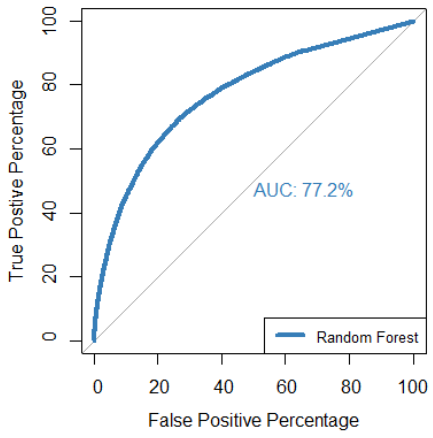

Figure 2: AUC of ROC plot for random forest classifier

4. DISCUSSION AND CONCLUSSION

The study objective was to compare the detection of careless responses between person-fit indices by themselves and random forest, including fit indices and other predictors. From the obtained results, we can conclude that random forest more accurately predicts careless responding, and this research took a methodological step forward in automatic identification of careless responding. By introducing different predictors, multiple dimensions are available, and a random forest can be used to investigate different parts of the data. In addition, careless responding can be conceptualized and examined as an item-person interaction rather than a static person feature. If desired, the random forest results can be aggregated to the person level (e.g., the proportion of responses from each person that were flagged as careless), allowing additional information at the person level. At this level, students can be labeled as careless responders or non-careless.

Person-fit indices as independent measures of carelessness may face some problems regarding ROC analysis. Sometimes, the true positive rates against false positive rates swing, cancel out, and end up in a very low AUC around 50% that is no discrimination. However, this issue does not occur in the random forest because of the way trees are constructed. Person-fit indices (and other predictors) can be removed from the random forest when they do not help improve classification accuracy.

One limitation of this study is that we relied on time cutoffs of each item response to create the criterion for careless responding. Like all options for "true" carelessness in responses, one could argue that our time-based flags of "true" careless responses are fallible in their own ways. However, empirical thresholds or time cutoffs have been used many times in previous research to detect careless responding (e.g., Wise & Kong, 2005; Wise & DeMars, 2010; Wise, 2015; Wise, 2017; Rios & Soland, 2020). Alternative criteria could come from surveys of students after they complete each formative assessment.

The result of this research will eventually be available as a trained random forest model to be used for applied researchers to detect careless responding in their data. They could enter the raw data to an R package to be developed in the future, and for the number of items in their test, they obtain a prediction of whether each answer is careless or non-careless. Then, within the context of their research, they can decide how they would like to aggregate and interpret carelessness (i.e., at the person level or at the item level) and make decisions according to the available results.

ABSTRACT

Study session dropout prediction allows for educational systems to identify when a student would stop a study session which gives vital information to prolong learning activity. Student session dropout can depend on many factors that are involved with the engagement when using the system. The student's knowledge level and their track records within the system are closely related to the student's willingness to continue with their study. Knowledge tracing as a task models the user's knowledge level given study history. The information from knowledge tracing can have significant impact on predicting the student's willingness to continue, which is why it is natural to train two tasks jointly for better generalization in dropout prediction task. While extensive research has been conducted individually on dropout prediction and knowledge tracing, the effect of jointly modeling two tasks has not been thoroughly investigated. Hence, we show that multi-task training of the study session dropout prediction model along with knowledge tracing boosts the performance of study session dropout prediction, especially on more challenging tasks and datasets. Specifically, with Transformer-based models, multi-task training significantly improves Area Under Receiving Operator Curve (AUROC) by 3.62% in further N-step dropout prediction task, which is a study session dropout prediction task under a more practical setting. Moreover, under label-scarce and class-imbalance settings, our method shows improvements of AUROC up to 12.41% and 11.22%, respectively. Our results imply that knowledge tracing is closely related to study session dropout prediction and can transfer positive knowledge in multi-task training, which provides a new way to better predict dropouts especially in difficult settings.

1. INTRODUCTION

The advantages of e-learning has gathered the attention of both educators and researchers. One of the lasting problems in e-learning is the ability to maintain the user's attention during the system use. For instance, students in mobile learning environments are more prone to distractions and exhibit difficulties in concentration [16, 20, 5]. Thus, being able to properly identify when these issues occur will allow an Intelligent Tutoring System (ITS) [1] to appropriately and preemptively intervene. This task is called Study Session Dropout Prediction and has been recently proposed by [21]. Predicting such session dropout is a crucial task in Educational Data Mining (EDM) to understand student's behaviors and learning environments, which can lead to increased learning effect.

However, study session dropout prediction has not yet been extensively studied. Many recent research works have instead focused on predicting student dropout in environments like universities or Massive Open Online Courses (MOOC) [3, 13, 27, 33, 35]. Interestingly, [22, 9, 26] has also shown that one of the main reasons students drop out from schools or classes is their academic performance which is highly relevant to their knowledge states. Given such knowledge, we hypothesize that study session dropout can also be attributed to the knowledge states of students.

Hence, in this paper, we jointly model study session dropout prediction with knowledge tracing, which is a heavily studied task that [12, 23, 8] that aims to predict the student's future performance on *knowledge components* (e.g. questions or concepts) given the student's historical data. In this study, we address this issue through a machine learning methodology known as multi-task learning [4]. Multi-task learning jointly trains multiple tasks together to formulate a comprehensive understanding of the nature of the data. Specifically, we implement a multi-task training model that is trained with both session dropout prediction and knowledge tracing.

The contributions of this paper are as such:

- We provide a multi-task training framework to jointly model study session dropout prediction and knowledge tracing.
- We show that our multi-task training framework boosts the performance of the trained model on study session dropout prediction. Also, we show that our method elevates the performance in further N-step dropout prediction task, where the model has to predict dropouts not only in immediate time step, but also in future time steps.
- We perform extensive ablation studies to show that multi-task training shows even higher performance on more difficult experimental settings such as label scarcity and class-imbalance. We also show with ablation studies that the thresh-

old of lag time that we use to define session dropout also affects the performance of multi-task training.

2. RELATED WORKS

2.1 Dropout prediction

There have been many attempts to predict dropouts in various environments. Traditionally, dropout prediction has been incorporated to predict student dropouts [3, 27]. Following the proliferation of internet, dropout prediction became applicable in online services. [2, 15] incorporated deep learning methods in *Spotify Sequential Skip Prediction Challenge*, where the task is to infer the songs that will be skipped in the second half session after the first half. Models such as denoising autoencoder and variants of Long Short Term Memory (LSTM) network were utilized. [13, 33, 35] used deep learning methods such as Convolutional Neural Network (CNN) to predict students' dropouts in MOOC. Study session dropout prediction has been studied to discover student's involvements in mobile learning environments. [21] utilized the Transformer network [31], which replaced the recurrent architecture of Recurrent Neural Networks (RNN) by self-attention blocks, to predict the study session dropout probability in mobile learning environment. We used **D**eep **A**ttentive Study **S**ession Dropout prediction (DAS) model in [21] with multi-task training approach in our experiments.

2.2 Multi-Task training

Multi-task training or multi-objective training is a method to train a machine learning model with multiple objectives [37], which tries to enhance the performance on original task by sharing features with auxiliary tasks. It has been used across various domains in machine learning, such as Computer Vision and Natural Language Processing. For example, in [24], the authors used multi-task training for face labeling by training a CNN to handle both likelihoods and pairwise label dependencies. Multi-Task Deep Neural Network (MT-DNN, [25]), is a BERT [11] based model with several task-specific layers for multi-task learning, which outperforms vanilla BERT's performance on the GLUE benchmark [32].

There are also several applications of multi-task training in an educational field. Huang et al. [18] presents a transformer-based model that identifies whether a given voice of a teacher corresponds to a question or not, which solve the problem as a multi-class classification problem to recognize question types. Geden et al. [14] proposed LSTM-based model to predict correctness rate of all questions instead of the average correctness rate for the related questions. In [19], Huang et al. suggests Deep Reinforcement Learning based exercise recommendation system whose reward function is designed to satisfy multiple objectives.

2.3 Knowledge Tracing

Knowledge tracing is a task of modeling students' knowledge level given their learning activities. Knowledge tracing and dropout prediction shares the aspect that they both model students' responses given their learning histories. Bayesian Knowledge Tracing (BKT) is a traditional method which treats student's learning activities as binary variables representing whether the student understands a certain concept or not [36]. Some works proposed to incorporate deep learning methods in knowledge tracing. [29] feeds the users' one-hot encoded learning activities into RNN-based model architectures to output the correctness prediction probability. [7, 28] are the works that use Transformer-based architectures for knowledge tracing. SAINT [7] has a similar architecture to DAS, which uses Transformer's both encoder and decoder structure.

3. METHODS

3.1 Study Session Dropout Prediction

Formally, a student's learning history is given as a sequence of interactions

$$I = (I^{(1)}, I^{(2)}, I^{(3)}, \ldots, I^{(T)})$$

where each $I^{(j)} = (e^{(j)}, l^{(j)})$ includes meta-data of the question $e^{(j)}$ that a student solves at j-th step (e.g. question id, category of the question, question text, ...) and the meta-data of the student's response $l^{(j)}$ (e.g. response correctness, elapsed time, timeliness, ...) at j-th step. Then the *study session dropout prediction* is to estimate the probability

$$\mathbb{P}[y_{DP}^{(j)} = 1 | I^{(1)}, I^{(2)}, \ldots, I^{(j-1)}, e^{(j)}]$$

that the session dropout occurs after solving j-th question. Note that a sequence can contain multiple sessions. As in [21], we define one-hour inactivity as a session dropout, so that the dropout label at j-th step is given by

$$y_{DP}^{(j)} = \begin{cases} 1 & lt^{(j)} := st^{(j+1)} - st^{(j)} \geq 1 \text{ hour} \\ 0 & \text{otherwise} \end{cases}$$

where $st^{(j)}$ is the *start time* at j-th step, i.e. the time that user start to solve the question, and $lt^{(j)}$ is the lag time for the j-th interaction.

3.2 Input Representation

The representation of each interaction $I^{(j)} = (e^{(j)}, l^{(j)})$ is formulated similarly to the settings in [21]. Here are some minor differences of feature settings between our model and the original DAS model in [21]:

1. Instead of *start time*, we use the *lag time* feature. It is more directly related to the dropout and leads to the substantial gain in the model's performance. Since the distribution of a lag time is long-tailed, we use the logarithm of the lag time instead of the lag time itself. (See Figure 2 for the distribution of the lag time). It is used as a decoder's input, not for an encoder.
2. We use *continuous embedding* for *elapsed time*, instead of discrete embedding. More precisely, we first clip the actual elapsed time with maximum 300 seconds, then normalize it by dividing it with 300. After that, we get a latent embedding vector for the elapsed time et by $\mathbf{v} = \mathbf{v}(\mathrm{et}) = \mathrm{et} \cdot \mathbf{w}_{et}$, where $\mathbf{w}_{et}$ is a single trainable vector which has same dimension as the model.

3.3 Model

In this section, we describe our methodology to jointly perform training in dropout prediction and knowledge tracing. We use the shared model f to generate the shared feature representations for both dropout prediction and knowledge tracing. An arbitrary model f takes the sequences of question embeddings $e = [e^{(1)}, \ldots, e^{(j)}]$ and response embeddings $l = [l^{(1)}, \ldots, l^{(j-1)}]$ to produce the shared feature representation for dropout prediction and knowledge tracing. Then, the feature representation is fed into the final separate prediction layers to output predicted dropout probabilities and response correctness:

$$\hat{y}_{DP} = \sigma\big(\mathbf{W}_{\mathrm{DP}}(f(e,l)) + \mathbf{b}_{DP}\big)$$
$$\hat{y}_{KT} = \sigma\big(\mathbf{W}_{\mathrm{KT}}(f(e,l)) + \mathbf{b}_{KT}\big)$$

Table 1: Test AUROCs and AUPRCs of DAS and RNN-based dropout prediction models. Further steps N of each task and its positive label proportions of the dataset are indicated in the top row ($N = 1$ corresponds to the original session dropout prediction task). Best result for each model is indicated in bold.

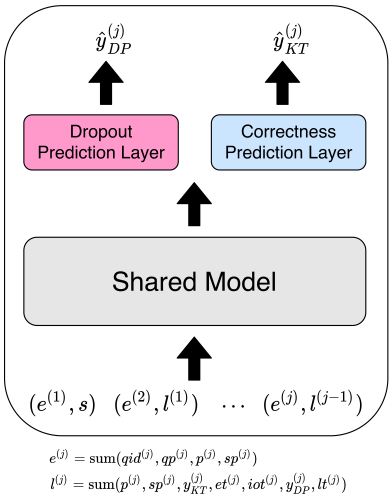

Figure 1: Overall architecture of our multi-task training scheme. Note that s is the starting token.

The major difference between our method and the previous dropout prediction models is that we are jointly training the model to predict both student dropout *and* response correctness, by using different prediction layer for each task at the end of the shared model. Using separate prediction layers, we produce both $\hat{y}_{DP} = [\hat{y}_{DP}^{(1)}, \ldots, \hat{y}_{DP}^{(j)}]$ and $\hat{y}_{KT} = [\hat{y}_{KT}^{(1)}, \ldots, \hat{y}_{KT}^{(j)}]$, which are predicted probabilities for study session dropout ($\hat{y}_{DP}$) and response correctness ($\hat{y}_{KT}$) for each time step. Training scheme of our approach is described in Figure 1. The major baseline that we use for our methodology is DAS [21], which is a Transformer-based model to predict study session dropout. The details of the architecture of DAS is described in Appendix A. We also do experiments with RNN-based model architectures - including LSTM and GRU [6, 17] - which are provided as baselines in [21] for comparison. For RNN-based models, we use encoder-only structure instead of encoder-decoder structure.

3.4 Training objectives

Typically, Binary Cross-Entropy (BCE) loss is used in 2-class classification tasks, which include the cases of dropout prediction and knowledge tracing. We use the BCE function to compute $\mathcal{L}_{\text{DP}}$ and $\mathcal{L}_{\text{KT}}$, which are the losses for dropout prediction and knowledge tracing. We train the model with the loss

$$\mathcal{L} = \mathcal{L}_{\text{DP}} + \lambda_{\text{KT}} \mathcal{L}_{\text{KT}}$$

where λ_{KT} is a balancing hyper-parameter. Our experiments are performed with $\lambda_{\text{KT}} = 0.5$.

4. EXPERIMENTS

4.1 Experiment setup

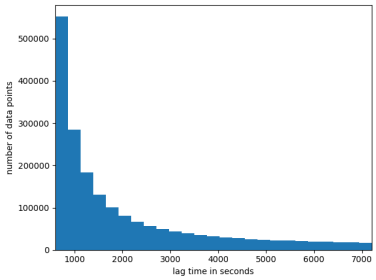

Figure 2: Distribution of data points with respect to the lag time. The lag time in the graph ranges from 600s (10 minutes) to 7200s (2 hours). The number of data points exponentially decays as their lag time increases.

Table 2: Test AUROCs and AUPRCs of the DAS model with various masking rates on *both labels (first 4 rows)* and *only positive dropout labels (last 4 rows)*. The first two columns indicate the rate of random masking and the proportion of labels in the training data for each mask rate. Best result for each masking rate indicated in bold.

We use the EdNet-KT1 dataset [8], the largest publicly available student interaction dataset collected by *Santa*[*], which is a mobile application for preparing Test of English for International Communication (TOEIC) exam. The proportion of the logs where session dropout occurred was 4.06% with the definition of dropout as one-hour lag time. The distribution of dropout labels w.r.t. the change of lag time in defining the dropout is described in Figure 2.

For RNN-based model architectures, we use the embedding and model dimension size of 256 and feedforward layer dimension size of 1024 with 2 number of layers. For DAS, we use the embedding and model dimension size of 512 and feedforward layer dimension size of 2048 with 4 number of layers. While training, we set the model's input sequence size as 100, and all the models are trained with Adam optimizer with Noam scheduling where the warmup step is 40000. We set the initial learning rate and the model's dropout rate as 0.001 and 0.1 respectively.

We evaluate our models with two metrics: Area Under Receiving Operator Curve (AUROC) and Area Under Precision Recall Curve (AUPRC). AUROC is the most widely used metric in the litera-

7200s	3.60%	0.8789	**0.8876**	0.3298	**0.3508**

Table 3: Test AUROCs and AUPRCs of the DAS model with various standards of lag time on defining dropouts (in seconds). The first two columns indicate the lag time used to define session dropout and the proportion of positive labels in the total dataset for each definition. Best result for each indicated in bold.

ture for evaluating the dropout prediction models because labels in dropout prediction settings are usually imbalanced. It is known that AUPRC is especially more informative than the AUROC when the dataset's labels are imbalanced [10, 30].

We evaluate the effect of multi-task training on two tasks. The first is the standard study session dropout prediction described in 3.1, where the task is to estimate the probability that the session dropout occurs after the current time step. However, in the actual service, it is more important to predict whether the user will dropout within several future time steps in order to respond to the user's engagement in advance. Thus, we also evaluate our method on *further N-step dropout prediction* task, which predicts whether the user will dropout within further N time steps. In further N-step dropout prediction, the number of future time steps that the model has to consider increases as N increases. We perform further N-step dropout predictions with $N \in \{5, 10\}$. For all tasks, we measure AUROC and AUPRC on LSTM, GRU, and DAS with and without multi-task training to validate the effect of our method.

4.2 Main results

The results of multi-task training on the study session dropout prediction are given in Table 1. The multi-task training with knowledge tracing improves AUROC and AUPRC for the dropout prediction across all models. We also present the effect of our method in further N-step dropout predictions in Table 1. The results show that in further N-step dropout prediction tasks, multi-task training increases the performance of the model by larger margins than in immediate dropout prediction task. Note that multi-task training shows higher increase in AUROC when $N = 10$ since the future steps that the model has to consider increases with N, leaving more room for multi-task training to help the model. Table 1 also includes the proportion of positive labels of the dataset in each task to explain the difference of AUPRCs between the tasks. Although further 10-step prediction shows lower AUROCs compared to other tasks, since its dataset is less imbalanced, it shows higher AUPRCs.

4.3 Ablation study

We performed ablation studies on immediate study session dropout prediction task for fair comparisons. We perform ablations on label scarcity, imbalanced datasets, and various standards on dropout definition as follows.

4.3.1 Scarce Label for Dropout Prediction

It has been known that multi-task training shows higher performance when the label of target domain is scarce [34]. To verify this notion, we evaluated the multi-task training on datasets with different levels of dropout prediction label scarcity. Specifically, we randomly masked out both positive and negative dropout labels in different proportions ranging in {50%,90%,95%,99%}. The results in Table 2 shows that multi-task training indeed shows higher performance when dropout prediction labels are scarce. Since at least some amount of labels are needed for the models to converge, the result with 99% mask rate fails to show meaningful results.

4.3.2 Imbalanced Dataset

As we mentioned before, study session dropout prediction usually suffers from the imbalanced dataset. In our case, the rate of the positive label is only 4.06% of the total data. We conjecture that our multi-task training approach is also helpful when the label of the dataset is extremely imbalanced. To show this, while training, we randomly masked out certain proportion of **positive** dropout labels during training, and evaluated the model on the same validation and test set as before. Note that this is different from 4.3.1 since 4.3.1 performs random masking on both positive and negative dropout prediction labels. The proportion of random masking also ranges in {50%,90%,95%,99%}. The results are given in the Table 2. Results show that multi-task training outperforms vanilla model more heavily on imbalanced datasets.

4.3.3 Definition on Dropout

Although we define one-hour (3600s) inactive lag time as a session dropout, other definitions of a dropout may be utilized to better analyze student's learning activities. Thus, we see how the effect of multi-task training varies with the change in the definition of a session dropout. Figure 2 shows the distribution of the number of dropout labels w.r.t. the inactivity duration (lag time). We compare the results with various lag time standards of a session dropout in $\{600s, 1800s, 3600s, 5400s, 7200s\}$. The results are given in Table 3. Results show that multi-task training tends to perform better in tasks with higher inactivity duration standards of a session dropout. This is because the tasks with higher lag time standards have more imbalanced datasets. Since imbalanced datasets tend to have lower AUPRC, tasks with higher lag time standards have lower AUPRCs.

5. CONCLUSIONS

In this paper, we proposed a multi-task training approach with knowledge tracing to boost the performance of study session dropout prediction. We hypothesized that the commonality between the dropout prediction and knowledge tracing tasks would be beneficial to predict dropouts. We empirically validated with Transformer-based and RNN-based models that multi-task training enhances the dropout prediction performance especially in further N-step dropout prediction, which is a more practical task in real service. Moreover, we performed extensive ablation studies to demonstrate that multi-task training shows even better performance on more difficult experimental settings. We remain the multi-task training with other tasks in the field of Artificial Intelligence in Education (AIEd) as the future work.

APPENDIX

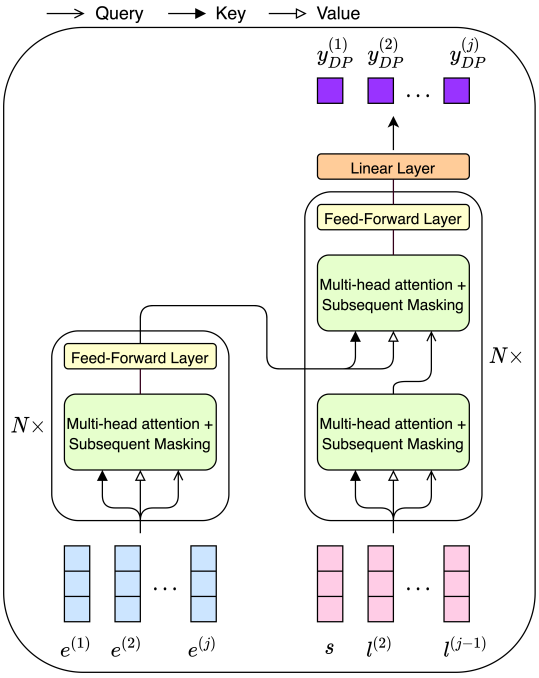

Figure 3: Overall architecture of DAS. Note that s is the starting token and N is the number of layers.

A. ARCHITECTURE OF DAS

In this section, we review the overall architecture of Deep Attentive Study Session Prediction (DAS) [21], which we use for the baseline of our model. DAS is a transformer-based model that consists of an encoder and a decoder. Encoder includes N encoder blocks where each block has a multi-head self-attention layer and a fully connected feed-forward layer. After each layer, residual connection and layer normalization are applied. Decoder also includes N decoder blocks with each block including a multi-head self-attention layer, a multi-head encoder-decoder attention layer, and a fully connected feed-forward layer. The encoder-decoder attention layer takes the output of the encoder as keys and values, and output of self-attention layer as queries to perform the attention mechanism. Each layer in the decoder block is also followed by residual connection and layer normalization. The encoder takes the sequence of question embeddings $e = [e^{(1)}, \ldots, e^{(j)}]$ and produces the outputs $h = [h^{(1)}, \ldots, h^{(j)}]$ that are fed into the decoder's encoder-decoder attention layers. The decoder takes the sequence of response embeddings $l = [s, l^{(1)}, \ldots, l^{(j-1)}]$ and encoder's outputs h, producing the hidden vectors which are fed through the final linear layer to output the predicted dropout probabilities $\hat{y}_{DP} = [\hat{y}_{DP}^{(1)}, \ldots, \hat{y}_{DP}^{(j)}]$. Note that s is the starting token for the first position of the sequence. The overall process of DAS can be described as:

$$h = \text{Encoder}(e)$$
$$\hat{y}_{DP} = \sigma\big(\mathbf{W}_{\text{DP}}\text{Decoder}(s, l, h) + \mathbf{b}_{DP}\big)$$

where s is the start token embedding. The overall architecture of DAS is described in Figure 3.

We will now describe the components of each block in encoder and decoder. Each block mainly consists of a multi-head attention layer and a fully connected feed-forward layer. Multi-head attention network in each block takes queries, keys, and values of the sequence as inputs. Queries, keys, and values of $head_i$ are computed by multiplying weight matrices W_i^Q, W_i^K, W_i^V to the inputs as follows:

$$Q_i = e_Q W_i^Q = [Q_i^{(1)}, \ldots, Q_i^{(j)}]$$
$$K_i = e_K W_i^K = [K_i^{(1)}, \ldots, K_i^{(j)}]$$
$$V_i = e_V W_i^V = [V_i^{(1)}, \ldots, V_i^{(j)}]$$

Then, multi-head attention with h attention heads is computed as:

$$\text{Multihead}(e_Q, e_K, e_V) = \text{Concat}(head_1, \ldots, head_h)W^O$$
$$\text{where } head_i = \text{Softmax}(\frac{Q_i K_i^T}{\sqrt{d_k}})V_i$$

d_k is the dimension of K_i, which is incorporated for scaling. W^O is the matrix to combine the outputs from multiple attention heads and to produce the final output of multi-head attention mechanism. Note that multi-head self attention uses same inputs to compute queries, keys and values while multi-head encoder-decoder attention uses outputs from the encoder as keys and values, which can be expressed as $Multihead(l, h, h)$. In order to prevent cheating from the future time steps, subsequent masks to the attention layers are incorporated. The fully connected feed-forward network applies linear transformation after adding non-linearity to the outputs of the multi-head attention layer as follows:

$$\text{FFN}(M) = \text{ReLU}(MW_1 + b_1)W_2 + b_2$$
$$\text{where } M = \text{Multihead}(e_Q, e_K, e_V)$$

Fine-Grained Versus Coarse-Grained Data for Estimating Time-on-Task in Learning Programming

ABSTRACT

The time that students spend on assignments, i.e. *time-on-task*, has been used frequently in prior research to understand student affect, study habits, and course performance, among others. The choice for how time-on-task is calculated, however, is typically based on available data. This data can be very coarse-grained, such as the timestamps from students' assignment submissions. Using coarse-grained data to calculate time-on-task has limitations, such as not being able to determine whether students take breaks when working on an assignment. In this work, we analyze the differences between two time-on-task metrics, one based on coarse-grained data—in this case, student submissions—and one based on fine-grained data—in this case, students' keystrokes during an assignment. We compare these two metrics and examine how well they correlate to find out whether time-on-task based on coarse-grained data can be an accurate metric for understanding the time spent by students on an assignment. Our results show that the correlation between the two metrics that are supposed to measure the same underlying phenomena—time-on-task—is only weak to moderate. This suggests that fine-grained data might be needed to accurately estimate time-on-task.

Keywords

time-on-task, fine-grained data, coarse-grained data, data granularity, keystroke data, programming process data, learning analytics, educational data mining

1. INTRODUCTION

Time-on-task—the amount of time that a student spends actively engaged in a task—is considered as one of the most important factors that contribute to learning and achievement [14, 30, 32]. Measuring time-on-task focuses on identifying *active time* that is spent on a task, instead of the overall time that includes breaks and time spent on unrelated activities. Time-on-task has been measured through various means: student self-reports [27], stopwatches [8], periodic observations [3], video recordings and eye movement data [4], and learning management system log data [17]. While all of these can be considered as proxies for time-on-task, accurately estimating time-on-task remains a challenging problem that deserves further attention [14, 17].

In this work, we study (a) to what extent two different types of log data—timestamped keystroke data and timestamped submission data from an introductory programming course—can be used to measure students' time-on-task and (b) to what extent time-on-task estimates produced with this data represent the same phenomenon. Our work is motivated by the need to distinguish between different types of data and the time-on-task estimates that can be produced with them. As numerous metrics have been used as proxies for time-on-task, if these metrics are not in line with each other, results from studies using them may not be comparable. That is, differences between observed results, or even contradictory results, could be explained to some extent by the difference in the chosen time-on-task metric.

Some studies similar to ours include work by Kovanović et al. [16] and Nguyen [23]. Kovanović et al. [16] built and compared a range of time-on-task metrics for evaluating students' performance, highlighting methodological issues. Nguyen [23], on the other hand, evaluated methods for identifying off-task behavior, also correlating the resulting estimates with academic performance. While these studies have used click-stream or event data from learning management systems such as Moodle, the data in our study comes from an introductory programming course where work on programming assignments is logged keystroke by keystroke.

This article is structured as follows. In Section 2, we discuss related time-on-task studies, starting with an overview of earlier studies on time-on-task and time-on-task estimates within learning programming, with a brief outline of studies that have analyzed different time-on-task estimates. We describe our context, data, research questions, and metrics in Section 3, and outline the analyses and results in Section 4. We discuss our findings and outline future work in Section 5.

2. RELATED WORK

2.1 Measuring Time-on-Task

Early work with time-on-task often involved on-site observations (e.g. in classrooms) where coders manually recorded

Juho Leinonen, Francisco Enrique Vicente Castro and Arto Hellas "Fine-Grained Versus Coarse-Grained Data for Estimating Time-on-Task in Learning Programming". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 648-653. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

and/or timed behaviors based on a coding rubric of on-task behaviors, also linking teacher's behavior with students' behavior (e.g. [2, 10, 15]). Over time, technology advancement led to the now-prevalent practice of mining *user interaction logs* from educational software used in classrooms or technology-augmented learning activities. This has made the analysis of user logs a vital component of more recent learning and behavior studies, such as in predicting help-seeking behavior [5] or assessing performance [9]. Time-on-task studies have likewise turned to this direction. Some examples (proxies for time-on-task in parentheses) include: analyzing the relationship of gamified elements to time-on-task (number of edits) [18] and comparing the impact of different course interventions to time-on-task (online interactions with peers and accessing course materials) [25]. Of note, both in earlier and more recent time-on-task studies, are the different measures or proxies used for time-on-task, and the methods used for identifying or approximating off-task activity and breaks. These are key factors that we explore in our comparison of coarse- and fine-grained time-on-task metrics.

In research focused on time-on-task in learning to program, a conventional approach has been to log user interactions within integrated development environments (see e.g. [13, 21, 22, 24, 29]). For example, Jadud [12] used the BlueJ IDE to capture code "snapshots" (copies of source code) whenever students compiled their programs, including compiler-reported errors and related metadata. Rodrigo et al. used BlueJ logs in combination with student surveys and observations to explore relationships between novice programmers' achievement, debugging, and syntax errors [26].

Submission data has been used to estimate students' *total elapsed time*, the total time between a student's first submission and last submission. Edwards et al. noted that the difference in total elapsed time between high- and low-scoring students is only small [6]. Similarly, the *time between compilation events* has been studied previously; Jadud observed that students are likely to recompile quickly after encountering a syntax error, but spend more time working on code after a successful compilation [11]. Definitions of *work sessions* also differ between studies. For example, Fenwick et al. [7] considered a "work session" terminated when no events were logged for 60 minutes. While the previous examples demonstrate the use of time from snapshots for estimating time-on-task, other studies in programming have explored using event counts (similar to other fields) for building predictive models of student achievement. For example, Ahadi et al. [1] used assignment-specific log data that included the number of "steps" that students took to solve each assignment for predicting course outcomes.

The time-on-task metrics in these (and other studies, e.g. [20, 28, 31]), however, suffer from similar problems of failing to capture the nuances around actual working time, as even the "work sessions" may fail to account for when and how students are working offline.

2.2 Analyzing Time-on-Task Estimates

Variations on time-on-task measures across studies and research instruments make it difficult to interpret and compare findings and bring into question whether or not the different metrics are indeed measuring or evaluating similar constructs. Some researchers have begun to explore this by looking at the different ways that researchers estimate time-on-task and analyzing how these estimation choices impact conclusions drawn from these measures.

Kovanović et al. [16], for example, looked at different time-on-task estimates from learning management system data and examined the impacts of these across courses from different subject domains. Their findings suggest that strategies for time-on-task estimation can have significant effects on learning analytics models of student performance. Using data collected from an introductory programming course, Leinonen et al. [19] examined a family of time-on-task-related metrics such as self-reported study time, log-based time spent on assignments, and event counts correlated with each other as well as course exam outcomes. They noted that while similar metrics such as edit counts and event counts tended to have higher correlations, exam scores were not strongly correlated with any of the metrics, except for the number of completed assignments.

While Leinonen et al. [19] did not analyze the impact of different break durations when estimating time spent on assignments, different break durations have been studied by both Kovanović et al. [16] and Nguyen [23]. Kovanović et al. and Nguyen both used time-on-task estimates based on timestamp differences between two subsequent events in learning management systems and highlight the importance of a good time-on-task estimation strategy.

Our work builds on this prior work by looking into data from an introductory programming course, where each keystroke associated with a course assignment was recorded and timestamped. Using this fine-grained log data, we study the impact of different thresholds for measuring off-task behavior, contrasting the keystroke data with submission-based data more commonly used in studies focusing on academic achievement in learning programming.

3. METHODOLOGY

3.1 Context and Data

The data for our study comes from a 7-week introductory programming course offered at a research first university in Europe. The workload of the course is 5 ECTS, which corresponds to roughly 100 to 125 study hours. In the course, students learn the basics of procedural and object-oriented programming in Java. The course uses a *many small assignments* approach, where many of the course assignments are small, but combine to form larger programs. After working on small assignments, students are given larger assignments as well, where they practice the content and constructs that they have learned earlier.

In total, the course had 147 programming assignments. The programming assignments are worked on in an integrated development environment (IDE), that logs keystroke data for plagiarism detection and research purposes. On each keystroke, the IDE collects the current timestamp and the modification to the source code of the assignment that the student is currently working on. Keystroke data is gathered only from course assignments. Additionally, information on when students submit their assignments is collected.

Students were informed about the data gathering on the course; our analyses included data from 137 students who consented to the use of their data for research purposes and who completed at least 10 assignments in the course.

3.2 Research Questions and Metrics

Our research questions are as follows:

RQ1. How do fine- and coarse-grained time-on-task metrics differ in terms of measuring time-on-task?

RQ2. Are there differences (a) between students and (b) between assignments on how well coarse-grained time-on-task correlates with fine-grained time-on-task?

In this study, we compare two different metrics for time-on-task that we call *coarse-grained time-on-task* and *fine-grained time-on-task*. The metrics are calculated for each student for each exercise they attempted and submitted.

Coarse-grained time-on-task is calculated as the difference between the timestamp of the first submission and the first keystroke event for that assignment. We used the first submission instead of the last submission since some students resubmitted assignments that they had previously completed "just in case" right before the deadline. However, the choice of first versus the last submission does not affect the results considerably: in 95% of the cases, students only had a single submission for each assignment.

Fine-grained time-on-task was calculated by computing the differences between keystroke timestamps in the data until the first submission of the assignment while ignoring any differences that were greater than a *break threshold* that is used to approximate off-task behavior or "outliers". Different values for the break threshold are explored and reported.

The key difference between the two metrics is that the fine-grained time-on-task takes into account the breaks that students take while working on assignments, whereas the coarse-grained time-on-task does not. If the break threshold is arbitrarily large, no breaks are removed when computing the fine-grained time-on-task, and the two metrics are identical.

4. ANALYSES AND RESULTS

4.1 Differences Between Time-on-Task Metrics

To answer *RQ1*, we first analyzed different break threshold values to examine how different thresholds affect the number of distinct study sessions in the data. We define a distinct study session as any sequence of snapshots for an assignment between breaks in the data, where what is considered as a break depends on the break threshold. We then examined how the choice of break threshold affects the correlation between the coarse- and fine-grained time-on-task metrics across the whole data set. The strength of the correlation between the metrics can signal whether the metrics are measuring the same phenomenon, i.e. time-on-task.

Figure 1, in Appendix, shows how having a different break threshold for the fine-grained time-on-task affects the number of distinct study sessions for thresholds between 30 seconds and 1200 seconds (i.e. 20 minutes). We see that having a very low threshold (e.g. anything under 100 seconds) results in a very high number of study sessions compared to having a higher break threshold (e.g. anything over 600 seconds, i.e. 10 minutes). The figure only shows the number of sessions up to a break threshold of 20 minutes since at that point, the decrease in the number of sessions is very small. What this essentially illustrates is that if a student takes a short break of under 200 seconds or so, they are quite likely to return to the task, but if the break is longer (e.g. over 10 minutes), they are not likely to return to the task soon. Based on this, in our data, a break threshold of around 600 seconds would seem reasonable as at that point, the rate of decrease plateaus.

Figure 2 (Appendix) shows the Pearson's correlation coefficient between coarse- and the fine-grained time-on-task metrics for different break thresholds between 30 seconds and 1200 seconds (20 mins.). We first note that for all the thresholds visualized in Figure 2, the correlation is weak since it varies between 0.33 and 0.37. The figure shows that the correlation increases slightly as the break threshold gets bigger, but similar to the number of study sessions, the rate of increase seems to plateau at around the 600 second (10 min.) mark. The correlation does continue increasing beyond what is visualized in the figure and eventually, at around 13 days, it reaches 1, where the fine- and coarse-grained time-on-task metrics are equal. This means that some students had a break of around 13 days within a single assignment.

4.2 Student and Assignment-Specific Correlations Between Time-on-Task Metrics

To answer *RQ2a*, we first calculated both time-on-task metrics for each student for each assignment they submitted. We then calculated the correlation between the metrics for each student separately, which leaves us with a single correlation per student. We examine the distribution of these correlations to understand if there are differences between students on how much the fine- and coarse-grained time-on-task metrics correlate. To answer *RQ2b*, we calculated the correlation between the coarse- and fine-grained metrics for each assignment separately, leaving us with a single correlation per assignment. Similar to *RQ2a*, we study the distribution of these correlations to see if there are assignment-specific differences in how well the two metrics correlate.

For analyzing student and assignment-specific differences in how well the coarse- and fine-grained time-on-task metrics correlate, we used a break threshold of 600 seconds (i.e. 10 minutes) for the fine-grained time-on-task metric. We chose 600 seconds as the results for *RQ1* showed that in our data, 600 seconds seems like a reasonable value to consider a student being on a break (Section 4.1).

Figure 3, in Appendix, shows the distribution of the correlations between the coarse- and fine-grained time-on-task metrics for individual students. The mean correlation is 0.47 with a standard deviation of 0.24 and the 95% confidence interval is 0.43 to 0.51. We notice from the figure that there are differences between students in how well the coarse- and fine-grained time-on-task metrics match each other. On average, the correlation seems moderate, with most students having a correlation between 0.2 and 0.6.

Figure 4, in Appendix, shows the distribution of the correlations between the coarse- and fine-grained time-on-task met-

rics for individual assignments. The mean correlation is 0.33 with a standard deviation of 0.21 and the 95% confidence interval is 0.30 to 0.36. We notice from the figure that similar to students, there are also differences between assignments. Compared to the between-students analysis (*RQ2a*), the assignment distribution is slightly more centered around the mean. Similar to the between-student analysis, the correlations for the assignments are also, on average, moderate.

5. DISCUSSION

5.1 Coarse- vs Fine-Grained Time-on-Task

We observed that our coarse-grained time-on-task metric poorly approximated our fine-grained time-on-task metric. The coarse-grained metric imitates metrics from earlier work where time-on-task has been calculated based on, for example, students' first and last submissions for an assignment [6], while the fine-grained time-on-task metric is somewhat similar to earlier works that utilized LMS trace data [16], although considerably more fine-grained.

We propose that the fine-grained metric explored in this work is a better metric for measuring time-on-task than a metric that relies on coarse-grained data, but removes outliers to keep time-on-task values meaningful. Prior work has suggested, for example, that large values are just ignored [16]. However, if we rely on removing outliers, we are bound to include data that is not accurate that was simply not caught by the outlier detection. For example, if two students both have a time-on-task estimate of two hours with a coarse-grained time-on-task metric, it is possible that one of them worked for ten minutes, while the other worked for a full 120 minutes. In this case, the actual time-on-task is drastically different, but the coarse-grained time-on-task estimate would be the same for both.

One downside of the fine-grained time-on-task metric is that it requires a break threshold to calculate time-on-task. Deciding on a good break threshold is not straightforward, and is most likely context-dependent. This work is not the first to note this issue: for example, both Nguyen [23] and Kovanović et al. [16] examined different cut-offs for outlier detection, which is similar to our work in examining different break thresholds.

5.2 Student- and Assignment-Specific Correlations

We identified student- and assignment-specific differences in how well coarse- and fine-grained time-on-task metrics correlate. This makes sense since the main difference between the metrics is that the fine-grained metric takes the breaks students take into account; thus, if a student does not take many breaks while working on assignments, the difference between the two time-on-task metrics will not be significant compared to a student who takes long breaks within single assignments. Here, factors such as possible previous programming experience and study fatigue may come into play and should be analyzed in future work.

Similarly, we found that there are differences between assignments in how much the two metrics correlate. Since the course has many small assignments, but also some bigger, more complex assignments, it makes sense that, for example, students might take more breaks during the bigger assignments compared to the smaller ones, which would have an effect on the correlation between the two metrics.

5.3 Conclusion and Future Work

In this work, we studied how two different time-on-task metrics built from programming log data correlate with each other. One of the metrics utilizes fine-grained keystroke data and takes the breaks students take during assignments into account by not including the breaks in its time-on-task estimate. The other time-on-task metric is more coarse-grained and includes any breaks students take during assignments in its time-on-task estimate.

Our results show that the correlation between the two metrics is at best moderate, which suggests that the choice of time-on-task metric can significantly impact the results of studies based on time-on-task analysis. This brings into question whether previous results that have used different metrics for measuring time-on-task are comparable with one another. Additionally, our results show that, at least in our context, there are also student- and assignment-specific differences in how much the two metrics correlate.

We acknowledge that we do not have a ground truth for time on task, i.e., both our metrics are only proxies. As part of our future work, we are looking into augmenting keystroke data from the programming environment with log data from other learning environments and self-reported time-on-task estimates. Similarly, in this work, we examined different break thresholds over all the data when identifying a break threshold; in future work, we will be looking at to what extent optimal break thresholds vary between students. We also acknowledge that we did not analyze how time-on-task relates to course outcomes, which has often been included in time-on-task studies (e.g. [16, 19, 23]). In the future, we will also be looking into how the studied metrics and different break thresholds relate to course performance.

The Impact of Learning Analytics on Student Performance and Satisfaction in a Higher Education Course

Dimitrios Tzimas, Stavros Demetriadis

Aristotle University of Thessaloniki
{detzimas, sdemetri}@csd.auth.gr

ABSTRACT

Learning analytics (LA) is collecting, processing, and visualization of big data to optimize learning. This article aims to interpret the impact of analyzing learning data for tertiary education. The article describes a semester-long mixed methods study for 63 students enrolled in a Greek technical university laboratory, retrieving data from the learning management system (LMS). We applied minimal LA guidance in the experimental group and no LA guidance in the control group. The research questions are as follows: Can a student-facing learning analytics approach at minimal level guidance improve students' LMS access and learning performance levels? Are the students' LMS access, discussion forums, and submitted assignments, critical predictors for students' course grades? What are students' opinions about learning analytics as a tool for data-driven decision-making strategy? The study followed the do-analyze-change-reflect LA model. The data collected included students' time spent on LMS, exercises, and discussion posts, while the dependent variable was the course grade. Results indicate that it increased the students' LMS access and satisfaction when we applied LA but not their final grade. Future research could apply higher effort interventions and stronger teacher guidance to provide insights into student performance, engagement, and satisfaction.

Keywords

Student-facing learning analytics, Performance, Satisfaction, Teacher guidance, Post-secondary education.

1. INTRODUCTION

Learning analytics is a multidisciplinary field between computer science and education that fosters the learning process based on big data monitoring [10]. In [29], the authors defined LA as the measurement, analysis and reporting of data about learners and their contexts, for purposes of optimizing learning and the environments in which it occurs. Furthermore, the LA tasks are a set of handy tools to collect and analyze the data accumulated in a smart classroom for data-based decision-making [1]. Consequently, without analytics, instructors cannot provide guidance at appropriate times when students encounter difficulties [11]. In parallel, institutions have embedded LA techniques to enhance retention rates, use resources effectively, and increase students' engagement, satisfaction, and motivation [26].

The authors conducted this mixed-methods study with the research objective of mapping student-facing learning analytics (LA) in real tertiary educational settings. The article is organized as follows: (1) we conduct a short literature review, (2) we explain how the research questions were formulated, (3) we illustrate the design and results of the experiment, and (4) we present the discussion and conclusions reached.

2. RELATED WORK

Student-facing LA is a subfield of LA and focuses on the reporting phase, such as LA dashboards, educational recommender and feedback systems [5, 6]. It is challenging to show students a dashboard or automated emailing systems and conduct surveys to extract usage insights [20]. According to [20], a well-established student-facing LA system consists of four learning design phases (do-analyze-change-reflect). To provide a theoretical framework and extract the research questions, we conducted a short literature review about student-facing LA. The studies can be classified in terms of (1) improvement of performance, (2) prediction of student course grade, (3) improvement of LMS access, and (4) student opinions and satisfaction of LA.

A series of studies [23, 30] have explored the idea of student-facing LA improving levels of performance. Students' final marks could determine the assessment of their academic achievement [19, 33]. In contrast, academic performance and attainment are not related to student access behavior perforce [17]. Nevertheless, we argue that only a few studies examine under LA interventions the correlations between LMS use, the number of submitted assignments, and forum posts as metrics for performance. Furthermore, we need more research to examine if the low effort LA interventions could positively affect students' performance. After all, explaining the students' learning performance is a continual research question.

LA predictive modeling is a core practice of scholars focusing on student success [22]. In [18], a data mining process constructs variables that reflect the theoretical evidence and measure a prediction model's accuracy. In addition, [31] presented a prediction model for failure-prone students using neural networks techniques. These studies emphasize that student-performance prediction is a dominant research domain. Despite the above studies, we argue that building a predictive model for students' performance based on critical predictors such as LMS participation and submitted assignments is an interesting research question.

Engagement can substantially impact students' performance [4, 14]. In [6], the authors have explored the idea of student-facing LA, improving levels of engagement. They have indicated that academic engagement is a multi-dimensional construct and refers to students' level of involvement [8, 15]. However, we argue that not many studies examine the effect of student-facing LA interventions on students' level of engagement.

Dimitrios Tzimas and Stavros Demetriadis "The Impact of Learning Analytics on Student Performance and Satisfaction in a Higher Education Course". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 654-660. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Targeted studies exist on students' opinions of LA [20, 28]. The [32] study empirically explored the effects of a mobile LA tool in student satisfaction. Nevertheless, we consider that students' opinions before and after LA interventions need further research and could extract valuable insights concerning students' satisfaction and expectations. The surveys' results will confirm or not the existing ones.

Drawing upon the findings of the above studies, our purpose is to investigate the open issues. It would be meaningful to know whether subjects in the feedback conditions gain learning benefits such as performance and satisfaction. In parallel, integrating the LA concepts into tertiary classroom practice has been slow [12]. This article replicates similar research and aims to interpret analyzing learning data for higher education institutions (HEI).

2.1 Research Questions

Within this context, the current experimentation study poses the following research questions:

1. Can a student-facing learning analytics approach at minimal level guidance improve students' LMS access and learning performance levels?

2. Are the students' LMS access, discussion forums, and submitted assignments, critical predictors for students' course grades?

3. What are students' opinions about learning analytics as a tool for data-driven decision-making strategy?

3. METHOD

3.1 Participants and Context

This study took place in the authentic context of a sixth-semester 13-week undergraduate department laboratory course, "digital signal processing" (DSP), at a Greek HEI computer science department between February 2018 and June 2018. The reason for selecting this particular blended course was the high dropout and failure rate in the past exams. This study focused on 31 students as an experimental group receiving the LA intervention ("treatment") with minimal teacher guidance tested for comparison purposes. Participants were 26% female. The control group had 32 students who received no particular LA intervention. The instructor had two-hour lectures and face-to-face meetings/office hours on Mondays every week with the students.

An overview of the LA tool that students used follows: The Open eClass platform is an open-source LMS and is developed by the non-profit civil company called "Greek Universities Network" (GUNET) (https://www.gunet.gr/en/). The platform's main features follow: Management of electronic courses and educational content; Student management; Information, communication, collaboration, evaluation and feedback tools. The structure of the course was as follows:

Week 1. Module 1: The nature of DSP was explored. To ensure transparency and institution-wide adoption [34], we informed the department principal in detail about the experiment, after which she enthusiastically gave her consent. It was then defined what types of data should be tracked and that the feedback (dashboard and messages) would be intended for students.

Week 2. Module 2: Fundamental signals. The first coding exercise was performed in addition to weekly discussion threads and office hours. We gave a detailed description of which student-facing LA will be used and how students will utilize them.

Week 3. Module 3: Digital signal sampling. For usability testing, the students described their initial experience of using LA. The students were surprised, as many claimed that it was impossible to support concepts such as monitoring, analyzing, and feedback.

Week 4. The first quiz assignment and second coding exercise took place. The instructor contributed to the discussion forum to give a sense of learning community. We provided verbal encouragement for students to access their statistics and figures via the LA tool to reflect and meditate.

Week 5. The second quiz assignment and third coding exercise took place—module 4: Fourier transformation principles. We discussed the self-reflection and meditation process.

Week 6. Active intervention and feedback with personalized messages containing the grades of the students' assignments, recommendations, and comparisons of their performance with aggregated data (e.g., participation in discussions and submission of assignments). The encouraging wording of the messages was designed to benefit pedagogically and not harm the student. For instance, "do you need some support?" or "you could participate more in the discussion forum." We provided personalized feedback with visualizations for tracking students' learning progress.

Week 8 and 9. Module 5: Digital filters. Provide in-class feedback (figure 1), recommendations, and scheduling for personalized scaffolding. Verbal suggestions informed students about what to do based on analytics.

Week 10 and 11. The third quiz and an exercise took place. We provided in-class information about absences, participation, and homework. Students received personalized messages with visualizations of their learning progress for mirroring, self-reflection, and motivation.

Week 12 and 13. A revision session and a collaborative quiz were conducted in addition to weekly monitoring and analysis. We used a think-aloud protocol to understand how students reclaimed feedback. A final questionnaire took place—Week 14. The final examination was conducted.

Figure 1. Personalized feedback with visualizations for mirroring.

3.2 Research Design

A mixed quantitative and qualitative method case study was utilized to provide an instantiation of the LA framework with a description of the methodology for others to use a similar process. To answer the first and second research questions, we conducted a causal research design.

3.3 Measures and Instruments

The target of our intervention is students' LMS access, performance, and learning satisfaction. The analysis object is discussion forum use, the number of exercises submissions, and LMS access, while all variables are numeric.

Performance: The performance is measured by a simple dependent variable, the final course grade, that has convenient properties for causal and statistical analysis. The grading system of the final exam is as follows: Scale: 0.00 – 10.00 / Pass: 5:00 (excellent: 8.50 – 10.00 / very good: 6.5 – 8.49 / good: 5.00 – 6.49). The independent scale variables and their definitions that we have considered were: "discussions" that counts the number of posts per student, thus the LMS discussion forum's involvement; "exercises" that counts the submitted assignments accumulated. Each weekly assignment asked true/false, multiple-choice, open-ended questions, and coding exercises; "hoursonlms" that counts, in hours, students' LMS access.

LMS access: Student engagement is a complicated measured construct but vital for students' success that encloses more than participation, motivation, and self-regulation [21]. Therefore, student LMS access in time is an indicator of student engagement.

Satisfaction: The instruments that we used to collect student opinion data are two student opinion questionnaires. An individual questionnaire was administered at the beginning of the course and another at the end. The questionnaire data incorporated participants' reflections on the activity and helped us to collect qualitative data about their opinions as an evaluation.

3.4 Data Collection and Analysis

The level of significance was set at p = 0.05. Graphically, we examined the same assumptions and checked for no outliers. Some visualizations (i.e., dot plot, histogram, a boxplot for density, skewness, and variability) were produced. Finally, for data processing and analysis, the SPSS 25.0 statistical application processed the data.

4. RESULTS

We first applied normality (Shapiro-Wilks) and variance (Levene) controls on available data. The results ($p > 0.05$) indicated statistical non-significance suggesting that sample data come from normal distributions and populations with the same variance, therefore appropriate for parametric test analysis.

4.1 Research Question 1

Hypothesis 1: The performance, as measured by the course grade of the experimental group, is not statistically significantly different from that of the control group.

The mean score of the experimental group (M = 6.08, SD = 2.62) was slightly higher than that of the control group (M = 5.49, SD = 1.60). However, the independent samples t-test comparing course grades between the groups revealed no statistically significant differences ($t = 1.077$, $p = 0.287$) (Table 2). Overall, the null hypothesis failed to be rejected.

Table 2. The t-test results of the experimental and control groups for performance

Group	N	Mean	SD	t	p
Experimental	31	6.08	2.62	1.077	0.287
Control	32	5.49	1.60		

Hypothesis 2: The experimental group's LMS access (in hours) is not statistically significantly different from that of the control group.

Table 3 shows that the mean of the overall LMS access for the experimental group was higher than that of the control group. The independent samples t-test comparing LMS use between the control and experimental groups revealed statistically significant differences ($t = 4.610$, $p = 0.000$). Overall, the null hypothesis is rejected.

Table 3: The t-test results for LMS access

Group	N	Mean	SD	t	p
Experimental	31	10.03	7.79	4.610	0.000
Control	32	3.41	1.84		

4.2 Research Question 2

Focusing on the experimental group, we examined the Pearson correlations (Table 4), extracting that the submitted exercises ("exercises") are highly positively correlated with the final course grade ("finalgrade"). Also, time spent on LMS ("hoursonlms") is weakly positively correlated with the final course grade. However, there is a tendency but no statistically significant correlation between forum posts ("discussions") and the final course grade.

Afterward, a simple regression analysis was conducted for "exercises" to estimate the final grade. The check (ANOVA) of the hypothesis that no regression showed that this hypothesis is rejected (F = 18.156, p = 0.000). To evaluate this regression model, the Pearson correlation coefficient (Table 4) (R = 0.620, $p = 0.000$) reflects the predictor importance; thus, we extracted a good predictor. Then, the model accuracy (quality) is 61.1% and the determination factor (R-squared = 0.385 < 0.5) is considered a low effect size. Finally, the model's equation is y=1.002*x+3.954 (y: final grade, x: exercises).

Then, a simple regression analysis was conducted for "hoursonlms" to estimate the final grade. The Pearson correlation coefficient (Table 4) (R = 0.392, $p = 0.015$) reflects the predictor importance. Thus, we extracted a weak predictor with a determination factor (R-squared = 0.154 < 0.3) to be considered a weak effect size. Furthermore, we observe a high correlation (R = 0.749, $p = 0.000$) between the above two predictors. As a result, we decided that there is no need to conduct a multiple regression analysis.

Table 4. Pearson correlations, in parentheses Sig. (two-tailed)*

	finalgrade	hoursonlms	exercises	discussions
finalgrade	1.000	0.392 (0.015)	0.620 (0.000)	0.284 (0.061)
hoursonlms		1.000	0.749 (0.000)	0.525 (0.001)
exercises			1.000	0.314 (0.043)

*Significant difference at the 0.05 level

4.3 Research Question 3

We applied two questionnaires to address the third research question (What are students' opinions about learning analytics as a tool for data-driven decision-making strategy?). Twenty-three students submitted the first questionnaire (appendix), and the purpose was to determine as a baseline their prior knowledge of the LA field. Fifteen students submitted the final questionnaire. The purpose was to determine their thoughts about the LA experience and their overall satisfaction and acceptance. Students gave responses in the free comments field. Based on the mining of students' opinions and perceptions, the LA experience increased students' learning satisfaction. To summarize, students argue that: LA feedback is helpful for their learning progress; they expect that LA is applied in most courses; student-facing LA tools via smartphone would have an added-value impact; peer-comparison progress dashboards increase their engagement.

5. DISCUSSION AND CONCLUSIONS

5.1 Research Question 1

Table 3 shows that LMS access was significantly higher for the treatment group who used LA. This result is consistent with that mentioned by [3] and [25]. Students were triggered using LA to submit more quizzes and exercises (cognitive activities). In addition, students increased their sense of belonging to an online community. However, the findings suggest that high LMS access does not necessarily affect performance [36].

The experimental group had slightly higher scores than the control group (Table 2). This result is consistent with the one mentioned by [27], who stated that "students valued the information, but, despite high engagement with the information, students' study behavior and learning outcome remained rather unaffected." In contrast, many studies [3, 13, 16, 24, 25] have stated that students tend to perform better when the students accept LA interventions. An explanation is that our LA approach resulted in delayed and low effort interventions, which affected the students' overall performance. The standard deviation (SD) values in Table 2 show high diaspora, especially in the experimental group, so we argue that the LA impact affected the students in an outspread way. We conclude that there is no performance improvement without the instructor's strong guidance and targeted interventions.

5.2 Research Question 2

Some of our findings are consistent with the results of other related studies. Based on Table 4, we observe moderate statistical correlations between time spent on LMS and the final grade and between the number of assignments' submissions and the final course grade. This result is aligned with that mentioned by [2] and [15]. Our prediction model for academic performance confirms the results of related studies; thus, we need models with higher accuracy and effect size [7, 9].

5.3 Research Question 3

We conclude that the students' satisfaction was high, in agreement with findings in [25]. Students' positive response to the usefulness of student-facing LA is in agreement with the literature [6, 30]. In addition, the students' responses in the reflection phase confirm the discussion of [20] that students should analyze their behavior using their self-regulated methods. In accordance with [35], the above findings strengthen understanding students' opinions of LA qualitatively rather than as technical methods. Furthermore, interpreting students' comments, we argue that students liked this new learning approach following personalized reports. Students would like LA personalized interventions with a smartphone application and comparisons of their learning progress with their classmates. In conclusion, students' sample quotes extract emerging themes: awareness of others in the class, motivation, increased satisfaction and self-regulation, and technical proposals.

5.4 Limitations

We acknowledge that there are certain limitations to this small-scale study that prevent its findings from being generalized. First, the small sample size and the context of the dataset limit the findings. The data covers one semester on a very domain-specific course at one Greek university, and institutional factors influence the results. Furthermore, the LMS captures a subset of all the events in a learning experience, while other student characteristics may influence student outcomes. It would be useful to search for other factors or latent variables that might differ between the two groups in order to improve the results. Second, engagement was measured in terms of quantity rather than quality. More factors that influence student engagement quality should be studied, such as teacher participation and student effort. Third, the questionnaire's answers indicate that students in the experimental group are satisfied with the LA tool; however, we do not know how LA impacts students' decision-making strategy.

5.5 Future work

It is our intention to replicate the study with another treatment group applying a strong (high effort) teacher guidance to see the impact in relation to the minimal (low effort) group. We will evaluate the impact of three levels of LA interventions: mirroring, metacognitive activities, and explicit guidance. Furthermore, we intend to focus on replicating the experiment in other course settings with larger populations, different profiles, and the use of a mobile-based user-centered LA application. It would be constructive to build and test a predictive model with higher accuracy and stronger effect size applying sophisticated machine learning or deep learning algorithms.

Appendix

First questionnaire

Question	Answer		
	Yes	**No**	**No answer**
Do you know what analytics is?	10	13	-
Do you know what learning analytics is?	6	17	-
Do you believe that the collection and processing of your learning data and behavior will be helpful to your learning experience?	22	1	-
Would you be interested in being informed about your learning progress concerning your classmates?	13	6	4
Would it be helpful to have feedback (e.g., personalized monitoring and individualized learning material) on your learning progress?	22	1	-

Final questionnaire

Question	Answer		
	Yes	**No**	**No answer**
Were the personalized notifications about your engagement, absences, and performance useful for the course?	14	1	-
Would you prefer more detailed information?	4	8	3
Would you prefer to receive notifications and messages through a smartphone?	10	2	3
Is the comparison of your learning progress with that of your classmates useful?	11	2	2
Please provide free comments: "It is the first time for me that a teacher has sent personalized messages to all students about their learning progress. I have nothing more to suggest. It would be great to convince the other teachers to do the same". "The whole procedure with the exercises, the open discussions, and generally the lecturers' teaching methods helped me very much to self-regulate. I enjoyed both class time and homework". "It was the first time that we had received such refined, analytical, and informed monitoring about our progress and performance on a course." "I would like access to an LA android-based application." "I liked the quizzes the most, and I would prefer to be informed via a smartphone app." "There was sufficient and motivational guidance from the instructor about online exercises." "Instructor's comments about the exercises on LMS were constructive, analytical, and motivational." "I would like more teacher guidance about the exercises, the learning material, and the overall learning procedure."			

Text Representations of Math Tutorial Videos for Clustering, Retrieval, and Learning Gain Prediction

ABSTRACT

With the goal of making vast collections of open educational resources (YouTube, Khan Academy, etc.) more useful to learners, we explored how automatically extractable text representations of math tutorial videos can help to categorize the videos, search through them for specific content, and predict the individual learning gains of students who watch them. In particular, (1) we devised novel text representations, based on the output of an automatic speech recognition system, that consider the frequency of different tokens (symbols, equations, etc.) as well as their proximity from each other in the transcript. Unsupervised learning experiments, conducted on 208 videos that explain 18 math problems about logarithms show that the clustering accuracy of our proposed methods reaches 85%, surpassing that of standard TF-IDF features (78% using log normalization). (2) In a video search setting, the proposed text features can significantly reduce the number of videos (up to 88% reduction on our dataset) and amount of video time (up to 82%) that users need to spend looking for desired content in large video collections. Finally, (3) in an experiment on Mechanical Turk with $n = 541$ participants who watched a randomly assigned tutorial video between a pretest & posttest, the text features and their multiplicative interactions with students' prior knowledge provide a statistically significant benefit to predicting individual learning gains.

Keywords: Open educational resources (OER), Crowdsourcing, Information Retrieval

1. INTRODUCTION

Consider a large repository (Khan Academy, edX, etc.) of open educational resources (OERs) such as tutorial videos, and a scenario in which the ultimate goal is to help learners to learn by recommending relevant and high-quality content that matches the students' needs. Knowing *what* the learner needs and providing the *right* content that suits them is crucial. We could estimate automatically the most beneficial content by analyzing their performance on prior examinations. However, a current challenge with contemporary OER repositories is that the content within each resource is typically poorly annotated, with tags that are too general, e.g., "algebra" or "linear equations" rather than "Simplify $\log_{10} 1000$.". Given the high labor and time involved in manual annotation, it is desirable to devise methods of *automatically* analyzing OER content and devising representations that can facilitate efficient search and categorization.

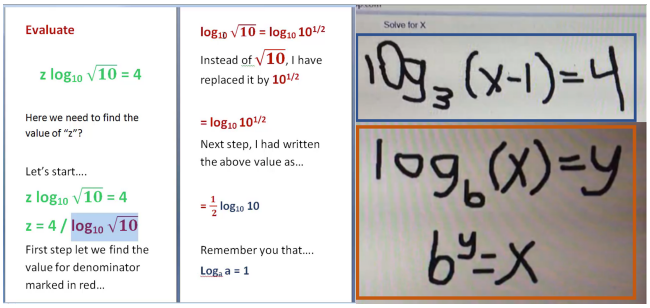

Figure 1: Example videos in our study. Right: Google's Speech-to-Text extracts the text "solve for x ok our problem is log base 3 of x minus 1 equals 4...".

While optimal character recognition and handwriting recognition are both mature fields, they are typically evaluated in much more constrained settings than math tutorials, in which math is mixed with natural language, and extraneous lines and other graphics can exist (see Figure 1). In full-fledged tutorial videos, this segmentation can be very challenging. Our research focuses instead on analyzing the speech transcript of the video (while ignoring other potential audio characteristics such as background noise, pitch, etc.). When a particular expression or equation is presented in a video, there is a high chance that the speaker will also say that expression/equation out-loud to the learners (Figure 1). Rather than manually transcribing the text from the video, we consider only fully automatic approaches based on automatic speech recognition (ASR; we used the Google Speech-to-Text API in our work, more detailed about the pilot test in Appendix B). Hence, the text representations we explore must contend with imperfect transcripts. We then assess the utility of the proposed representations for three tasks: (1) *cluster* the videos automatically into the specific math problems that they explain; (2) *search* through a library of videos for one that explains a particular math problem; and (3) *predict* the individual learning gains of students who

watch the videos in a pretest/treatment/posttest paradigm. In these ways, we hope to make available to students the *right* content that is already available, but not easily findable, among large-scale OER repositories.

We conduct our investigation on a collection [14] of math tutorial videos about logarithms, and another dataset from YouTube on basic algebra. Our goal is not just to make coarse distinctions between videos about "algebra" versus "geometry", but rather fine-grained distinctions about specific math problems. Mirroring our goals from the previous paragraph, our research questions are the following: **RQ1**: How accurately can the devised text features cluster videos into *fine-grained* categories about the specific problem they are solving, and which aspects of these representations are most important? **RQ2**: By how much can we reduce the search time to find a relevant video? **RQ3**: Are the text features predictive of the individual learning gains of students who watch these videos in a pretest/posttest setting?

2. RELATED WORK

Text Representations: There are several prominent text representations used for language modeling: (1) Term frequency and Inverse document frequency (TF-IDF) [12]: TF-IDF features typically do not require training and are thus suitable for unsupervised settings. (2) Word embedding models [8, 7] based on neural networks trained using supervised learning. (3) Sentence-level models such as BERT [8] that capture higher semantics compared to word embeddings.

Video Categorization & Clustering: For categorizing video content automatically, much of the prior work has focused on other fields than math tutorial such as films, sport videos [2], [4], [11]. Most prior methods on video categorization focus on visual aspects such as frame transitions, object detection and segmentation. Some as them use the audio (e.g. [2]) such as the audio frequency and amplitude statistics. We are unaware of any previous research that clustered video content at the low-level tags of individual math problems.

Video Retrieval in OERs: There has been increasing interest in the task of video retrieval of OERs. Many works in have pursued combined feature representations with both textual and visual information [13, 15, 3]. Hürst [3] found that the lecture slides are more useful than the corrected transcriptions. In our work, while we focus solely on text representations, the features we devise could be easily combined with visual features.

Estimating the Effectiveness of OERs: For the task of estimating the effectiveness (e.g., associated learning gains) of viewing tutorial videos, researchers have pursued various approaches, including estimating their effectiveness through correlated measures such as engagement while watching the video [10, 6, 1]. For estimating the effectiveness of OERs in general, one can also use a combined experimental and reinforcement learning-based approach such as bandit algorithms [9]. While Rafferty et al. [9] suggested the potential use of *context* (for example, features of the OERs as well as of the students' prior knowledge) for predicting learning gains, they did not actually pursue that approach.

3. TEXT REPRESENTATIONS

In this paper we explore unsupervised representations of the transcripts of math tutorial videos. When designing the representations, we considered the following characteristics: (1) Similar content should involve similar tokens. A math video whose transcript consists of just "two plus three", for example, is unlikely to be similar to a video whose transcript is "four times x". (2) The most important tokens tend to recur within a video transcript. Conversely, tokens that are uttered only once are often less important or even be transcription errors. (3) The relative order of nearby tokens is important for deciphering the math content. For example, "four over two" and "two over four" are different fractions, but the difference is reflected only in the relative order of tokens, not in their frequencies. For characteristics (1) and (2) above, we created several variations of "1D" text representations that capture which tokens occur more frequently in each video. With the additional characteristic (3), we also explored "2D" text representations that can capture the relative order within a fixed radius from token i w.r.t. token j for each (i, j) pair. We note that extracting the precise mathematical expression from the transcript is inherently ambiguous. For example, the two distinct expressions 2^{x+2} and $2^x + 2$ would likely both be spoken as "two to the x plus two". Fortunately, our objective is not to capture the math content perfectly, but to capture enough of it to enable effective clustering, search, and prediction of learning gains. Below we describe different kinds of unsupervised text representations that vary in terms of token type, order dependency, and summarization method.

3.1 Token Types

3.1.1 Individual Token

As our simplest representation, we call each word (separated by space) a *token*, and then we count the number of math-related tokens, defined as: (1) numbers (digit-only), (2) operations (e.g. $+, -, \times$), or (3) variables (an alphabet). For the operations, we map synonyms to the same token, e.g., 'plus' to '+', 'to the [power]' to '^'. Additionally, we add the words corresponding to each digit 0 to 9 (i.e. 'zero', ..., 'nine') as math-related tokens. For variables, we used a restricted alphabet consisting of $\{b, c, n, m, w, x, y, z\}$ (we omitted 'a' since it is also a common English word).

3.1.2 Expression Token

To infer which math problem in video, it might be useful to extract the entire expression.For example, "2 plus 3" could be considered as one token "2+3" not '2', '+', and '3'. Specifically: (1) We mark all tokens in the transcript as either math-related or non-math-related. Tokens that are labeled as math-related are literals (LIT) and operators (OP) such as plus (+), $\sqrt{}$, etc. (2) For each contiguous sequence of math-related tokens, we read the tokens one-by-one and concatenate them into one expression according to the rule: starting with LIT followed by OP, LIT, ... (alternately).

3.2 Token Count Vector

Given the sequence of tokens in each video, we then compute either a 1D vector or 2D matrix of frequency statistics (which are finally summarized as described in Section 3.3). In the subsections below we let $\mathcal{T}$ be the set of all tokens that appear in any of the videos.

1D (No Order Dependencies): The count vector of each video contains $|\mathcal{T}|$ components, each of which records the frequency of token occurs in video.

2D (First-Order Dependencies): With the goal of encoding the *relative order* of tokens, we computed a 2D *matrix* M, of size $|\mathcal{T}| \times |\mathcal{T}|$, such that M_{ij} is the number of times that token i appears before token j in the transcript. In this approach, we introduced a "radius" parameter k to limit the distance of token pairs (i, j) that need to be considered. For example, if $k = 4$, all token pairs (i, j) such that the distance between i and j is ≤ 4 will be counted, otherwise, ignored.

3.3 Token Summarization Methods

Given the token count vector computed in Section 3.2, we then summarize each count x using a summarization function f. We considered the following functions: (1) **Raw Frequencies**: We let $f(x) = x$. (2) **Binarized Frequencies**: Binarizing the counts x might be less susceptible to noise; hence, we tried setting: $f(x) = 1$ if $x \geq 1$ and $f(x) = 0$ if $x = 0$. (3) **Weighted Frequencies**: It might be beneficial to weight down tokens which appears once because it might be noise from the extraction process; important tokens should be mentioned multiple times in video; token found only once (we call it $t_{=1}$) are either insignificant or incorrectly extracted. Instead of removing $t_{=1}$, we introduced the parameter r to downweight $t_{=1}$. In this case, instead of having the raw frequencies, We fixed the weight of $t_{>1}$ (appear *more than* once) as 1; however, we downweight $t_{=1}$ by r. We thus let $f(x) = 1/r$ if $x = 1$, $f(x) = 0$ if $x = 0$, and $f(x) = 1$ if $x > 1$. Note that $r = 1$ is equivalent to Binarized Frequencies.

4. DATASET

We applied the text representations to two sets of tutorial videos: (1) *Logarithms* and (2) *Algebra*, see Appendix A.

5. CLUSTERING

Given the different feature types, we test whether they serve as an effective basis for clustering the videos. In this section, as ground-truth cluster labels, we took the math problem (there were $K = 18$ unique problems in total) that each video explained as its label. Note, however, that we could also cluster the videos by the *category* of problems that they explain (see Section 4); we do so in Section 7.

Methods: For each of the different text representations, we applied K-means clustering to group the videos into $K = 18$ clusters, followed by the Hungarian algorithm [5] to optimally match the estimated cluster to the ground-truth indices. Since K-means converges to different local minima depending on the random initialization, we executed the algorithm 512 times and then reported the average of accuracy for the clustering with lowest sum of squared distance.

Results: Table 1 shows the clustering accuracy results. All three methods yield accuracies that are much greater than the *random* baseline, which achieved only 18.27% accuracy.

Weighted Frequencies: We tried multiple values of r ($r = 1$ is equivalent to the Binarized Token Counts). We also added $r = 0.5, 0.25$; this contrasts with our intuition for when it weights $t_{=1}$ more; we added this as a sanity check that the accuracy should be getting worse. Table 1 shows that the weighted frequencies increase the accuracy significantly up by 10% on average. $r = 2$ performs the best among $r = 2, 4, 8$. As r gets larger, we see a slight decrease in accuracy.

1D vs. 2D: Table 1 (right) shows clustering accuracy with the 2D approach. For the radius $k = 2$ on the Expression token (and using weighted frequencies with $r = 2$), the accuracy increases around 2% compared to with 1D. However, we can see lots of variance in the accuracy over the different k, and hence the advantage may not be statistically reliable.

Comparison to TF-IDF: Our token summarization methods can be seen as variations of TF-IDF, where only the TF term $f(x)$ is used; in other words, we used a constant 1 for the IDF term. (We experimented with several IDF functions but found that they all worked worse than just 1.) The weighted frequency scheme we tried can be seen as a coarse (piecewise-constant) approximation to the (smooth) log function commonly used as the TF function in TF-IDF. Using TF-IDF (with log for TF and 1 for IDF) and Expression Tokens, the clustering achieved 78.67% for the Expression Token (down about 5% from our *weighted* frequency method). For the Individual Tokens, it performed similarly in accuracy compared to the weighted frequency methods. (See the "log" column in Table 1.) In summary, the results provide some evidence that our text representations may yield a worthwhile accuracy advantage over TF-IDF.

6. SEARCHING

Here we explore whether the proposed text representations could be used to create a simple search engine to reduce the amount of *video time* they would need to watch. Using the text representations, we can build a simple search engine as follows: (1) From each video i in a collection $\mathcal{S}$, we transcribe its speech into text (using Google ASR) and then extract its text representation v_i. Then, (2) for any search query (e.g., "Simplify: $\log_4 16$"), we likewise extract its text representation q using any of the methods presented in Section 3. Finally, (3) we rank all the videos in $\mathcal{S}$ by the *cosine similarity* between v_i and q.

Experiments: Here we consider a general setting in which *multiple* math problems may be explained in a *single* video. A search engine that can pinpoint which *segment* of a video explains the solution could save the user significant time compared to watching the whole video. For this setting, there is a trade-off between granularity and accuracy: the search engine may be more accurate if the segment length is longer, but the user can save more time if the segment returned to them by the search engine is shorter. Hence, we introduced a segment length parameter, L. We divided each video into multiple segments of length L. Each segment has its own (sub-)transcript and its own problem that it explains. Hence, we treat each segment as its own "video". Our goal is to find *any* segment in the video that explains the problem in the user's query q. As a baseline, we used a simulation (averaged over 20 runs) to estimate the sum of the segment lengths (in seconds) that a user would have to watch before finding a relevant segment.

Results on the Algebra dataset: We analyzed the 234 videos of the Algebra dataset that contain multiple problems; in

Token Types	1D								2D					
	Raw	Weighted: r						log	Radius k (for Weighted: $r = 2$)					
		0.25	0.5	1	2	4	∞		1	2	4	8	16	∞
Individual	54.33	25.48	41.35	67.31	72.11	68.75	64.90	73.56	64.90	63.46	59.13	57.69	62.02	49.04
Expression	50.48	20.67	44.71	70.19	**83.65**	83.17	80.29	78.67	83.65	**85.58**	75.96	71.64	73.56	51.44

Table 1: Clustering accuracy on the logarithm videos for 1D text representations with different token types and summarization methods, and the clustering accuracy for 2D representations and different token types (all with weighted summarization: $r = 2$).

total, these videos explain 300 algebra problems. We varied the segment length L over the set {15s, 30s, 1m, 2m, 4m} (see Figure C.1 in Appendix). The results shows that the best text representations were 2D Binarized Individual Token ($k = 8$). In particular, the 2D representations showed an advantage (compare the pairs of {blue, pink}'s *solid* and *dashed* lines). We found that radius $k = 8$ for 2D Representation preforms best across each method. For the Interval Length, the percent decrease, at $L \in \{30s, 1m\}$, in watch time is highest (i.e., the most helpful, see Figure C.1 in Appendix). As L continues to grow, the results go down and at $L = 15s$, the performance drops. This exemplifies the trade-off between segment length and available information.

Results on the Logarithm dataset: In this dataset, each video contains *one* log problem. For each of 18 logarithm problems, we search for *any* of the videos that solve that particular problem. Comparing the results with *random* baseline, the results show the same trend as for the Algebra dataset: The 2D Representation gives the best results. We found, for instance, Binarized Individual Token yields the results of 89.96%, and 93.19% for 1D and 2D ($k = 8$), respectively. The same holds true for Weighted Expression Token ($r = 2$) with the results of 91.25% and 93.20%. For the 1D approach, the best representation was TF-IDF (with log for TF and identity for IDF); the reduction was slightly lower (92.85%).

7. LEARNING GAIN PREDICTION

In this section, we investigate whether the text representation can be used to predict the learning gain of students who watch the videos as an educational intervention. The high-level idea is that the effectiveness of each tutorial video can be estimated by the *interaction* of the *content* within the video and the student's prior knowledge. In contrast to some prior work that predicted the *average* learning gains of a video over many students, here we tackle the arguably harder problem of predicting *individual learning gains* of each student, measured as the difference in test scores on the curriculum before and after watching the video.

The Logarithms dataset (Section 4) contains pretest/posttest scores of students who received a tutorial videos as an intervention. Hence, we use each participant's pretest score and the text representation of the video they watched as predictors to estimate their learning gains (posttest minus pretest score). Rather than use the text representation as a feature vector itself, we instead use the *category label* assigned to the problem (Section 5) by the clustering algorithm as a 0-1 indicator variable with an associated model coefficient; hence, our models can find interactions between a student's prior knowledge and the topic in the video they received.

7.1 Prediction Models

We considered both linear models with mixed effects, as well as deep non-linear models based on neural networks, but we found that the latter overfit too easily and gave unstable results; hence, we present only the linear models. Let $p_{ij}, j = 1, 2, 3$, be student i's prior knowledge (pretest score) within the 3 problem categories (j) on logarithms. Let $c_{ij}, j = 1, 2, 3$, be 0-1 indicator variables that reflect whether student i's assigned video belongs to each category j. (Note that each video is assigned to exactly one of the three categories.) We can compute c_{ij} using either (a) Manually Labeled Categories (MLC) from human annotators, or (b) Automatically Labeled Categories (ALC) from the text representations and clustering algorithm (Section 5).

Prediction Model: We constructed a model that considers multiplicative interactions between the student's prior knowledge p_{ij} in each problem category and the cluster label c_{ij} of the student's assigned video:
$y_i = \sum_{j=1}^{3} (w_j p_{ij} + v_j c_{ij} + u_j (p_{ij} \times c_{ij})) + \epsilon_i$. Importantly, this model contains multiplicative interaction terms $p_{ij} \times c_{ij}$.

Results: We found that the interaction $p_{ij} \times c_{ij}$ using MLC has a statistically significant effect on the learning gain ($F_{11,\,582} = 5.839, p = 5.11e-09$), and so does this interaction using ALC ($F_{11,\,582} = 6.425, p = 4.125e-10$). The RMSE is 0.464, which is slightly better (about 3.1% relative decrease) compared to prediction model 1. Specifically, we found that, for example, u_3 is *negative* and statistically significant ($p = 0.0005$) in the ALC model. The negativity of u_3 means that, if $p_{i3} \times c_{i3}$ is low, then the learning gain is high (and vice versa). In turn, $p_{i3} \times c_{i3}$ is low either because (1) p_{i3} is low and $c_{i3} = 1$, i.e., an individual knows little about topic 3 and receives a tutorial about topic 3, yielding high learning gain; or (2) p_{i3} is high and $c_{i3} = 0$, i.e., an individual already understands topic 3 and receives on another (more helpful) topic, yielding high learning gain. Both the MLC and ALC interactions were stat. sig., suggesting that the text representations can group videos in ways that predict individual learning gains.

8. CONCLUSION AND FUTURE WORK

We have devised novel text representations to represent the content of math tutorial videos. On a dataset of hundreds of math videos and hundreds of students who watched them, we showed that the representation can be used to (1) accurately (around 85%) cluster the videos into the math problems they solve (RQ1); (2) search for specific video content in a large repository of videos, thereby saving the user considerable (up to 88%) search time (RQ2); and (3) predict individual learning gains, in conjunction with features of the students' prior knowledge, with stat. significance (RQ3).

APPENDIX

A. DATASET

Here we described each dataset we use in the experiment in more detail.

Logarithms: This is the dataset collected by Whitehill & Seltzer [14], which contains both a repository of 208 math tutorial videos about logarithms. Most videos are between 1-3 minutes long. In total the collection spans 18 logarithm problems, with 9 to 17 videos per problem. Relevant only to Section 7, the dataset also contains students' pretest and posttest scores of 541 participants from Amazon Mechanical Turk who watched the videos. There are 226 males, 207 females, and 108 of undefined, with the average age of 33.71 $\pm$9.84. Specifically, each participants were asked to answer 19 logarithm pretest problems, which was classified into 3 main categories: (1) the logarithmic term without variables e.g. $\log_9 1$, (2) the logarithmic term with variables e.g. $\log_w \frac{1}{w}$, and (3) the logarithmic equation e.g. solve for x where $x \log_4 16 = 3$ (category 1, 2 and 3 contain 102, 61, and 45 videos, respectively). Then, they were assigned to *one* random video among 208 logarithm tutorial videos, and were asked to complete a posttest (same level of difficulty as the pretest but slightly different problems).

Algebra: For the search task, we collected another dataset, containing 234 algebra math tutorials on Youtube As of 234 videos, 213 of them contains *one* math problem and 21 of them contains *multiple* math problems (total of 87 math equations); total of 300 expressions on entire dataset. We manually annotated which equation (e.g. $2x^2 - 2x - 12 = 0$, $x + 7 = 10$) each video explains. For videos with multiple math problems, we marked the start end time of each.

B. SPEECH-TO-TEXT TRANSCRIPTION

All the feature types we explore are based on obtaining an *approximate* transcript of the video from an ASR. In particular, we use Google Speech-to-Text API. As a pilot test of its accuracy on the OERs in our dataset, we manually annotated 10 videos (in total of 3044 words in the ground-truth transcripts). Google's API achieved a word error rate (WER) of 5%, which intuitively seemed sufficient, which intuitively seemed sufficient. An example of extracted speech is shown in Figure 1 (caption). After obtaining the transcript for each video in our collection, we then tokenized it and summarized the token frequencies.

C. ADDITIONAL FIGURES

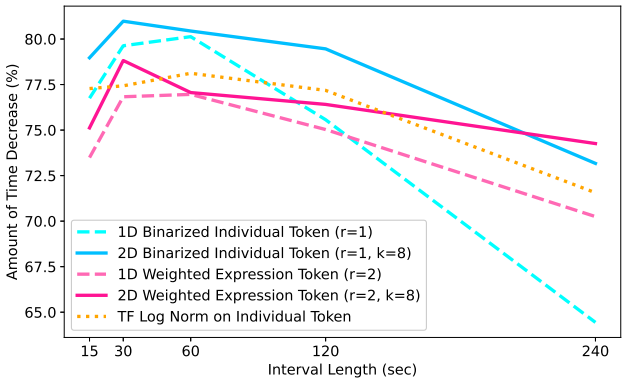

Figure C.1: The decrease in time needed to find specific math content in a set of math tutorial videos. Each line shows a different text representation over different segment lengths.

Predicting Young Students' Self-Evaluation Deficits Through Their Activity Traces

ABSTRACT

Self-evaluation is a key self-regulatory process that can already be mastered by young children. In order to assess self-evaluation skills of children, we introduced a random prompt asked randomly after 1 out of 15 exercises into a literacy web-application for primary school student, in order to evaluate the perceived difficulty [Too easy, Good, Too difficult] of the exercise they just solved. Comparing students' actual performance with their responses to this prompt can provide information about their ability to self-evaluate, and thus detect students who could improve their self-evaluation skills. We collected more than 1,000,000 responses from 300,000 students and used these data as well as performance data on each question of each exercise to predict a student's response to the next prompt, thereby estimating how likely they are to having a self-evaluation deficit. The results show (a) that a student's past responses to self-evaluation statements impacts the quality of future predictions (b) that the impact of past responses - vs their current performance - is greater when the student has low capacity for self-evaluation (c) that including older student data (answers from several sessions ago) helps in improving the accuracy of the prediction. These results pave the way (1) for adaptive polling by identifying when the model is unreliable, giving them the statement then instead of randomly, (2) for adaptive feedback, by knowing the students the most likely to show a deficit, to provide remediation.

Keywords

Self-Regulated Learning, Primary school, Self-evaluation, Prediction, Remediation, Adaptive polling

1. INTRODUCTION

Improving children's self-regulated learning (SRL) skills is a key component of their academic performance, as self-regulated students generally know better "how to learn", which can have a positive impact in all disciplines [22]. A key SRL process is self-evaluation [17], which is a skill already developed in children as young as 5 years old [19]. It is therefore a particularly interesting SRL aspect to target when working with young children. The most reliable way to assess SRL deficits is through direct questions to the students [1], but constant prompting can lead to an overall degraded perception of the learning environment [3] and it is therefore critical to limit prompting to the minimum. Hence we are interested here in trying to predict students' answers to assessment on perceived difficulty which are used to assess students' tendencies to overevaluate or underevaluate. The second aspect we investigate is relative to the features that are the most relevant for this prediction.

2. RELATED WORK

The EDM community has recognized early on the interest of studying SRL through data mining [21], and previous works have been more particularly interested in detecting SRL behaviors from traces [5], discussion forums [9, 8] or proxy behaviors such as gaming the system [4], explaining such behaviors with sequence mining [20, 2], mixture models (for procrastination, a proxy of SRL) [13] or coherence analysis [18]. Other works have focused on analyzing the differences in use of SRL strategies [6], providing feedback to encourage them [7] or predicting their use [15]. However, as far as the authors are aware, no previous work has specifically attempted to predict how a student would answer to a question aiming to measure a SRL deficit (self-evaluation or any other), and none of the aforementioned work focused on young children (5-7 years old). It is worth noting that although young children's abilities to use SRL strategies may be more limited than in teenagers, they seem to have comparable monitoring skills [16]. Indeed, recent work on a dashboard supporting SRL in a mathematics software program for 9-10 years old (only slightly older than our targeted students) showed a significant improvement in SRL skills for students in the dashboard group compared to those without the dashboard [12].

3. SELF-EVALUATION ASSESSMENT

3.1 Context

Lalilo is one of the many web applications used by teachers in the classroom to help them implement a differentiated pedagogy. At the beginning of 2021, it is used by 40,000 English and French speaking kindergarten and elementary classes every week to strengthen literacy through series of exercises adapted to the students' level, while providing the

Thomas Sergent, Morgane Daniel, François Bouchet and Thibault Carron "Predicting Young Students' Self-Regulated Learning Deficits Through Their Activity Traces". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 667-671. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

teacher with a dashboard to evaluate the students' activities and progress. It is therefore a relevant testing ground for evaluating and then trying to correct some students' SRL deficits. A typical session lasts 20 minutes (on average) with the student performing around 15 short exercises with 3 to 7 questions each. Student activities (e.g. logging in, time spent on an question/exercise, mistakes) are traced and we will focus on students' answers to an exercise, thus we will call **trace** only the answers to this set of questions of the same type within an exercise.

3.2 Data collection

To assess some aspects of students' SRL skills, we introduced a random prompt is once every fifteen exercises when a student finishes an exercise (i.e. on average once per typical learning session). This prompt includes a **perceived difficulty** statement asking the student *"How difficult was this exercise for you?"* with 3 possible answers: "Too hard", "Just-right", "Too easy"). Comparing the answer to the perceived difficulty statement with the real performance aims at measuring the **self-evaluation** ability of the students, i.e. their ability to correctly estimate the difficulty of the questions they just answered. Before introducing the assessments, we checked qualitatively in a classroom using Lalilo that statements were understood by 1st grade students (details not presented here). We collected traces from Kindergarten, 1st grade and 2nd grade classes based in France, Canada and USA learning in French (FR) or English (EN) between January 18 and February 24, 2021 on the Lalilo platform. We kept only the traces for which students had answered to a prompt and further on we call trace the answers to the exercise with the associated answers to the prompt.

4. METHODS

4.1 Dataset

Given the history of a student answers to the perceived difficulty prompt and their performance on the current exercise, we want to predict which answer is the most likely to be given by the student to the next prompt (and thus extrapolate their self-evaluation skills). If the student's performance - which will be defined in the Feature engineering subsection - was "excellent" (resp. "poor") and they answered "Too hard" (resp "Too easy"), they were considered as having an underevaluation (resp. overevaluation) deficit. We filtered out students who had strictly less than 8 traces with answers to prompts so that our model would not overfit on results of students with very few answers, as students with very few answers were overrepresented in our initial dataset. We finally had 424,173 traces with an answer to the perceived difficulty statement from 34,083 students having on average 12 traces with self-evaluation answers (SD = 5.93).

4.2 Feature engineering

We engineered several new features that could have a predicting power in our results.

Basic performance feature. In addition to the trace and student IDs, used for filtering but not for prediction, we extracted for each trace the *answer correctness list*, a boolean vector of a length of 3 to 7 (number of questions per exercise).

Enriched performance features. From the answer correctness list, we extracted 5 additional features: the *good answer count* (i.e. the number of 1s in the vector - the higher the value, the better the student may feel they have succeeded), the *total answer count* (i.e. the length of the vector), *the success rate* (i.e. the ratio between the good answer count and the total answer count) and the *second half success rate* (i.e. the success rate on the last half of a trace - a student with self-evaluation deficit may suffer from a recency bias, influencing positively [resp. negatively] their perception of their performance when answering correctly [resp. incorrectly] to the last questions of the exercise).

Exercise features. We hypothesize that self-evaluation deficits are not uniform across one's knowledge. In particular, a student's deficit may be stronger in some types of exercises or on exercises about a given topic. To assess this impact, we added 5 features that relate to the exercise finished just before the two difficulty statements: *exercise template* (for example a multiple choice question or a word composition exercise), *lesson index* (there are around 1,000 lessons in Lalilo - although they are not entirely linear, the higher the value of this feature, the more advanced the content is; when working on English (resp. French) data, the lesson index FR (resp. EN) is empty), *lesson type* (lessons are organized in a tree structure - lesson type represents the first level category), *lesson subject* (lesson subject represents the second level category in the tree), *language* (English or French).

Previous feedback modalities. In order to help students' in their performance assessment, they are randomly given an audio feedback (such as "In the last exercise, you found 3 correct answers of 5 questions") and/or a visual gauge of as many green ticks and red crosses as they had good and bad answers in the previous exercise. Even when these synthesis exercise-level performance indicators are not there, the students always have an immediate question-level true/false feedback. We have previously shown the positive impact of these two indicators in correcting some self-regulation issues, and we therefore hypothesize that they need to be taken into account when predicting how the student will assess the difficulty. Hence we added two binary features, *gauge* and *audio* which indicate whether these performance feedback were given before the two difficulty statements. A feedback is also provided after answering to the prompt, when students display a self-evaluation deficit (as defined in 3.2), encouraging them to be more confident or warning them to be more careful; we therefore encode this as a third binary feature, *remediation*, indicating whether the student received a feedback the last time the difficulty was assessed.

Self-evaluation deficit lag features. Self-evaluation deficits are expected to be a recurring phenomena in students' answers, i.e. a student who has under/overevaluated themselves a few times is likely to under/overevaluate themselves again in the future. Hence we added 3 lag features for the last 3 perceived difficulty assessments. Moreover, since it is possible that the last 3 assessments were not allowing the student to exhibit a deficit (e.g. a student cannot appear to be overevaluating if their performance is at 100% on the last 3 exercises where they were asked to assess the difficulty), we also added 3 lag features for the last 3 perceived difficulty assessments where the student's performance was equal to the performance on the current exercise. Performance is a categorical value which is worth "poor" if the success rate is below 34%, "excellent" if the success rate is at 100% and "medium" otherwise.

Overall previous self-evaluation deficit. If students are stable over time in their assessment, we expect that taking into account the whole history would have a positive impact on

the prediction. We therefore introduced 5 additional features: *self-evaluation answer rank* (the number of times the student has been asked a self-assessment), *number of "Too easy" (resp. "Too hard") answers* (the number of times the student previously answered "Too easy" (resp. "Too hard") to previous assessments), and *"Too easy (resp. Too hard) answers ratio"* (the ratio between the two previous features). Additionally, similarly to what was done for the lag features, we also considered the 5 equivalent features exclusively on previous assessment given after an exercise with a similar performance level.

4.3 Algorithms

We used Catboost [14] and LightGBM [10] to perform the predictions, two gradient boosting algorithms based on Decision Trees whose main assets are: (a) their ability to natively deal with categorical features and (b) their explainability, allowing to study feature importance in each prediction with SHapley Additive exPlanations (also called SHAP values) [11]. They also have recently won Kaggle competitions on a variety of datasets. We used MultiClass as a loss function, set the number of iterations at 200 and kept the other hyperparameters at their default values. As their results were very similar for the global prediction task (cf. Table 1), we used CatBoost model only for the other tasks.

4.4 Analyzing features importance

We first measured the improvements allowed by feature engineering to the global prediction scores using 5-fold cross validation and stratifying by student so that no student traces are both in training and testing folds. For all feature importance measures subsequently described, we created a training and a testing set - also stratified by student - and measured the feature importance in the testing set. We studied the importance of various features in our model using the SHAP package [11]. We also compared the importance of features across the three classes so as to highlight the features that have the most impact on each class specifically.

If students showed a given deficit regularly - we defined a threshold at 50% of "underevaluation" (resp. "overevaluation") over the traces with 100% (resp. below 34%) success rate - we tagged the student as having an "underevaluation (resp. overevaluation) deficit". We then trained our algorithms on a dataset with students tagged as having a deficit and on a dataset with students tagged as having no deficit. Our hypothesis was that feature importance would vary between these two models: the predictions were expected to depend more on past answers than current performance for students tagged with deficits compared to the other students.

Finally, we measured the evolution of the performance of the model depending on the self-evaluation answer rank that is predicted. To do so, we analyze the evolution of Cohen's Kappa coefficient, measuring the quality of our prediction of the perceived difficulty, on a cohort of students of the testing set having answered a given amount of prompts. We computed this coefficient for each self-evaluation answer rank and expected the quality of the prediction to improve as students would be better and better characterized by their features.

5. RESULTS AND DISCUSSION

5.1 Global features importance analysis

Firstly, both Catboost and LightGBM allow to predict with a reasonable overall performance the students' perceived difficulty (cf. right part of Table 1). Secondly we see that all features additions improve the model except the previous feedback ones. Specifically, adding features describing what a student did in the past improves the predictions significantly.

Table 2 ranks the top 10 features with their mean absolute SHAP values. Interestingly, the success rate of the student and the success rate on the second half of the correctness list are only the 5^{th} and 8^{th} ranked features. It means that past information about the previous answers of students to self-evaluation prompts influences more the prediction than their current performance, although they are being asked "How difficult was **this** exercise for you?". Specifically, the last three answers to the perceived difficulty question bear a significant weight in our model's predictions, as well as the global "Too easy" and "Too hard" ratios. As expected, the "Too easy" ratio has a huge importance for the "Too easy" class as has the "Too hard" ratio for the "Too hard" class and both ratio are highly ranked for the "Just-right" class. Indeed, we did not input the "Just-right" ratio as the model can learn it from the combination of "Too hard" and "Too easy" ratio. We can note that the success rate feature is mainly important for the "Too easy" and "Too hard" class, which is logical as an excellent (resp. poor) performance is not likely to lead to a "Too hard" (resp. "Too easy") answer. We can also see on Figure 1, as the "Too hard" ratio is equal to 0, it drives the prediction score of the "Too hard" class downwards while it drives the prediction score of the "Just-right" class upwards. Furthermore, the 3 last answers to the perceived difficulty statement of this student were "Just-right", "Too easy", "Too easy" and their success rate on this trace was 100%; the predictions of the "Too easy" class are therefore also driven upward by these features.

5.2 Features rank from self-evaluation deficits

Figure 2 shows the feature importance rankings for students detected as having or not self-evaluation deficits. Students with deficits consistently choose how to answer to the prompt more based on past answers (in particular the "Too easy/hard" ratios), as opposed to students with no deficits who rely more on the success rate to this exercise, as one should. These results are in line with our hypotheses.

5.3 Predicting power based on answer rank

Figure 3 shows the kappa evolution depending on the number of past self-evaluation assessments. The kappa for the first answer is around 0.13, then quickly climbs around 0.4 for the next four traces; and finally slowly increases until plateauing around 0.6. The kappa of 0.13 for the first answer is consistent with Table 1: at the beginning, Student features are empty and the model can only rely on Trace features. With Trace features only, the model reached a Kappa of 0.1084 which coincides with the kappa value of 0.13 in Figure 3. We can then deduce that the model is more and more able to predict answers to the perceived difficulty statement.

Table 1: Prediction metrics after 200 iterations of the Catboost and LightGBM algorithms depending on the features used. We measure mean and standard deviation (in parenthesis) on 5-fold cross validation.

	Trace features			Student features			
Algorithm	Enriched perf.	Exercise	Feedback	Lag	Overall prev. self-eval.	Accuracy	Kappa
CatBoost	Yes					0.4662 (0.0006)	0.0866 (0.0030)
CatBoost	Yes	Yes				0.4737 (0.0018)	0.1084 (0.0022)
CatBoost	Yes	Yes	Yes			0.4736 (0.0018)	0.1081 (0.0026)
CatBoost	Yes	Yes	Yes	Yes		0.6676 (0.0034)	0.4522 (0.0053)
CatBoost	Yes	Yes	Yes	Yes	Yes	**0.6701** (0.0028)	**0.4575** (0.0042)
LightGBM	Yes	Yes	Yes	Yes	Yes	**0.6706** (0.0034)	**0.4565** (0.0032)

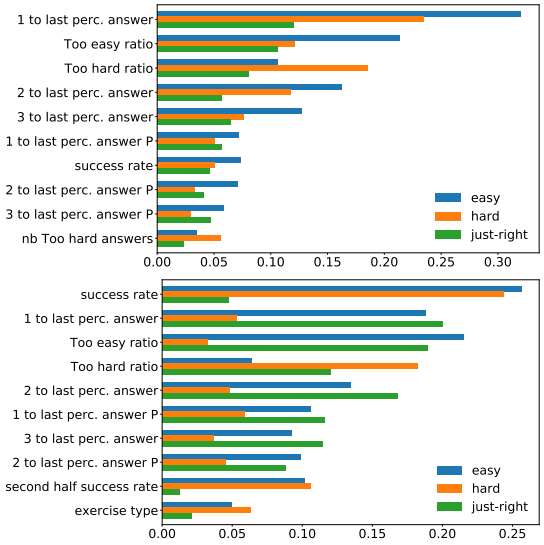

Figure 2: Top 10 features impact for class prediction of students detected as having (top) or not (bottom) a self-evaluation deficit

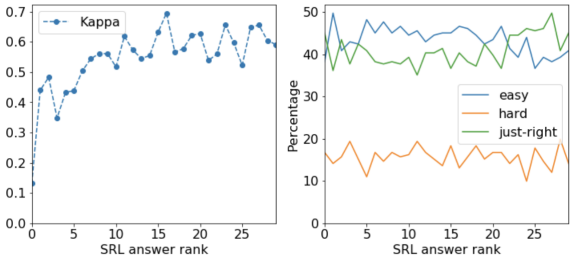

Figure 3: Kappa value and total number of traces of each class in the testing group, based on the self-evaluation answer rank

Table 2: Average feature importance rank by class, sorted by total SHAP value (top 5 in bold)

Features	Too easy	Just-right	Too hard
"Too easy" ratio	**1**	**1**	14
1 to last perc. answer	**2**	**2**	**3**
"Too hard" ratio	6	4	**1**
2 to last perc. answer	**3**	**3**	9
success rate	**4**	9	**2**
3 to last perc. answer	**5**	**5**	10
1 to last perc. answer P	7	6	12
second half success rate	8	19	**4**
3 to last perc. answer P	9	7	11
exercise type	10	15	**5**

6. CONCLUSION AND FUTURE WORKS

Using a large volume of trace data from primary school students, we leveraged students' past data to significantly improve the prediction of the answers to future self-evaluation prompts. The results also indicate that the more data we have about a student, the better our predictions are. Using feature engineering, we ranked features by the additional predicting power they provide, and found results consistent with SRL theories (in particular that prediction of answers for well-regulated students depends mostly on their success rate). This paves the way for adaptive polling (as opposed to the current random one), prompting only students likely to display a self-evaluation deficit, allowing us to better target remediation. The main limit of the current work is the specificity of the context: it would be particularly interesting to study the main features used in another context with a different type of students. We are also targeting one of many existing SRL deficits, and expanding research on predicting other deficits to encourage the training of multiple SRL skills seems important as well. Future works also include further feature engineering to refine what features may have more impact than the current ones.

ABSTRACT

We describe a data mining pipeline to convert data from educational systems into knowledge component (KC) models. In contrast to other approaches, our approach employs and compares multiple model search methodologies (e.g., sparse factor analysis, covariance clustering) within a single pipeline. In this preliminary work, we describe our approach's results on two datasets when using 2 model search methodologies for inferring item or KCs relations (i.e., implied transfer). The first method uses item covariances which are clustered to determine related KCs, and the second method uses sparse factor analysis to derive the relationship matrix for clustering. We evaluate these methods on data from experimentally controlled practice of statistics items as well as data from the Andes physics system. We explain our plans to upgrade our pipeline to include additional methods of finding item relationships and creating domain models. We discuss advantages of improving the domain model that go beyond model fit, including the fact that models with clustered item KCs result in performance predictions transferring between KCs, enabling the learning system to be more adaptive and better able to track student knowledge.

Keywords

Knowledge component model, domain model, learning transfer

1. INTRODUCTION

This paper describes preliminary progress to create a multimethod pipeline to determine the knowledge model (or domain model) that allows the most accurate prediction of performance in an adaptive learning system using a quantitative model of practice. A broad use of quantitative models of practice is to predict performance and make pedagogical decisions [1; 2]. To do this effectively, models typically assign sets of problems or items specific skill tags (often called knowledge components, or KCs). Having such an identification allows a system to monitor which skills have been learned and which need more practice. The matrices representing these item assignments to skills are called Q-matrices [4]. Because the act of tracing student learning is so important for pedagogy, the assignment of items to KCs is crucially important for systems to make pedagogical decisions. Without such an assignment, a system would conceivably need to schedule all items for practice to ensure mastery, so the assignment or "domain model" must be accurate for a system to perform well. Improvements in the domain model may result in better pedagogical decisions in a system. This paper describes a more general approach to improve these critical domain models, a tradition that has included much prior work [3; 5; 14; 15; 19; 20; 22].

In addition to improving domain models, we highlight how these methods may alter how many quantitative models work by enabling models where multiple knowledge components can influence a single practice trial. While such models are not new [13], specifying them with experts is time consuming and error prone. Despite this difficulty, domain models that include the potential for multiple KCs affecting a single performance also typically capture transfer when a shared KC is used in multiple items. In addition to making models more accurate, this transfer has large potential impacts on pedagogy in a complex adaptive instructional system since transfer in an adaptive system means that a KC's performance may bias the selection of other items that share KCs. This transfer will occur because the shared KC will affect the item predictions, making items sharing a KC more or less likely to be practiced.

2. ANALYSIS METHOD

We have developed an automatic domain model improvement algorithm with a highly configurable analysis pipeline.

2.1 Step 1

First is the preprocessing stage. In this stage, some matrix-based method will produce some featural vector of information representing each item. There are two ways this method might process the data from an educational system, either all at once or sequentially in the order the student saw the items. In the first case, this would include methods such as SPARFA-Lite, which assumes one observation for each skill for each student [14]. Our example in this paper uses the SPARFA-Lite model and a simpler model based on covariance clustering [20]. For our examples, Step 1 meant averaging KCs performances for each subject to get a student performance by KC. More advanced methods such as tensor analysis can proceed with sequential data for each student. However, this is future work not presented here.

2.2 Step 2 Infer Feature Matrix

In this step, the method is applied to the data to get some matrix. Currently, the pipeline has two possibilities at this stage, but we plan to include multiple methods in future work as we look to our long-term goal of building a shareable tool for the EDM community.

2.2.1 Covariance Clustering

Developed by Pavlik, Cen, Wu, and Koedinger [20], covariance clustering is a method to describe how each item or existing KC in a domain model is related to all other items or KCs (using a measure of conditional log odds to represent covariance). This method computes a vector for each item representing the conditional

Philip I. Pavlik Jr., Luke Eglington and Liang Zhang "Automatic Domain Model Creation and Improvement". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 672-676. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

probability table for success and failure for the items/KCs relative to all other items/KCs. The pairwise relationships between each vector are similar to the relationships inferred in POKS (Partial Order Knowledge Spaces, [7; 8]), a method related to Falmagne's work [10; 11]. An advantage of covariance clustering is that it characterizes each pairwise relationship between items/KCs in terms of the relationship with all other items/KCs. Pavlik et al. [20] used clustering to establish how to group items by using this KC/item relational vector as the set of features.

2.2.2 SPARFA-Lite

Developed at Rice University by Lan, Studer, and Baranuik [14], SPARFA is a factor analysis method to extract factors from binary-valued data. It provides an association matrix similar to a dAFM Q-matrix with graded associations of concepts with items. The "Lite" version simplifies the method by reducing the parameters and allowing automatic inference of the optimal number of concepts. This method works differently than dAFM, but it provides similar results, allowing for direct comparisons. Also, the ability to infer the optimal number of concepts may be a useful constraint when applying other algorithms.

2.3 Step 3 Cluster Principal Components of Features

In this step, the information matrix is clustered using some method to group items into clusters. Our current implementation first uses RSVD (Randomized Singular Value Decomposition) to simplify the information matrix. We see from the pattern in the results section how the quantity of RSVD components influences the clustering result. We are currently using K-means clustering for clustering, so our search is across both RSVD number of components (N) and K for the number of K means clusters.

For this step, we have also done considerable experimentation with the cmeans fuzzy clustering method, which provides a 0 to 1 index of how strongly each KC is associated with each cluster. Typically, we have used this by specifying a threshold (which can be optimized with search) over which an item belongs to each cluster or not. This assignment allows for membership in multiple clusters, which means that unlike the method in Step 2.4, the item is assigned to potentially many clusters. Typically, when we use this method, we have weighted the effect of prior practice for the KC clusters according to the number of KC clusters involved in a performance. This weighting is not necessary for the simpler K-means implementation since the added KC column only assigns each KC to 1 KC cluster.

2.4 Step 4 Fit with New Model

We used the new model as an overlay such that we created a column with the cluster id for each KC for each trial. This overlay procedure means that while the KC and clusters are independent, practicing an item may affect other items if they share a cluster. To do this, we first describe our starting model, which was simply PFA (Performance Factors Analysis, [17]) using the logarithms of practice counts for successes and failure (adding 1 to each to permit the logarithms). Where θ values are Student ability and KC difficulty respectively, and *S* and *F* represent the count of prior success and failures for the KC *j* for the student *i*.

$$logit(p_{ijt}) = \beta_1 \log_e S_{ij} + \beta_2 \log_e F_{ij} + \theta_i + \theta_j$$

The new model was defined using cluster-id (c) as a KC in an additive compensatory model. Prior research suggests such compensation among KCs works well for prediction [6; 16].

$$logit(p_{ijt}) = \beta_{1j} \log_e S_{ij} + \beta_{2j} \log_e F_{ij} + \beta_{3c} \log_e S_{ic} + \beta_{4c} \log_e F_{ic} + \theta_i + \theta_j$$

Two versions of this model with clusters were compared; the first version was as described, and the second version was a control condition where the cluster column was sampled at random from the Q-matrix. This control condition should exhibit the same amount of overfitting due to adding parameters but none of the benefit of a coherent clustering solution. These models are compared using 2 to N components and 2 to K clusters by iterating to Step 3 to search a space of models.

In the context of our future work, we plan to allow users of our tool to specify candidate models with different configurations and terms using a logistic knowledge tracing R package freely available [18]. It is possible that different learner models may be implemented at this step since the Q-matrices we are creating may be used in many types of learner models.

2.5 Step 5 Splitting and Merging

Just as steps 3 and 4 may iterate to find optimal K and N, steps 4 and 5 may iterate to refine the model in Step 4. This step describes our future planning for a tool to optimize Q-matrix type models of knowledge domains.

Splitting takes the original KC model and uses the KC model from the clustered features to determine hypotheses for how KCs might be split. So if a KC in the original model is in 2 clusters, the model would test whether that that was best represented by the default model (include the effect of the cluster and the KC for each KC) or whether the cluster was unnecessary and the fit was just as good by splitting the KC into two different KCs and dropping the effect of the cluster KC. Further, we could also test whether the specific clusters proposed for each KCs even improves fit by removing them entirely as a third hypothesis. Two of these three possibilities correspond to Learning Factors Analysis (LFA) [5], and the third (including the cluster instead of using a split) advances the approach.

Merging uses the cluster model like LFA, but instead of splitting KCs, the clusters are used to evaluate three hypotheses about whether existing KCs can be merged into a single KC. One hypothesis is that the KCs are best represented as separate but influence each other through the shared cluster membership. The second hypothesis is that the specific cluster was unnecessary, and the two KCs should be merged into 1 KC. Finally, the third hypothesis is that the 2 KCs are separate and that the cluster predictor should be omitted.

Step 5 is similar to backward and forward stepwise regression methods, and so it is clear this method would be very likely to cause overfitting due to the way it will tailor the model term to capture the data iteratively. To prevent this problem, the solutions produced are robustly cross-validated. By tuning the model to maximize cross-validation accuracy, we aim to find quantitative thresholds for when to add or subtract terms from the model with a result that is efficient and parsimonious.

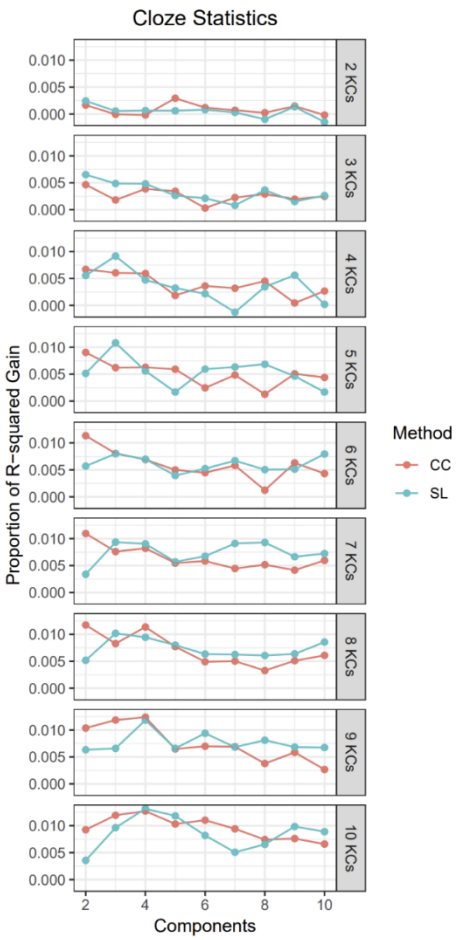

Figure 1. Changes in fit including differing numbers of additional clusters for Cloze dataset using covariance clustering (CC) or SPARFA-lite (SL).

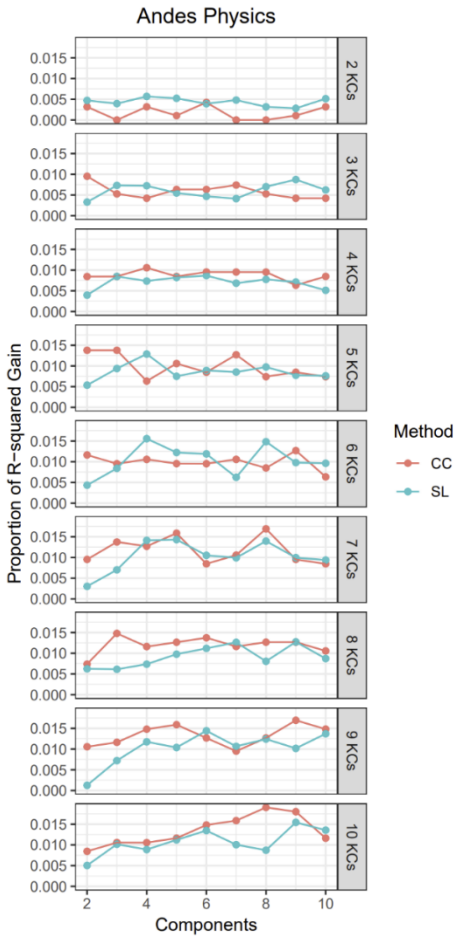

Figure 2. Changes in fit including differing numbers of additional clusters for Andes Physics data using covariance clustering (CC) or SPARFA-lite (SL).

3. DATASETS

The statistics cloze dataset included 58,316 observations from 478 participants who learned statistical concepts by reading sentences and filling in missing words. Participants were adults recruited from Amazon Mechanical Turk. There were 144 KCs in the dataset, derived from 36 sentences, each with 1 of 4 different possible words missing (cloze items). The number of times specific cloze items were presented was manipulated, and the temporal spacing between presentations (narrow, medium, or wide). The post-practice test (filling in missing words) could be after 2 minutes, 1 day, or 3 days (manipulated between students). The stimuli type, manipulation of spacing, repetition of KCs and items, and multiple-day delays made this dataset appropriate for evaluating model fit to well-known patterns in human learning data (e.g., substantial forgetting across delays, benefits of spacing). The dataset was downloaded from the Memphis Datashop repository.

In the Andes dataset, 66 students learned physics using the Andes tutoring system, generating 345,536 observations. Participants were given feedback on their responses as well as solution hints. Additionally, participants were asked qualitative "reflective" questions after feedback (for more details, see [12]).

4. RESULTS

Figures 1 and 2 show the result for the two datasets. The proportion of R-squared gain indicates the improvement in R-squared for the true clustered model compared to the random comparison R-squared model as a proportion of the random comparison R-squared model. Because of the result's preliminary nature, we have not been able to produce smoothed figures through cross-validation. However, the results consistently show beneficial effects. In general, both methods have similar accuracy.

Both methods can achieve similar improvements via different parameters. However, it does appear that the efficacy of the methods differs somewhat across datasets. Covariance clustering found the best solution in the Andes dataset, with SPARFA-Lite having the best solution in the Cloze dataset. This preliminary result suggests that applying multiple approaches to the same dataset may be advisable, especially when the underlying domain structure is unknown. Different domain modeling algorithms may differ in their ability to detect this underlying domain structure.

To understand better the results shown in Figures 1 and 2 we can query the model for the parameters for the cluster KCs to confirm that they are meaningful due to the structure of PFA. Normally we would expect the cluster KC coefficients for success and failure to be more different if the model was labeling real KCs since it is typically the case that successes predict future success more than failures. Indeed, test comparison shows exactly this pattern; for

example, considering the model with 10 components and 10 KCs in for the Physics data with covariance clustering applied, we see the success is .56 higher than failure. In contrast, for the randomized model, the value was .12 higher for success than failure (best explained as the overfitting we might expect for such a mechanism).

5. DISCUSSION

In the present paper, we described our ongoing work to automate both the process of searching for domain models and the search method (e.g., covariance clustering vs. SPARFA-Lite). Many approaches have been proposed to infer domain [3; 5; 14; 15; 19; 20; 22], but there has been little comparison. However, comparison among approaches is important because their different underlying assumptions and limitations will interact with the learning domain's true underlying structure. For example, if the learning domain is calculus, various prerequisite skills from other branches of mathematics may be necessary (e.g., algebra, trigonometry). In other domains, learning one KC before another may enhance learning but not be required. Learning how to compute a sample's mean may facilitate learning to compute the *median* due to contrasting their different procedures. However, neither is a prerequisite to learn the other. Domains vary in the extent that learning one KC may transfer to another, and the researcher may not have strong theories a priori that could help constrain the KC model search. Thus, choosing one method with specific assumptions and limitations across different knowledge domains may be inadvisable and result in suboptimal KC model solutions.

5.1 Future Plans

5.1.1 Additional domain model methods

There are several methods we hope to include in the system to analyze student data to produce the inference matrix, for example:

dAFM - Developed at Berkeley by Pardos and Dadu [15] and shown to improve the Piech [21] deep knowledge tracing algorithm. This method is a deep learning model that uses backpropagation to infer a Q-matrix type representation with graded skill assignments instead of binary assignments. The authors show how the model is a continuous neural network generalization of the AFM model used in the LFA method [5].

Tensor factorization – We have also been working with implementations of tensor factorization. Tensors allow the solution to integrate multiple sources of data, including a representation of time in the sequence of practice.

These methods may be more accurate because they allow the representation of sequence to capture order effects in the model that may be due to learning. However, another view might be that it makes it more vulnerable to the selection effects that led to particular practice sequences. In other words, domain model search algorithms that are sensitive to effects over time may be more likely to incorporate artifacts due to pedagogical decision rules (e.g., "drop item from practice after N successes"). For instance, in systems in which items are dropped from practice after a few successes (e.g., Assistments), the sequential order and temporal spacing will be different than in practice schemes in which items are not dropped from practice (e.g., [9]). In short, domain model extraction from datasets that were generated by an adaptive learning system will be influenced by the decision rules inherent to that system.

5.1.2 An ensemble approach to address individual model search limitations

We also intend to allow multiple approaches to be allowed within a single KC model development pipeline. For instance, approaches like dAFM have shown promise to improve KC models but require an initial KC model. However, this apparent limitation is only a problem if the goal is to find a single approach that resolves the problem of KC modeling. Instead, the goal can be reoriented towards finding the best ensemble and ordering of approaches that can be used in order to develop an optimal KC model. As an example, an optimal KC model may be created by making an initial model with SPARFA-Lite, followed by a final model using dAFM. Requiring a starter model is only a limitation if complementary approaches cannot be combined.

5.1.3 Integrating with learner model development

Learner models and domain models are strongly interdependent but frequently developed and refined independently. This separation probably limits progress on both fronts. Using relatively simple learner models when searching for improved domain models may lead to misleading results if the chosen learner model does not accurately represent learning, forgetting, transfer, and other important learning factors. Similarly, developing learner models without considering the chosen KC model's plausibility may lead to spurious results. Recently, we developed a framework to facilitate learner model development named Logistic Knowledge Tracing [18]. We aim to integrate automated KC model search and refinement into the LKT framework.

5.1.4 Representing transfer does more than improve model fit

Representing transfer among KCs can have significant pedagogical consequences that will not be apparent from model fit metrics (e.g., reduced RMSE, increased AUC). For instance, imagine a student is learning three items (A, B, and C). If the domain model considers A and B to be related because they share KC, practicing item A will influence both *when* and *how much* B is practiced. Depending on the strength of the transfer, practicing A may result in B being practiced being, being practiced before C, being practiced after C, or not being practiced until much later when forgetting has occurred (if the learner model assumes forgetting). The entire order of practice may change.

Another issue is the efficiency effect of such transfer. Consider that if the three items are independent, students may practice all three as necessary for mastery. In contrast, if item A affects item B through a shared KC, it will increase or reduce the amount of practice needed for mastery of B, which can reduce costly overpractice. In short, accounting for transfer among KCs may greatly improve practice *efficiency*, which may not be apparent when comparing domain models in terms of model fit metrics (e.g., RMSE, AUC, AIC). Ultimately, comprehensive evaluation of new KC models requires simulations or experiments to determine their effects on how practice is scheduled within an adaptive learning system. This need comes from how a new KC model may interact with pedagogical decision rules (e.g., mastery learning) and learner models (e.g., BKT, PFA) within an adaptive learning system to change the *sequence* of practice (e.g., due to quantifying transfer among items differently). These changes to the sequence may have significant impacts on student learning.

ABSTRACT

Offering students immediate, formative feedback when they are programming can increase students' learning outcomes and self-efficacy. However, visual and interactive programs include dynamic user input and visual outputs that change over time, making it difficult to automatically assess students' code with traditional functional tests to offer this feedback. In this work, we introduce Execution Trace Based Feature Engineering (ETF), a feature engineering approach that extracts sequential patterns from execution traces, which capture the runtime behavior of students' code. We evaluated ETF on 162 students' code snapshots from a Pong game assignment in an introductory programming course, on a challenging task to predict students' success on fine-grained rubrics. We found that ETF achieves an average F_1 score of 0.93 over 10 grading rubrics, which is 0.1–0.2 higher than a high-performing syntax-based code classification approach from prior work. These results show that ETF has strong potential to be used for code classification, to enable formative feedback for students' visual, interactive programs.

Keywords

execution traces, feature engineering, computer science education, code classification, formative assessment

1. INTRODUCTION

Real-time, formative feedback promotes students' learning gains and self-efficacy [7, 3, 12, 18]. To provide such formative feedback in real-time, CS instructors commonly write test cases, allowing students to run their code against these test cases when programming [9, 5, 6, 4]. However, visual, interactive programming projects, such as creating apps and games [16], include dynamic user interactions, and visual outputs that change over time, making it challenging to use test cases to assess these programs [14, 13, 20].

In contrast to test case-based approaches, data-driven methods allow instructors to offer formative feedback by grading a smaller set of programs instead of writing test cases [11, 21, 10, 22]. These methods start with transforming code into input vectors using **feature engineering**, typically by extracting syntax elements from an abstract syntax tree (AST), where nodes and their children correspond to specific code elements (e.g., if statements). However, when applying these syntax-based feature extraction techniques to classify programs, prior work showed mixed results, which are often not high enough to ensure the quality of student feedback [11, 1, 2]. Some prior work has used **execution traces** to classify students' sorting programs based on their specific strategies, and has shown that execution-trace-based classification achieved higher accuracies than a syntax-based classification approach [8]. However, no prior work has conducted feature extraction on the execution trace of visual, interactive programs, which include dynamic user interactions and various changing outputs. In this work, we extract features from execution traces that capture the runtime behavior of visual, interactive programs. We designed an execution trace-based feature engineering approach (ETF) to transform students' source code into feature vectors, for classification algorithms to build models based on rubric-based labels (e.g., the presence of a key-triggered movement). We evaluated ETF by classifying 162 students in-progress and submitted code snapshots. We found it to achieve high prediction performance with an average of 0.93 F_1 score over 10 grading rubric items, which is 0.1–0.2 higher than a high-performing syntax-based code classification approach. Our work has the following contributions: 1) We designed and implemented a novel, execution trace-based feature engineering (ETF) approach to extract temporal patterns in students' visual, interactive programs; 2) We evaluated the ETF approach on students' code snapshots for a widely-used, representative visual, interactive program assignment.

2. RELATED WORK

Syntax-based approaches extract patterns inside a code AST, use the presence or absence of a feature, or the count of the feature to generate input vectors. As an example,

a) Automated Program Execution

clock time	step	ball		
		position	direction	TouchSprite
1.974s	119	x:194, y:14	146	{ }
1.992s	120	x:200, y:6	146	{ }
2.019s	121	x:205, y:-3	214	{paddle}
2.024s	122	x:183, y:-35	214	{ }

b) Dumping Execution Traces

Figure 2: Step 1: Generating Execution Traces.

we explain a recently-applied AST n-Gram feature extraction approach [17, 2] by making an analogy to Natural Language Processing (NLP): In NLP, an n-Gram with $n = 1$ is a *1*-Gram feature taken from each word; and an n-Gram feature takes a continuous sequence of n words to extract relationship between words (e.g., orders); in an AST, *1*-Gram features represent each *node* in students' code. And to extract structural relationships, Akram et al. [2] designed the use of n-Grams to represent n-length sequences of code, where a ***vertical n-Gram*** is created by a depth-first search of leaves; a ***horizontal n-Gram*** is created by a breadth-first search of all direct children of each AST nodes (e.g., in Figure 1) [2]. *1*-Gram and n-Gram-based AST feature extraction approaches have both been applied for student code classification tasks. Compared to *1*-Gram feature extractions, prior work has shown that n-Grams provide more predictive features for code analysis. For example, Akram et al. used n-Grams with n ranging from 1 to 4 to extract features, and used a Gaussian Process model to infer scores on 642 students' code pieces, in a block-based programming environment. This achieved an R-square of 0.94, higher than the 0.88 achieved by the baseline *1*-Gram approach [2, 1].

On the other hand, recent work by Paaßen et al. used **execution-trace-based** distance measures to classify programs into different strategies (e.g., bubble sort v.s. Insertion sort), and found that execution- race-based classification achieving 90% accuracy, higher than the 80% accuracy achieved by syntax-based approaches [8]. This shows the potential of using execution traces to classify students' programming code.

3. THE ETF APPROACH

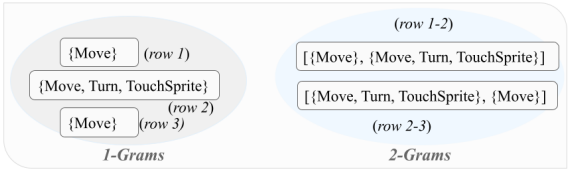
ETF starts from collecting a set of students' programming code, along with a class label for each piece of code, (i.e., positive or negative). ETF is designed for programs that have the following properties: 1) respond to **dynamic user inputs** (e.g., mouse, keyboard). 2) has **object-specific program states**, corresponding to visual output on the screen. 3) Program behaviors can be **a function of time**; and can also **change over time**.

An Example Assignment. As an example, consider the Pong assignment, which consists of a paddle sprite and a ball sprite. The ball moves around the stage [19], and a player can use the keyboard to control the up and down movement of the paddle to catch the running ball. If the paddle catches the ball, the player score increases; but if the paddle misses the ball and the ball hits the back wall, the game ends. ETF conducts feature engineering on such visual, interactive programs in four steps, described below.

step window	ball				
	Move?		Turn?	TouchSprite?	
119 - 120	✓	{right, down}	✗	✗	
120 - 121	✓	{right, down}	✓	✓	{paddle}
121 - 122	✓	{left, down}	✗	✗	

Summary Trace:
row 1: {Move({right, down})}
row 2: {Move({right, down}), Turn, TouchSprite({paddle})}
row 3: {Move({left, down})}

a) Step 2: Generating Summary Trace



b) From Step 3: 1-Grams and 2-Grams

Figure 3: Step 2&3: summarizing traces & generating features.

3.1 Step 1: Generating Execution Traces

Visual, interactive programs include program states that can be represented as ***properties*** that change over time. For example, in Snap*!*, these properties can include: 1) ***Time***: how much milliseconds has passed from the start of program execution; 2) *inputs*: including `KeysDown` (which key is pressing); `MouseDown` (if mouse pressing); `MouseX` and `MouseY` (x, y positions of mouse) 3) *global variables*: the names (`Var.Name` and values `Var.Value`) of global variables; 4) *sprite-specific properties*: properties that are related to specific sprites, such as (`x`, `y`) (x, y coordinates); `dir` (directions); `TouchSprite` (which sprites the current sprite is touching); `TouchEdge` (which stage edge the sprite is touching); `size` (sprite size); `OffStage` (whether the sprite is moved out of the stage); the names (`Var.Name`) and values `Var.Value` local variables. The dumped execution trace tables use sprite names to label sprite-specific properties (e.g., to distinguish `ball.x` from `paddle.x`[1]).

Systems such as Snap*!* and Scratch make use of ***step functions*** to update the above properties based on the current properties and the current user inputs [14, 19]. We instrumented the step function in Snap*!* with a trace logging tool, so that with each Step, it adds a row in an ***execution trace table*** with the properties listed above, and dumps the trace table at the end of the execution. Figure 2 gives an example of a part of the *execution trace table*, in which one row logs one discrete Step created by the step function, with each entry maps to a *property* (i.e., a concrete program state).

3.2 Step 2: Summarizing Traces

ETF algorithm scans through the execution trace table in a sliding window of multiple steps (default as 2), apply a ***Trace Abstraction Function (TAF)***. The TAF looks for properties based on ***candidate properties***, and only returns properties that were found in the sliding window as a *summarized property set*. A *candidate property* can be an ***abstract property***, describing the changes between steps in the execution trace, such as movement and variable change; A *candidate property* can also be an original trace *property* which were already recorded in the execution trace. In each sliding window, the TAF function returns a *summarized property set* that includes all found properties, for example, in the step window 120-121 of Figure 3, all candidate properties were found because there is a change in po-

[1]ETF uses these properties to summarize trace and generate features (Section 3.3). To allow comparison across students, sprites need to have consistent labels across student programs.

sition (`Move`), a change in direction (`Turn`), and a non-empty `TouchSprite` column in Step 121. This creates a *summarized property set* {`Move`, `Turn`, `TouchSprite`}, shown in Row 2 of the *summary trace* (Figure 3). In addition, TAF's candidate properties also include possible types of ***parameters***, which describe detailed information of the property.

For Pong, ETF used 9 types of ***candidate properties***. Except 2 program state properties: (`KeysDown` and `ChangeVar`), the rest 7 are sprite-specific properties and are labeled with the sprite names (e.g., `Paddle.Move`). Among the 9 *candidate properties*, 4 were original trace *properties*, directly returned when the corresponding property in the last step of the sliding window is non-empty: `KeysDown`, `TouchSprite`, `TouchEdge`, and `OffStage`, using the same parameters with the corresponding execution trace entry at the last step of the sliding window, explained in Section 3.1. Others are 5 *abstract properties*, that only checks if a property changes between the first and last step of the sliding window (and if has middle, omit those middle ones). 1) `Move`$\langle\leftarrow, \rightarrow, \uparrow, \downarrow\rangle$. Returned when a sprite position changes. Its parameters are the direction toward which the sprite moves. 2) `Turn`. Returned when a sprite changes direction. 3) `ChangeSize`$\langle$`+, -`$\rangle$. Returned when the Sprite changes its size to bigger (+) or smaller (-). 4) `ChangeVar`$\langle$`variable names`$\langle$`+, -`$\rangle\rangle$. Returned when a global variable's value has been changed to bigger (+) or smaller (-). 5) `ChangeLocalVar`$\langle$`variable names` $\langle$`+, -`$\rangle\rangle$. Returned when a local variable's value has been changed to bigger (+) or smaller (-).

3.3 Step 3: Generating n-Gram-based Features

ETF next transforms *summary trace* created by Step 2 into a set of features using n-Gram-based approach, where an n-Gram takes a contiguous sequence of n items in data (Figure 3). ETF extracts features of 4 types: 1) ***1*-Grams**, extracting **simultaneous** behaviors, taken from each row of the summary trace. 2) ***2*-Grams**, connecting adjacent *1*-Grams sequentially; 3) **Power Sets.** We extract n-Grams of not only the full property set in each row of the *summary trace*, but also of subsets of the property set, such as the 2-set of just `Move` and `Turn` from t *1*-Gram {`Move`, `Turn`}. When constructing power sets for *2*-Grams, we apply the power set on the types of properties that are possible in this *2*-Gram. 4) For all the n-Grams extracted above, we keep both ***non-parameterized n-Grams***, where we do not record the parameters, as well as ***parameterized n-Grams***, where each property would include its parameters when they were logged in the summary trace. Next, ETF collects distinct features from all students' feature sets as the ***full feature set***, which consists of distinct features from all students.

3.4 Step 4: Filtering Features

Merging duplicate features and removing rare features. Based on the *full feature set* generated from Step 3, if features have the exact same distribution among programs, the ETF algorithm then merges these features as one feature; and it calculates the support of each feature based on the proportion of student programs that include this feature, and remove features that have support lower than a certain threshold, determined by a hyperparameter tuning process, described in Section 4.2.

Generating $\vec{x}$ vectors. After generating, merging duplicates, and removing rare features, we use the resulting feature set as the independent variables, and for each student program, we use 1 as representing the presence of a feature in the student program (i.e. the n-Gram appeared at least once in their abstracted execution trace), 0 as the absence of the feature, and generate 0-1 digitized $\vec{x}$ vector for each student's code snapshot, which is used as vector input for a classification model.

4. EVALUATION

We investigate our research question: **How accurately does ETF perform rubric-based code classification of students in-progress and submitted code, and how does this compare to syntax-based approaches?**. We first a) compare performance of ETF features and syntax-based features **across models**; and next b) compare ETF features and syntax-based features **across rubrics** on a fixed model. Our analysis of a) and b) follows the same procedure, where we started by generating ETF and syntax-based features separately (Section 4.1). We next performed the same feature filtering, training and evaluation procedure on the features we created (Section 4.2).

Dataset. We evaluated ETF on 42 students' 162 code snapshots for a Pong game assignment, sampling student code snapshots at 10 minutes (42), 20 minutes (40) and 30 minutes (38) of work, as well as their final submissions (42), on 10 target evaluation items: key_up/down, upper/lower_bound, space_start, edge_bounce, paddle_bounce, paddle_score, reset_score, reset_ball. A detailed description and the prevalence of the data can be found in our prior work [19].

4.1 Generating Features

Generating ETF features. We used the procedure described in the Step 1 – 3 (Section 3.1–3.3) of the ETF approach to generate ETF features. We first automatically run the program based on inputs. To ensure coverage, we used the same inputs (up/down arrow key, follow/evade ball) as our in prior work [19], defined using SnapCheck. For each program snapshot, we re-executed the program 5 times. Each run of student programs generated one execution table.

Generating AST *n*-Gram and *1*-Gram Features. We first compare ETF it with a representative, syntax-based feature extraction approach that has performed well in prior evaluations by using the AST n-Gram feature extraction approach [2]. Similar to Akram et al.'s work, we extracted all n-Grams from all ASTs, using $n = 1$ to 5 for *vertical n-Grams*, and $n = 1$ to 4 for *horizontal n-Grams* (explained in Section 2). Similar to many AST feature extraction approaches [10, 11, 22], we used a single label for all literals (`literal`).

4.2 Feature Filtering & Evaluation

We applied the same feature filtering and evaluation to the ETF, AST n-Gram, and AST *1*-Gram features:

Feature Filtering. For fairness of comparison, after collecting features, we used the Step 4 from the ETF algorithm to filter features for all ETF, AST n-Gram, and AST *1*-Gram features. For each type of the three features, we

Table 1: F1 scores of AST 1-Grams, AST n-Grams, and ETF Features, over different models.

	AST 1-Grams	AST n-Grams	ETF Features
Logistic Regression	0.771	0.779	0.932
AdaBoost	0.78	0.78	0.922
Random Forest	0.763	0.773	0.926
MLP	0.764	0.771	0.908
Gaussian Process	0.739	0.728	0.923
SVM	0.759	0.771	0.93

started by using ETF to automatically merge duplicate features (Step 4.a), and remove features that have support smaller than a certain threshold in the training set (Step 4.b). The threshold is set as a hyperparameter (tuned as described below).

Classification Models. To ensure that our comparison was not model-specific, we used 6 different models on the feature set: Logistic Regression, AdaBoost, Random Forest, Multi-layer perceptron (MLP), Gaussian Process, and SVM. Among them, the Gaussian Process model with an RBF kernel was also employed by Akram et al., and has shown to be the best performing model in the rubric-based performance inference task that they have applied [2].

Training & Evaluation. We employed 10-fold cross-validation to evaluate how accurately these different features predict the rubric-based performance. Within each round of cross-validation, we used another 2-fold cross-validation to tune the hyperparameters (i.e. nested cross-validation [15]). For all models, we included a minimum feature support threshold hyperparameter, T, below which we exclude the feature (e.g. ETF feature or AST n-Gram feature) from the final feature set, with the minimum support threshold as a hyperparameter, tuned based on 5 values: $\{0, 5\%, 10\%, 15\%, 20\%\}$. Additionally, since different feature extraction approaches may perform best with different values of model-specific hyperparameters, we also tuned hyperparameters for each classification models, based on the following values: *Logistic regression*: with penalty in {L1, L2}; *Random Forest*: with n_estimaters (i.e., number of trees in the forest) in $\{100, 200, 300, 400, 500\}$; *AdaBoost*: with learning rate in $\{0.01, 0.1, 1\}$; *MLP*: with learning rate in $\{0.001, 0.01, 0.1\}$; ' *SVM*: We used a linear kernel, with the regularization parameter (C) in $\{0.01, 0.1, 1, 10, 100\}$; Gaussian Process models optimize kernel hyperparameters during model fitting, we therefore did not tune hyperparameters for the Gaussian Process classifier. The values of the minimum feature support threshold and the model-specific hyperparameters were determined by their F_1 scores in the nested 2-fold cross-validation, based on a grid search on 5*#(model-specific hyperparameter values) possible types of hyperparameter combinations, during each round of the 10-fold cross-validation. Since many of our target labels are imbalanced, the accuracy score offers less information on how well our model performs in predicting target labels. We therefore use F_1 scores to tune hyperparameters. To ensure that data from a given student was not contained in *both* training and testing sets, all cross-validation splits were done on the 42 **students** (instead of on the 162 snapshots).

4.2.1 Results

Comparison Across Models. Using each of the 6 models described above, we predict students' rubric-based performance, calculated its F_1 score among the 162 students' data using 10-fold cross validation, creating one F_1 score for each rubric. We next averaged F_1 scores for each classifier across all rubrics, shown in Table 1. We saw that the AST n-Gram approach performed similar to the *1*-Gram approach (5 in 6 cases), and that ETF features generated F_1 scores that were consistently 0.14 to 0.2 higher than the AST n-Gram features, showing that all classifiers benefited from the execution-trace-based information extracted by the ETF features, with overall F_1 scores between 0.9 and 0.93. This result shows potential for us to make use of ETF features to correctly analyze students' current progress, which should enable automated, formative feedback in future work, to help a student who is stuck in the middle of programming.

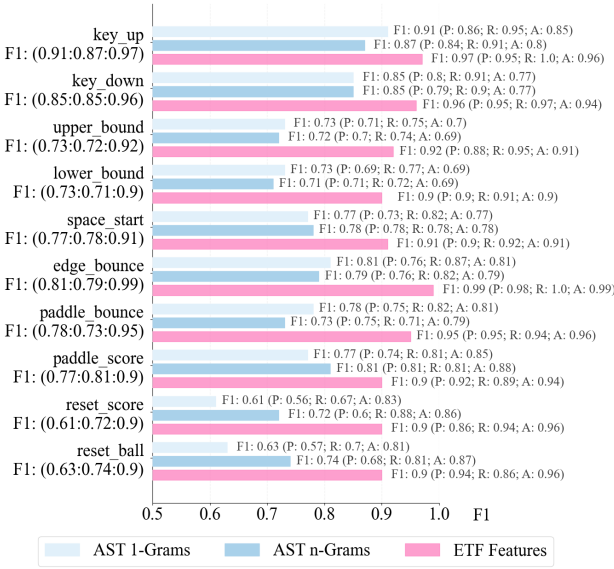


Figure 4: The F_1 score (F1), Precision (P), Recall (R) and Accuracy (A) of ETF, *n*-Gram, and *1*-Gram features on each rubric, using an SVM model. x-axis starts from $F_1 = 0.5$.

Performance Across Rubrics. We next investigate the performance of the three feature extraction approaches **across rubrics**. Since all model show similar trends, we select SVM and present performance on all rubrics in Figure 4. We found 1) The naive AST *1*-Gram features had relatively lower F_1 scores on rubrics that had less prevalence in data (e.g., *reset_score*, *reset_ball*); 2) Comparing to AST *1*-Gram, the AST n-Gram features produced higher F_1 scores for *paddle_score*, *reset_score*, *reset_ball*, showing that AST n-Gram extracted more useful feature for these three rubric items. However, the ETF features performed relatively well across all rubrics, with its F_1 scores ranging from 0.9 to 0.99, showing that ETF features have strong potential to enable formative feedback on a variety of fine-grained, specific rubrics.

In conclusion, we presented a novel, effective approach that extracted useful features from execution traces (ETF), leading to high predictive accuracy. Our results show strong potential for using ETF to monitor student progress and offer automated, formative feedback.

ABSTRACT

Online education technologies, such as intelligent tutoring systems, have garnered popularity for their automation. Whether it be automated support systems for teachers (grading, feedback, summary statistics, etc.) or support systems for students (hints, common wrong answer messages, scaffolding), these systems have built a well rounded support system for both students and teachers alike. The automation of these online educational technologies, such as intelligent tutoring systems, have often been limited to questions with well structured answers such as multiple choice or fill in the blank. Recently, these systems have begun adopting support for a more diverse set of question types. More specifically, open response questions. A common tool for developing automated open response tools, such as automated grading or automated feedback, are pre-trained word embeddings. Recent studies have shown that there is an underlying bias within the text these were trained on. This research aims to identify what level of unfairness may lie within machine learned algorithms which utilize pre-trained word embeddings. We attempt to identify if our ability to predict scores for open response questions vary for different groups of student answers. For instance, whether a student who uses fractions as opposed to decimals. By performing a simulated study, we are able to identify the potential unfairness within our machine learned models with pre-trained word embeddings.

Natural Language Processing, Unfairness, Deep Learning, Word Embeddings, Pre-Trained Word Embeddings, Simulated Study

1. INTRODUCTION

In recent years, natural language processing (NLP) has been at the forefront of machine learning in multiple fields. Linguistics provides another source of information outside the standard data from user logs. Instead of relying on correlational assumptions from this data, inferences can be deduced directly from the users linguistics. While utilizing linguistics in education isn't genuine, modern machine learning and natural language processing has helped to automate the analysis and provides effective tools for learning.

The development of more advanced deep learning has brought a deeper semantic understanding of words within these linguistical models. The emergence of word embeddings were an important development in machine learning and NLP, but the publishing of publicly available pre-trained word embeddings, such as such as GloVe [21] or Wikipedia or Word2Vec [19], provided researchers with a powerful tool for optimizing algorithms with linguistics. While word embeddings were powerful for studies within areas such as MOOCS (i.e [14] [20]), smaller studies, with less robust linguistic data, were unable to utilize this modern approach for semantic relationship of words.

Since research has shown that some of the semantic meanings inferred from pre-trained word embeddings can elicit undesirable biases [2], the major question then becomes, does this underlying bias suggest the algorithm or predictive model will make unfair decisions? For instance, if an algorithm utilizes linguistics and NLP with pre-trained word embeddings will the predictions be unfairly made from those underlying biases. Our research attempts to explore:

1. Whether, through 3 simulated studies, the format a student writes an answer (i.e. fractions vs. decimals) effect the scoring model and potentially elicit unfair scoring?
2. What effect, through 3 simulated studies, if any, do *'distractor'* words have on the unfairness?
3. Whether or not underlying bias in pre-trained word embeddings can lead to unfairness in open response scoring models in middle school mathematics?

2. BACKGROUND

2.1 Intelligent Tutoring Systems

In recent years, online educational technologies have been on the forefront of learning for students. A common online educational technology, intelligent tutoring systems (ITS) [4],

John A. Erickson, Anthony F. Botelho, Zonglin Peng, Rui Huang, Meghana V. Kasal and Neil Heffernan "Is It Fair? Automated Open Response Grading". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 682-687. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

has been prevalent in education for many years. Some of the most common ITS are ASSISTments[11], McGraw Hill's ALEKS^{TM} and/or Carnegie Learning's Cognitive Tutor^{TM}. Through the use of both machine learning and software engineering, these systems have been shown to be effective at increasing the scores of students with end of the year standardized math exams[25] and the effects of their intelligent tutoring closely resembles the effect face to face tutoring has on students[31]. Other ITS, such as AutoTutor[9],have attempted to resemble the face to face tutoring more directly by developing automated conversations and dialogues between students and ITS [9]. However, most of the support and benefits of these ITS have been limited to questions with structured answers (i.e. multiple choice or fill in the blank questions).

2.2 Automation of Intelligent Tutoring Systems

Automated support of ITS is a draw for many teachers; one study noted that many utilize multiple choice questions for the efficiency and accuracy of grading [26]. However, since most of the automation is limited to questions with structured answers, the content which teachers provide is limited. Studies have looked to utilize NLP to automatically evaluate work or questions which require a student's unique linguistics (i.e. open response questions, or essays) including [29][28][24][1][7][30][17]. While most of this research has been primarily focused on content outside of mathematics, our previous research, [6], looked to help teachers diversify the content which they provide students in middle school mathematics by utilizing traditional and modern NLP to develop an automated scoring model for open response middle school mathematics questions. A more diverse set of question types can be beneficial to students and can elicit differing levels of cognition, as studies [18][15] note.

2.3 Natural Language Processing

Towards the goal of automating open response questions, or any linguistical/NLP prediction task, the major task is in how to numerically represent words thus that a machine learned algorithm can generate an accurate prediction. One of the more simplistic approaches utilizes the frequencies of each unique word within the corpus, whats commonly known as a *Bag of Words* approach. While undoubtedly easy to interpret and not computationally intensive, this approach has been utilized in studies such as [13] and is the foundation of more advanced approaches such as[27][10][22]. This has evolved into utilizing deep learning to generate word embeddings such as GloVe[21] and Word2Vec[19].

2.4 Pre-Trained Models

Embeddings are only as powerful as the data their train on. Not all researchers have robust corpuses, thus embeddings can be misleading. Pre-trained embeddings, such as GloVe or Word2Vec, publish their own embeddings generated from Wikipedia and GoogleNews. As these pre-trained word embeddings have grown in popularity, word embeddings have expanded to utilize bidirectional encoder representations from transformers (referred to as BERT[5]) to create pre-trained word embeddings, as well. Similarly, this has evolved from word level embeddings to pre-trained sentence and document level embeddings[23][3][16].

2.5 Fairness

When it comes to linguistics, the way someone speaks, the way someone articulates can be unique to themselves. Similarly, the way someone writes is personal to themselves and specific to their topic. So when algorithms are being pre-trained on data which isn't the researchers own data, there are questions to be asked. Research[2], has been able to identify some potentially harmful semantic relationships present in common pre-trained word embeddings. For instance, [2] was able to identify that Google's pre-trained Word2Vec on GoogleNews elicited some harmful stereotypes. There in lies the important question, if we omit variables which could cause unfairness in the automated scoring, are we continuing to avoid unfairness if we utilize pre-trained word embeddings. To identify this, we utilized Absolute Between-ROC Area (ABROCA) [8].

3. STUDY 1: SIMULATION STUDY

This research developed a simulated study to attempt to identify if pre-trained word embeddings are utilized within an automated scoring model for open response answers, do they influence the model to make unfair predictions. An example of this would be if a group of students state their answer with a fraction and surrounding text, does the predictive model generate scores similarly for those students that use decimals along with surrounding text? Through this simulated study, we are able to gain a deeper insight into what/if any unfair scoring occurs when utilizing the pre-trained GloVe word embeddings trained on Wikipedia between groups.

There are 3 studies within this simulated study to help achieve this goal. First, we develop answers which contain differing distributions of answers which contain fractions and decimals and generate the ABROCA value at the differing distributions. Second, we attempt to see if decimals and fractions alone generate differing ABROCA values. Third, we attempt to see if we replace decimals in the text with unknown tokens (more reliance on distractor words), do the ABROCA values differ at differing distributions? These studies will help provide deeper insight into the potential unfairness an automated scoring model can be producing when utilizing pre-trained word embeddings

3.1 Data Generation

At the foundation of this simulated study is the generation of the *student* dataset.The generation was split into two facets, the training dataset student answers and the test set student answers. This was performed such that the model would not be able to have any identical answers between the training set and the test set. Essentially, that the predictions aren't being made because the model has already seen that exact series of embeddings associated with a certain score.

Towards simulating authentic student answers, the generation of the corpus was founded on the goal of utilizing random selection. For the training set, as Table 2 shows (see Appendix A), there are 4 different length student answers in this corpus. There are answers which are 6, 5, 4 and 3 word length answers. The generation of the student answers can be surmised into 4 steps and visualized with Table 2 (see Appendix A). First, select whether it will be a student answer which uses decimals or fractions. Then,

randomly select what length the answer is. Once a length is randomly selected, another random selection is made between the two structures (i.e. 'Structure' within Table 2 in Appendix A). Finally, randomly select text from **Fill "1"** and **Fill "2" Fractions** or **Fill "2" Decimal** to fill the identifiers **'1'** and **'2'**.

This is the same approach that is utilized within the test set corpus generation as well. Table 3 (see Appendix A) shows that however there are different structures and phrases to select from than the training. Allowing for variability between test and training; thus, guaranteeing that a answer structure used in training isn't the same as in the test. From this, we can ascertain the model's predictions were not only based on identical phrases it has seen.

3.2 Methodology

This study sets out to identify if an automated scoring model for open response questions, which utilizes pre-trained word embeddings, elicit unfair scoring. With the answers generated, we set out to sample these simulated answers such that there is a balance of student answers which utilize fractions and decimals. The training set is comprised of student answers drawn from the pool of simulated answers containing fractions (considered as *Group A*), as well as answers sampled from similar student answers containing fractions and decimals as determined by a defined proportion threshold (considered as *Group B*).

A threshold was set for selecting decimals and fractions to control the balance of answers. This lends itself to our goal of being able to identify whether or not the format a student writes an answer, i.e. using factions vs. decimals, effects our ability to score student open response answers. Thus, with ABROCA, fairness can be identified at each threshold.

For the test set, a similar approach is taken. So the training and test set have both Group A answers which are distractor words and fractions, and Group B answers which have distractor words and a proportion of fractions/decimals (based on the same threshold for both training and test data).

To improve the reliability of the results, we re-sample/re-select the test dataset 10 times and evaluate the model's ability to score an open response answer. This form of cross validation allows us to see if the ability to predict the score was only for that unique set of words, or was the performance consistent across multiple iterations.

All of the studies will incorporate a Long Short Term Memory (LSTM) [12] model which utilizes the pre-trained word embeddings to automatically score open response answers and ABROCA is calculated. This is then used to run 3 studies. First, when incrementally increasing decimals being used in Group B, does the LSTM scoring model become more unfair? Second, whether or not fractions or decimals are the culprit of the potential unfairness in the automated scoring model by having answers just be fractions or decimals without distractor words? Third, when incrementally increasing unrecognized words (referred to as gibberish) being used in Group B, does the LSTM scoring model become more unfair? So does an imbalance in recognized words cause more unfairness between groups?

3.3 Results

In the end, Figure 1a showed that with the simulated study, when there is an increase in the proportion of decimals in Group B, there does not appear to be unfairness in the way Group A and Group B are evaluated. This is evident from the scale of the y-axis of Figure 1a, the ABROCA falls betweem 0.02 and around 0.04.

The second study, which there were only decimals and fractions in the test set (no distractor words), stayed constant at a ABROCA value of 0. The model was not unfair, it was able to equally evaluate both groups even when just isolated fractions and decimals.

The final simulation study, managed to show that increasing the imbalance between recognized and unrecognized tokens between groups increased the unfairness (ABROCA near 0.18). Figure 1b shows that the ABROCA score does indeed increase with more unrecognizable words within GloVe's pre-trained word embeddings. It should be noted that Table 1 shows some of the phrases used in the generated student answers were commonly associated with more correct answers

Table 1: Sample of Phrases and Their Associated Avg. Score

Generated Phrases	Avg. Score
my answer is	0.718750
i picked	0.622222
i guess the answer is	0.600000
i think it is	0.600000
i think the answer is	0.590909
i worked out	0.585366

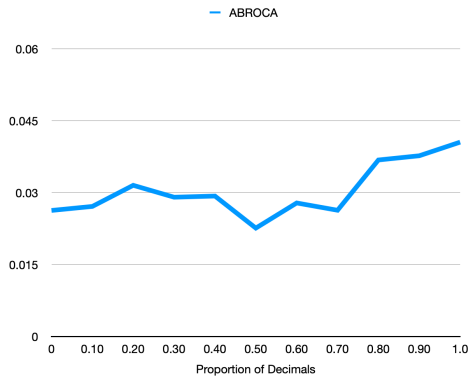
In the end, these simulated studies proved the largest risk for unfairness exists when there is differential coverage of answer-related tokens within applied methods utilizing pre-trained NLP embedding methods. So when answers consist of equally recognizable words within GloVe's pre-trained word embeddings, there's unlikely to be unfairness in the grading. There wasn't evidence that the inherent bias built into the pre-trained word embeddings elicited more unfair scoring of student answers in, in terms of this simulated study. But if there are unbalanced recognizable words and tokens in the student answers, attention needs to be paid to potential unfairness in the automated scoring.

4. STUDY 2: FAIRNESS IN REAL CONTEXTS

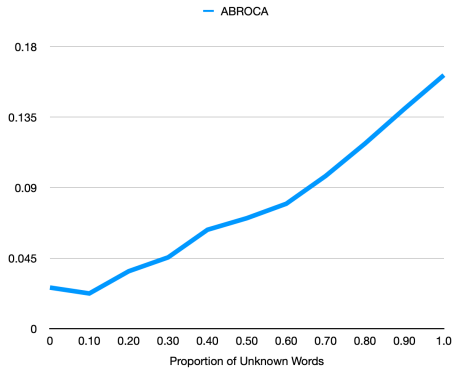
While a simulation study is powerful on its own, it is difficult to recreate authentic student data. For the final overall study of this research, we look to once again utilize ABROCA to identify if our own algorithm, trained on genuine student open response answers within ASSISTments, is unfair in its grading of women and men.

4.1 Data

The data consists of 141,612 graded authentic student open response answers across 2,042 unique problems. There were a total of 25,069 unique students who answered and 891 teachers graded those answers. Lastly, the scoring. This was performed on a 5 point scale, where students receiving a 4 is a perfect score.



(a) Study 1: ABROCA Values at Incremental Fraction/Decimal Thresholds



(b) Study 3: ABROCA Values at Incremental Fraction/Unknown Words Thresholds

It should be noted, to be able to perform the fairness analysis using ABROCA, gender was inferred. This performed by cross checking names with the census data. If the name was found only on the women or only on the men's list, it was labeled as such. In any names fell into multiple genders, it was labeled as unknown and excluded from this analysis.

4.2 Methodology and Results

Towards developing our predictions, we utilized another pre-trained algorithm, mentioned earlier, called SBERT. This is a pre-trained sentence embedding algorithm which allowed us to generate a single vector representation of each student answer. We then utilize a Canberra distance to identify which student answers are the most similar. Whichever was the most similar, that was the score we would assign. This approach managed to out do our previous models [6].

While utilizing, once again, ABROCA to identify potential unfairness, we apply this to our algorithm. We were able to show that our SBERT model with Canberra distance manages to fairly score both Male and Female student open response answers. Our model managed an ABROCA of 0.007, which is quite small, suggesting that our algorithm is indeed scoring fairly across these groups.

5. LIMITATIONS AND FUTURE WORK

While there were indications of unfairness in cases where there were unbalanced identifiable tokens within the student open response answers, this analysis is strictly middle school mathematics. This type of analysis would need to be applied to additional datasets to get a broader understanding of the potential unfairness in other subjects and age ranges. In terms of our analysis of our SBERT model for scoring student open response answers, while there wasn't unfairness identified, more work needs to be done to explore the embeddings themselves. Pre-trained word embeddings have been shown to have bias built in, but what bias is present in the pre-trained sentence embeddings? This is a question we look to explore further.

6. CONCLUSION

Overall, this study set out to run a simulated study to help identify potential unfairness within models utilizing pre-trained word embeddings. While there is bias present in the embeddings themselves, our simulated study didn't show this bias causing unfair scoring. However, our analysis did show that when developing models with pre-trained embeddings, unfairness can begin to occur when there is an imbalance of recognized tokens in the student answers. More specifically, our simulated study showed that when groups within the data use differing levels of recognized tokens, it increases the chance for unfair scoring.

While our simulated study showed how unfairness can present itself within a scoring model, our model on authentic student data did not show this unfairness. We were able to conduct an analysis of our model with ABROCA to compare our performance scoring identified male and female students.

In the end, we were able to utilize a simulated study to help identify potential unfairness in automated scoring models which utilize pre-trained word embeddings. Its been widely noted that those embeddings have bias built in, but our simulated study couldn't show an unfairness in the scoring of differing groups of simulated student answers. However, this study did suggest that there is a notable risk to fairness in cases where there are differences in the number of words that are unrecognized by pre-trained models across populations.

ABSTRACT
Executive functions (EF) are a set of psychological constructs defined as goal-directed cognitive processes. Traditional EF tests are reliable, but they are not able to detect EF in real-time. They cause a test effect if implemented multiple times. In contrast, learning games have the potential to obtain a real-time, unobtrusive measurement of EF. In this study, we analyzed log data collected from a game designed to train the EF sub-skill of shifting. We engineered theory-based game-level and level-specific features from log data. Using these features, we built prediction models with students' accuracy and reaction time during play to predict their standard measure of the EF shifting skill during the post-test and delayed post-test as well as to predict learning gains. Our model that predicts the post score has a correlation of 0.322 and that for the delayed post score is 0.303. The findings suggest that theory-based feature engineering and varying levels of granularity are two promising directions for cognitive skills prediction under the goal of game-based assessment. Also, accuracy, reaction time, and player progression are important features.

Keywords
Prediction, Game-Based Assessment, Learning Games, Executive Functions, Cognitive Skills.

1. INTRODUCTION
Executive functions (EF) are defined as "cognitive processes used for effortful, controlled, and goal-directed thinking and behavior" [29, 3, 4]. The unity/diversity model [24] views EF as consisting of related yet separable skills, which include updating, shifting (also termed cognitive flexibility), and inhibition. EF plays an important role in cognitive development and is associated with academic success [6], metacognitive skills [7], science learning [15], and language acquisition skills [10].

Game-based assessments allow educators to assess students' learning while they are playing a game and thus in a manner that can be highly efficient, fast, and entirely unobtrusive. Using games as assessments creates a context in which learners are likely to be highly engaged, which may optimally reflect their abilities [16, 28]. Using log data from digital games to evaluate learning is sometimes referred to as a "stealth assessment" [20] and has been used in the past decade to assess complex skills, such as creativity [33] and problem-solving, [34] based on log data. Log data collected during gameplay provides a record of student behaviors associated with EF and can be used for the prediction of EF [25]; however, is it possible to use log data collected from a game designed to train EF to measure EF *and* to develop a framework for game-based assessment?

Past studies of game-based assessments have focused on complex thinking skills, such as problem-solving [34]; however, there are constraints of game-based assessments of EF. First, it is necessary to determine the granularity or time scale for which we can detect students' EF in log data. Second, we need to separate log data related to EF training from log data related to other aspects of play to achieve a high performance of models. Third, we need to generate theory-based features relevant to EF skills. Accuracy and reaction time have been identified as indicators of EF [8].

This paper aims to provide proof of the concept for game-based assessments of the EF sub-skill of shifting. Shifting is one dimension of EF defined as the ability to switch attention between different "tasks, operations, or mental sets" [21]. The research questions include:

1. How do students' gameplay data predict their executive functions during a post-test and a delayed post-test?
2. Which features, including accuracy or reaction time, are important for predicting EF in games?

2. RELATED WORK

2.1 Games for EF Training and Measurement
Sustained and active engagement is widely thought to be critical for cognitive skills training games to be effective [2]. Incorporating gamified design features is one well-established mechanism for promoting meaningful engagement [9].

Digital training games can not only enhance EF [22, 27] but can also be used as a reliable means for measuring EF and other cognitive skills. For example, past work has examined the design and validation of computerized tools for measuring working memory capacity [21]. Previous research has also examined the use of a digital game for the detection of executive functions validated by a task for medical purposes in older adults using computational modeling [12]. Further work is needed to validate game-based measures of cognitive skills [35], especially those that are sensitive enough to detect variations among neurotypical individuals and that are appropriate for child and adolescent populations.

2.2 Game-Based Assessment

In previous research, the analysis of log data as a means of a formative assessment has yielded promising findings [11] and has been used for predicting a variety of cognitive and behavioral constructs, including quitting [19], knowledge [1], computational thinking [30], persistence [26], and implicit learning [31].

Evidence-Centered Design (ECD) [23] has been used effectively to develop game-based assessments in contexts that teach specific knowledge domains [14]. According to ECD, an assessment framework should take these models into account:

- *Task model:* Which actions is the learner taking within the system?
- *Evidence model:* Which features (e.g., from log data) can be used as evidence of learner actions?
- *Competency model:* How are these features associated with a set of standards or criteria that demonstrate effective learning has taken place?

Accounting for these three ECD models is helpful for feature engineering and predictive modeling. In game-based learning contexts that teach knowledge and skills, connecting a task model to an evidence model should be relatively straightforward given that the log data provides a detailed record of the learner's action sequence. Unlike game-based assessments of knowledge domains, where standards are clearly defined and may be validated by an expert review of content, in cognitive skills training game-based contexts, further work must be done to align an evidence model with a competency model. Accuracy and reaction time have been identified as two major aspects of an EF measurement [24], with evidence suggesting they each contributes uniquely to EF performance among children [8] and adolescents [5]. Yet, the way to distinguish the nuanced forms of accuracy and reaction time at varying levels of granularity and the way to combine them for predictive modeling within a game are currently unclear.

3. DATASET

3.1 Game Design

All You Can E.T. (AYCET) [17] is a game that trains the EF sub-skill of shifting. Its early prototype, The Alien Game, has been shown to improve EF after 1.5 hours of play for high school students [16] and two hours for college students [27]. In the current study, we used the "hot" version of AYCET, a version that maximizes the playfulness of the game. As Figure 1 shows, a player is asked to feed aliens with the appropriate food based on a certain rule. The rule changes multiple times at each level, thereby requiring the player to shift. As the player progresses in the game, the rule becomes more complicated.

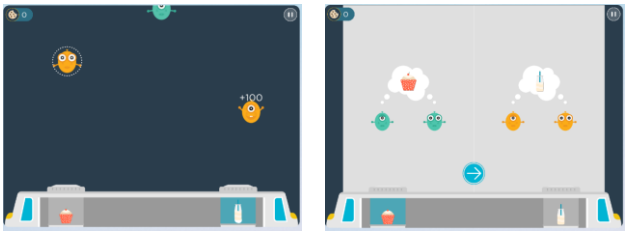

Figure 1. Feeding aliens and instructions for a rule.

3.2 Participants

Participants were recruited from three middle schools and two high schools in urban school districts in the Northeastern United States. They completed the study during non-instructional time at their schools. Among the 448 students who consented, 137 students were strategically randomly assigned to one of the three conditions to play AYCET throughout the study. Of those, 56 were removed because they demonstrated off-task behaviors, and thus the log data could not reflect their true ability. This resulted in an analytic sample of 81. Details of participant removal are discussed in the Data Cleaning subsection.

The 81 participants (M_{age} = 13.9 years, SD_{age} = 1.6, 46.1% female) included 39 in grade 7, 18 in grade 8, and 21 in grade 9. They reported a culturally and linguistically diverse background. Among them, 51.3% reported speaking Spanish at home, while 47.4% reported English and 1.3% Mandarin. As for ethnicity, 78.2% were Hispanic/Latino, 1.3% were Asian, 17.8% reported two or more ethnicities, 1.3% reported another ethnicity but did not specify, and 1.3% did not know. A few participants did not report their demographic information.

3.3 Study Procedure and Data Collection

The four-week intervention was conducted at the participating schools. Before gameplay, students completed a pretest. Then, they played the game for four sessions, each of which took about 30-40 minutes. The cumulative amount of time of play was 2-3 hours. After play, students completed a post-test, and an additional 4-8 weeks later, they completed a delayed post-test. The EF sub-skill of shifting was measured by the Dimensional Change Card Sorting (DCCS) task [36] in the pretest, post-test, and delayed post-test.

The log data consisted of 144,187 data points or actions, recording whether students fed each target ("alien") correctly or not and the reaction time for each target. This means that each alien required one action from the student. In this study, students played levels 1-30. There are 30-80 aliens per level.

In this study, each session began a few levels back from the last level played. After a few sessions, students were mandatorily pushed to level 11 to ensure they had enough time to play more difficult levels. This affected 72% of the students who were at level 9 or lower at the moment. On average, they were pushed by 4.3 levels.

3.4 DCCS Test and Score

The DCCS task [36] was used to measure the EF sub-skill of shifting in the pretest, post-test, and delayed post-test. Scoring was based on the National Institute for Health (NIH) scoring procedure [37]. This is a combination of the accuracy score and the reaction time score. The score ranges from 0 to 10. Floor or ceiling effects were not observed with our participants, as the top 25% of pretest scores ranged between 7.78 and 9.36.

4. METHOD

4.1 Data Cleaning

Based on the researchers' observations, we removed 33 participants for the following reasons: (1) did not complete one of the DCCS tests, (2) were off-task during the DCCS test, or (3) experienced technical difficulties that would affect their performance in the DCCS test. Furthermore, 23 participants were removed due to off-task behaviors (e.g., sleeping, non-stop talking, etc.) or an absence for at least one intervention session.

Eighty-one students remained in the analytic sample. The retention rate was 59.1%, which is acceptable for two reasons. First, data collected in the classroom setting are usually messier than that in the lab setting. During the study, a few participants went to the bathroom for a long time, which would be less likely to happen in a lab setting. Second, the game's focus on training EF required a

degree of attention that some students were not willing to invest. Some students found it difficult to remain attentive for an extended period of time.

4.2 Labels

Table 1 lists the labels for prediction. The post score and delayed post score were directly measured by the DCCS test. We next calculated the post-learning gain and delayed post-learning gain.

Table 1. Labels

Name	Description
post score	The EF score for the post-test.
post-learning gain	Relative gain of the EF score for the post-test compared with the pretest. Based on Hake's formula of learning gain [13], it is calculated as (post score - pre score)/(10 - pre score) because the EF score ranges from 0 to 10.
delayed post score	The EF score for the delayed post-test.
delayed post-learning gain	Relative gain of the EF score in the delayed post-test compared with the pretest.

4.3 Feature Engineering

We generated 20 game-level features and five level-specific features for each level that indicated student performance and progress. They capture information related to accuracy and reaction time in various mathematical formats and granularities.

Level-specific features were features for a single level. They included the average reaction time, the standard deviation of reaction time, accuracy, the number of correct hits (i.e., an action of feeding an alien with the correct food), and the number of wrong hits (i.e., an action of feeding an alien with the wrong food) across all aliens in a single level. Accuracy was calculated as the number of correct hits divided by the total number of aliens in a level.

Game-level features were aggregated features across all levels. They included: (1) the average, maximum, minimum, range, and standard deviation of a student's accuracy across all levels after calculating the accuracy for a single level across all aliens in that level; (2) the average, maximum, minimum, range, and standard deviation of a student's reaction time across all levels after taking the average reaction time for a single level across all aliens in that level; (3) the total number of correct hits (82% of all aliens among all students), wrong hits (16%), and missed hits (i.e., an action that the student did not feed an alien) (1%); (4) the highest number of stars a student received across all levels and the total number of stars a student received in the game; (5) the number of levels a student skipped by choice (which only happened before level 10) and due to the mandatory push; and (6) the highest level and the total number of levels a student played (as a student may skip a few levels).

4.4 Model Training

We used the linear regression for predictive modelling in RapidMiner 9.3. We evaluated the model's performance using ten-fold cross-validation at the student level to ensure the model would be generalizable to a new student population. During this process, students were randomly split into 10 groups. For each possible combination, we used forward selection to select features and then built the model based on the training data. Forward selection was an iterative process. First, a single-feature model that would achieve the highest Pearson correlation was chosen. Next, the remaining features were subsequently added one-by-one to the model if they could appreciably improve the model goodness of fit. In addition, to avoid collinearity, we set the minimum tolerance for eliminating collinear features as 0.05 and set "eliminate collinear features" as true in the linear regression operator.

In addition, we explored different combinations of features for feature selection. Missing values existed for many level-specific features. Thus, we began with the first feature set containing all game-level features and level-specific features of the level with the smallest missing value rate. After that, in each round, we added level-specific features of another level based on the ranking of the missing value rate. We stopped doing so at a level that contained missing data for 16% of students. The last model contained 65 features. In this way, we controlled for over-fitting and ensured the models were trained on representative levels.

5. RESULTS

5.1 Intervention Effect

The paired samples t-test show that the post score (mean = 6.98, SD = 1.56) is significantly higher than the pretest score (mean = 6.31, SD = 2.12) ($t(80) = 3.01$, $p < 0.01$, *Cohen's d* = 0.34). Also, the delayed post score (mean = 7.16, SD = 1.33) is significantly higher than the pretest score ($t(80) = 3.90$, $p < 0.001$, *Cohen's d* = 0.43). The boxplot of three EF scores is shown in Figure 2.

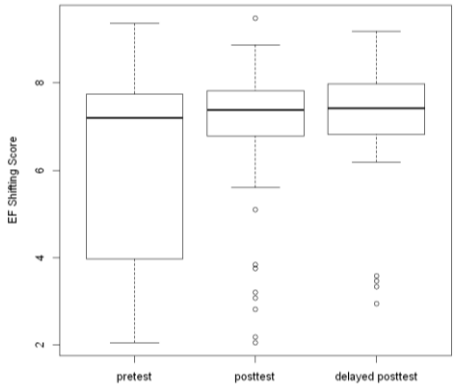

Figure 2. Boxplot of three EF shifting scores.

5.2 Correlation between Features and Labels

Among the 65 features for modeling training, five features had an absolute value of correlation with the post score between 0.3 to 0.42. Eight features had an absolute value of correlation with the delayed post score between 0.3 to 0.45. Features were weakly correlated with two learning gain labels as the absolute values of all correlation coefficients are below 0.25. Missing values for each feature were replaced with the average value of that feature.

5.3 Findings from Predictive Models

Cross-validated metrics for the best models of each label and their features are summarized in Table 2.

Table 2. Summary of the predictive models

	Post Score	Post-Learning Gain
RMSE	1.586	0.682
Correlation	0.322	0.294
Selected Features	- 2.087 * numLevelsSkippedByChoice - 0.008 * numWrongLevel11 - 0.028 * numWrongLevel12	0.414 * avgLevelAvgRT + 0.065 * numLevelsSkippedByPush - 0.001 * numCorrectLevel3 + 0.004 * numCorrectLevel4 + 0.493 * avgReactionTimeLevel2 - 0.428 * avgReactionTimeLevel13

Table 2 (continued). Summary of the predictive models

	Delayed Post Score	Delayed Post-Learning Gain
RMSE	1.540	0.470
Correlation	0.303	0.260
Selected Features	2.189 * avgLevelAvgRT - 0.268 * numLevelsSkippedByPush - 0.012 * numWrongLevel3 + 0.006 * numCorrectLevel12 - 2.154 * avgReactionTimeLevel3 + 1.693 * stdReactionTimeLevel3 - 2.306 * stdReactionTimeLevel12 - 0.528 * avgReactionTimeLevel12	0.841 * avgLevelAvgRT - 0.262 * highestLevelAvgRT + 0.001 * totalWrongHits + 1.434 * avgCorrectLevel1 - 0.003 * numWrongLevel3 + 0.007 * numCorrectLevel12 - 0.009 * numWrongLevel12 - 0.611 * stdReactionTimeLevel12

The models that only used game-level features had a low performance. Excluding level-specific features only did not greatly affect model goodness when predicting the post score, with a correlation of 0.308 and RMSE of 1.589. Features included *numLevelsSkippedByChoice*, *totalWrongHits*, and *numLevelsPlayed*.

6. DISCUSSION AND CONCLUSIONS

Playing AYCET significantly improved students' EF. The effect sizes of EF gains were medium, and that for the delayed post-test 4-6 weeks later was larger than that for the post-test. This difference in effect sizes may be attributed to either the long-term intervention effect by the EF game or students' natural development of EF. Though more evidence is needed, long-term effects of cognitive skills training have been found [18, 32].

We explored the possibility of a game-based assessment of EF using a game originally designed to train EF. We present four linear regression models that use the log data to predict students' EF score of shifting in the post-test, delayed post-test, and the relevant learning gain scores. With correlations around 0.3, these models achieved good performance for preliminary work. This corresponds to the second challenge of this study, which is to separate log data related to EF training from log data related to play in the game context. Good performance of predictive models indicates that a learning game is a promising tool to measure EF.

We generated an extensive list of game-level and level-specific features consisting of accuracy and reaction time indicators. Both accuracy and reaction time features are important in predicting EF but are two potentially distinct dimensions of EF. Generally, at the game level, a moderately higher reaction time and a more consistent reaction time (while controlling for other factors) are positively associated with EF. In addition, a lower reaction time and perhaps a more consistent reaction time are positively associated with EF. As for accuracy features, both correct hits and wrong hits are important for predicting EF.

In addition to accuracy and reaction time features, the number of levels skipped, particularly by the player, was indicative of EF. This means that player progression and player performance are both important for predicting EF.

Most selected features are from level 3 and level 12. This may suggest the key time window, which is the moment after students become familiar with the game mechanics and the moment after a drastic change in difficulty (recall the mandatory push; see section 3.3) may best demonstrate their ability to perform shifting. Varying the difficulty of levels or allowing for some time for students to achieve level 12 may contribute to a better game-based assessment of EF.

Responding to the first challenge, namely, the granularity and time scale for prediction, we found that level-specific features provide more promising results than game-level features only. It is worth further exploring variables at the action-level.

7. IMPLICATIONS AND FUTURE WORK

We explored the techniques of feature engineering and model training to investigate the game-based assessment of EF. The model performance is promising among studies that relate log data with a post-test measure in learning games [33, 34]. Another implication of this work is it sets the foundation for the real-time detection of EF and may provide the basis for dynamic interventions.

Limitations in the current work inspire us to explore more possibilities of game-based assessments for EF. First, a level may be played multiple times by a student. In the current study, all attempts of the same level were aggregated. In the future, we will distinguish multiple attempts of the same level by generating features such as the number of attempts and performance change over attempts. Second, we found that students' performance one or two levels after a challenging level is important. This game mechanic of difficulty change may not apply to other games. We have tried to interpret the model in the context of the specific game design. Third, students experienced a mandatory push in this study (see section 3.3). This is perhaps why features for level 12 were selected. To examine the generalizability of our findings, we will compare the prediction models built under two conditions, one of which replicates the push, while one does not; however, for practical reasons, it is also of interest to determine whether features that only cover earlier levels can predict the post-test and delayed post-test scores as this would require less game play for the assessment. Fourth, we filled the missing data with the average value of a feature. We did so by assuming data were missing at random. More robust methods, such as multiple imputations, could be used moving forward.

In the future, we are interested in generating theory-based features at the action-level (i.e., alien-level) per student, hoping to allow for the real-time detection of EF and for an even better model. An action-level feature may be a student's change in accuracy and reaction time within the first three aliens when the rule changes within a level. Another action-level feature may be the performance curve under different rules within a level. Both features align with the definition of the EF sub-skill of shifting and are not tied to specific levels, so they may produce more generalizable results. Methodologically, we are also interested in comparing the linear regression with other models, such as Support Vector Machines or the Random Forest. Substantively, it may be worth considering accuracy and reaction time as separate outcomes given research suggesting each contribute uniquely to performance on EF tasks in young children [9]. Further work may also apply methods of student modeling to other EF sub-skills, such as inhibition and updating in games that target these skills.

8. ACKNOWLEDGMENTS

Special thanks to Dr. Ryan Baker and Dr. Luc Paquette for their constructive suggestions for the data analysis. This work was supported in part by a research grant from the Institute of Educational Sciences, US Department of Education (Grant #R305A150417). The opinions expressed are those of the authors and do not represent views of the Institute or the U.S. Department of Education. We would like to thank the students and teachers who participated in this research.

ABSTRACT
Over the last decade makerspaces have become more popular and prevalent in formal and informal learning environments. A finding, however, is that makerspaces are often male-dominated, and females can feel a sense of intimidation in the space. Furthermore, maker-centered learning typically adopts an open-ended structure which makes it difficult to identify students who are struggling. In this paper, we explore the use of quantitative data from survey and motion sensors to potentially assist instructors in uncovering gender differences and promoting gender inclusion. Results suggest that there are different pathways for male and female students to thrive in makerspaces. Based on survey results, male students tend to have higher self-efficacy, resulting in more self-confidence in their abilities and more positive feelings. Findings from applying network analysis on the motion sensor data show that female students persevere more consistently and use empathy to form closer ties with peers for mutual support. These findings suggest that quantitative data could help raise instructors' awareness of gender differences and use that information to cater to the unique learning needs of each group of students. Overall, this work represents preliminary steps in instrumenting makerspaces to promote gender inclusion and support maker-centered learning.

1. INTRODUCTION
While many authors have espoused the learning benefits of makerspaces [5], other researchers have recognized the inherent difficulties of supporting student learning in makerspaces' open-ended environment [13]. First, students are expected to solve problems independently in open-ended learning environments. Such independent work may lead to feelings of isolation, and instructors may not be aware that students are struggling. Second, the iterative nature of work in the makerspaces makes it difficult for instructors to continuously monitor students' progress. Without a clear feedback system, it is challenging for instructors to differentiate when students need instructional support.

Edwin Chng, Stephanie Yang, Gahyun Sung, Tyler Yoo and Bertrand Schneider "Leveraging Survey and Motion Sensors Data to Promote Gender Inclusion in Makerspaces". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 694-698. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

However, new sensing technology (such as motion tracking) offers an opportunity to address some of these challenges. The key benefit of using motion sensors is that they can be deployed to monitor students' learning in a continuous and unobtrusive manner. Therefore, we aim to examine how the use of quantitative data can help instructors overcome inherent challenges of assisting students in makerspaces.

For our scope, we examine how students from different genders interact in makerspaces [2;8;11], and we hope to promote gender inclusion in makerspaces. Eventually, we hope that the use of quantitative data can assist instructors in identifying the right form of support for each diverse group of students.

2. LITERATURE REVIEW
Makerspaces draw learners from a diversity of disciplines and provide multiple entry points to participation leading to "innovative combinations, juxtapositions, and uses of disciplinary knowledge and skill" [12]. However, makerspaces situated in formal learning environments are often male dominated [7]. Hence, it is an increasing priority for makerspaces to include women who are underrepresented in these communities. Central to this goal is understanding how women interact within makerspace courses. While some studies have not found gender to be a salient factor [2], other studies have shown that women often report feeling intimidated and excluded [8;11]. Most studies conducted in this area have also been qualitatively based profiles. Yet, for instructors to better support women in these spaces, more research must be conducted on gender differences in the cognitive, non-cognitive and affective domains and understand how these differences contribute to the outcomes of empowerment and community-building in maker-centered learning [5].

In this regard, the use of quantitative data from motion sensors could help provide alternative insights into gender differences. Researchers in the field of multimodal learning analytics have long explored the use of sensors to gather information on student learning because data can be collected in a sufficiently high frequency to draw rich inferences [3]. Since social interactions are an important part of makerspace projects, we focus this paper on capturing them using motion sensors. The successful utilization of motion sensors in capturing student interactions have been suggested by a couple of researchers [4;9]. One common thread in these previous works is the use of physical proximity as a rudimentary proxy for interaction. While being in close proximity is a necessary condition for interaction to occur, it is arguably not a sufficient condition. Therefore, in addition to the use of physical proximity as an indication for interactions, this study will layer on two other criteria (see Section 5.3). In essence, we hope that the use of quantitative data from motion sensors can paint a broader picture of women's experiences in makerspaces to improve instructor support and inclusivity.

3. CONTEXT OF STUDY

Quantitative data was collected from 14 female and 8 male students enrolled in a 15-week makerspace course (no students identified as non-binary). Kinect sensors were deployed 24/7 to gather skeletal joint data from students and survey tools were used weekly to assess students' learning experiences.

3.1 Course overview

The graduate-level makerspace course took place at a school of education in the northeastern part of the United States. With a focus on digital fabrication, the course aims to equip students with the necessary skills and knowledge to handle modern tools such as laser cutters. Each week, students are expected to work on a course assignment that typically involves the creation of a digital fabrication product for educational purposes. Depending on the requirements of the assignment, students could either work individually or collaborate. In addition to these weekly assignments, students also pair up to complete mid-term and final projects. While instructional support is available in the form of office hours and individual consultations, students largely work independently with minimal intervention from instructors.

Because of the open-ended nature of makerspaces, the course is designed with several scaffolds. Every week, the same cycle of design-prototype-create is adopted for each course assignment. In this manner, students continually receive opportunities to refine their skills. The presence of these weekly cycles also provides the research team with a natural unit of analysis and all quantitative data collected is aggregated at the week level.

3.2 Kinect Setup

Six Kinect v2 sensors were deployed in the makerspace to collect skeletal joint data. The sensors were positioned to achieve maximum coverage of the space (see Figure 1). When an individual's presence is detected in the Kinect's field of vision, the Kinect starts to record the x,y,z coordinates of the individual's head joint, left and right shoulder joints, left and right elbow joints, and left and right-hand joints. When there are multiple individuals present in the space, each Kinect sensor has the capability of recording up to 6 individuals at 30 Hz (i.e., 30 observations per second).

4. RESEARCH QUESTIONS

RQ1: What gender differences can be extracted from quantitative data collected from a makerspace?

RQ2: Which quantitative factors can account for students' development of a sense of empowerment and community spirit?

We examined students' sense of empowerment and community spirit in the second research question because these are key attributes of a maker mindset [5].

5. METHODS

In order to investigate how different genders work and interact in the makerspace, we constructed social networks from Kinect observations and derived network measures for each student (described in section 5.2 and 5.3). Additionally, we conducted weekly surveys of students to better understand their learning experiences (section 5.1). These surveys not only served as a triangulation measure for the Kinect observations, but also complemented the data by providing a more holistic description.

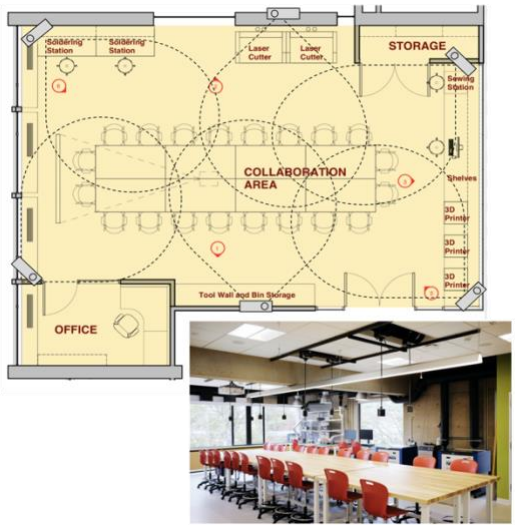

Figure 1. Layout of makerspace with positions and fields of vision of the Kinect sensors (top). Picture of the makerspace (bottom)

5.1 Survey Data

Surveys were administered to students after class each week. These surveys were crafted based on a literature review of surveys and to validate the questions, we conducted a validation study with students from a previous iteration of the course.

Table 1. Details of the surveys administered

Dimensions	Survey item	Scale	Source
Cognitive	- Tool Use - Time Committed	Likert 1-7 Numerical	General questions
Non-cognitive	- Perceived Competence - Self-Regulation - Motivation	Likert 1-5	[10; 15]
Affective	- Frustrated - Nervous - Interested - Inspired	Likert 1-5	[14]
Maker's attribute	- Sense of empowerment - Community spirit	Likert 1-5	[5]
Maker's mindset	- Can-do attitude - Empathy - Curiosity - Perseverance - Resourceful - Collaborative	Likert 1-7	[5]

Referencing Table 1, students' learning experiences were captured based on three dimensions: cognitive, non-cognitive, and affective. The two dimensions of maker's attribute and maker's mindset act as proxies for student outcomes. To determine gender differences, we conducted t-tests on these survey scores.

5.2 Kinect Data

Kinect observations were used for this study to infer the social interactions amongst students. Examining student interactions is key because communities represent an indispensable resource for students working in an open-ended environment. The following steps were taken to clean and process the Kinect data.

1) Student identification: Even though the Kinect sensors have no ability in establishing the identities of students, they capture video images from their fields of vision. These images were fed into OpenFace [1] to identify students.

2) Data homography: The coordinate system that the sensors operate in is relative to the actual positions of the sensors in the space. Hence, there is a need to convert the data into a coordinate system that better represents the 3D positions of the skeletal joints. Data homography was used to achieve this. A research team member stood in front of each sensor at nine different locations, forming a grid. Using the marked-out grid locations on the floorplan of the space and the measured positions of the skeletal joints, the coordinate system of sensors was translated into a coordinate system that is based on the floor plan (Figure 1).

3) Deduplication of skeletal joints: Finally, data from all six sensors were combined into a single coordinate system. However, because the sensors had overlapping fields of view, there was a possibility that multiple sets of skeletal joints were recorded for the same individual. In this case, deduplication was carried out to remove the additional skeletal joints for the same person.

5.3 Social Network Analysis

Once the Kinect data was processed, social networks were constructed. The social networks are built based on the episodes of student interaction. A student is said to have interacted with another if both students are one meter apart, have significant amounts of hand movement, and are either both sitting or both standing. The first criterion is based on the theory of proxemics [6], which states that humans maintain a comfortable distance of one meter during interactions. Admittedly, a proximity of one meter is a necessary but not sufficient criterion for establishing social interactions. Therefore, two other criteria were added to increase the probability of capturing true episodes of student interaction. The second criterion is based on the hands-on nature of the makerspace course. For two students who are in close proximity, having significant amounts of hand movement is likely an indication of collaboration. The third criterion is based on the observation that students tend to share the same eye level when working with each other. It is rare to observe two students working together with one individual standing and another sitting. While these three criteria are not perfect indicators of social interactions, observations of students working in the makerspace and crosschecks conducted by looking at screenshots from the sensors validated their use as a proxy for social interactions.

After we identified episodes of student interactions, social networks were generated based on the amount of time each student spent interacting with others. In essence, the nodes of the social network represent the individual students while the edges between nodes are weighted according to the amount of interaction time spent between students. From the weekly social networks, network measures were computed to obtain weekly network scores for each student.

Table 2. Details of network measures used

Network measures	Definition	Scale
Degree Centrality	This represents the fraction of nodes that a node is connected to.	0 to 1
Average edge weight	This is the mean of all the weights of all the edges connected to a node.	0 to inf
EI homophily index	This index is calculated by taking the difference between out-group and in-group connections and dividing by the total number of connections. For instance, in EI gender, a node for a female student would have male connections as out-group connections and female connections as in-group connections.	-1: Complete homophily (only in-group connections) 1: Complete heterophily (only out-group connections) 0: Equal number of in-group and out-group connections.

T-tests of the network measures were then conducted to extract gender differences, which addresses the first research question. For the second research question, the identified gender differences were used to build regression models for students' sense of empowerment and community spirit.

6. RESULTS

RQ1: What gender differences exist in a makerspace (from the quantitative measures)?

Table 3. Results of t-tests for gender differences

Measures	Statistical differences (t-test)
Survey: Perceived Competence	Males students (mean=5.2) reported having a higher level of perceived competence than female students (mean=4.8), t(20)=2.25, p=0.03.
Survey: Interested	Males students (mean=4.0) reported feeling more interested in the course than female students (mean=3.7), t(20)=2.21, p=0.03.
Survey: Inspired	Males students (mean=3.7) reported feeling more inspired in the course than female students (mean=3.4), t(20)=2.22, p=0.03.
Survey: Empowerment	Males students (mean=3.9) reported having a greater sense of empowerment than female students (mean=3.5), t(20)=3.11, p=0.002.
Survey: Empathy	Females students (mean=6.0) reported having more empathy than male students (mean=5.5), t(20)=2.14, p=0.04.
Survey: Perseverance	Females students (mean=5.9) reported having more perseverance than male students (mean=5.3), t(20)=2.71, p=0.008.
Network measure: EI gender	Males students (mean=0.02) have more diverse gender interactions than female students (mean=-0.16), t(20)=4.19, p<0.001.

Several items were different for males and females. First, males reported having higher perceived competence, which suggests that males are more confident individuals when it comes to assessing their abilities. Second, males recounted feeling more interested and inspired in the course. This shows that males possess more positive feelings towards the course. The lack of statistical significance for the negative affective states indicates that males and females might be struggling equally in the course. Third, males described developing a stronger sense of empowerment. This implies that males feel they have benefitted from the course and can move on to accomplish more challenging tasks.

Although males reported doing better in the course than females, the t-test results also indicate that females may possess some

alternate mechanisms for thriving in the course. Females score higher on empathy, which suggests females relate better to others in the community. Additionally, females score higher on perseverance, which hints at positive struggles from females. Lastly, for the network measures, females score more negatively in the EI index for gender, which implies that females interact more with other females, possibly for more community and emotional support.

RQ2: Which quantitative factors can account for students' development of a sense of empowerment and community spirit?

Findings from the survey data suggest that male and female students in this study differ in their perceived competence, positive feelings, empathy, perseverance and diversity in gender interactions. A linear regression model was built based on these to predict the students' sense of empowerment and community spirit.

Table 4. Regression models for sense of empowerment and community spirit (*p<0.05, **p<0.01, ***p<0.001)

Outcomes (→) Predictors (↓)	**Sense of empowerment****	**Community spirit*****
	F (4,17) = 6.85 p-value = 0.0018 R^2 = 0.6172 RMSE = 0.7915	F (1,20) = 16.72 p-value = 0.0006 R^2 = 0.4554 RMSE = 1.0513
const	coef. = -1.034 S.E. = 1.582 p-value = 0.522	coef. = -2.672 S.E. = 1.614 p-value = 0.113
Empathy		coef. = 1.123** S.E. = 0.275 p-value = 0.001
Perceived competence	coef. = 0.770 S.E. = 0.369 p-value = 0.052	
Positive feelings	coef. = 0.232* S.E. = 0.109 p-value = 0.048	
Perseverance	coef. = 0.954** S.E. = 0.242 p-value = 0.001	
EI gender	coef. = -0.441** S.E. = 0.111 p-value = 0.001	

Based on the regression analysis, students' positive feelings, perseverance, and diversity in gender interactions are significant predictors for their sense of empowerment. Even though perceived competence is not statistically significant, its low p-value of 0.052 hints that it might be a contributing factor to students' sense of empowerment (which corroborates with RQ1's findings). Similarly, the presence of positive feelings in the model echoes previous findings of males having more positive feelings and a greater sense of empowerment. However, it is unclear if students developed a greater sense of empowerment due to their positive feelings or if students felt more positive because they experienced empowerment. Lastly, the inclusion of perseverance and diversity in gender interactions as significant predictors demonstrates that initial learning difficulties in makerspaces can be overcome if one perseveres and that reaching out to fellow members for peer support can aid in the process of learning. Since females have expressed higher levels of perseverance and more in-group preferences previously, this finding reveals a potential pathway for female students to develop a sense of empowerment.

The regression analysis of community spirit shows that empathy is the sole significant predictor. Furthermore, the regression model with only empathy included has an R^2 value of 0.4554, which means that empathy as a factor alone can explain close to half of the variability in community spirit. This is not an unexpected finding as empathy remains a much-needed ingredient for the fostering of good relationships. This result also hints at possible contributions from females in building makerspace communities since they possess higher levels of empathy.

7. DISCUSSION

The findings of this paper indicate that males in this study are more confident in their technical ability and have more positive feelings associated with the makerspace. These findings run parallel to qualitative results in the literature which show that males tend to display more initial interest in makerspaces and technically oriented making activities [8]. While males self-reported more confidence in their abilities, females in this study were more persistent. Additionally, females reported higher measures of empathy and tended to interact more with other females when in the makerspace. These results are in line with qualitative findings from [11] indicating that females tend to appreciate having other females in the space.

In terms of promoting gender inclusion, the methods used in this study can help reveal to instructors the salient differences between genders operating in their own makerspaces. When awareness of gender differences is promoted, instructors can be naturally prompted to take more active steps to cater to distinct learning needs. Additionally, these findings serve as a reminder for instructors to avoid taking on a deficit view of any gender. On the surface, it might appear that males are thriving better than females in makerspaces, but the lack of statistical significance for the negative affective states signals that males and females struggle equally. Instead, our results suggest that males and females thrive in their unique ways in makerspaces, with males using their higher individual self-efficacy, and females using their greater group empathy skills. Neither males nor females should be viewed in a deficit perspective, and the removal of any gender bias would certainly go a long way in promoting gender inclusion.

Limitations of the current study include the relatively small sample size and the fact that the survey results were based on self-reported measures. These factors call into question the generalizability of our findings, and future work should seek to corroborate these results. Additionally, any reader of these findings must be careful to not fall into gender stereotypes. These results are reported on an aggregated basis, which may or may not be applicable to any individual student. Moreover, these findings are a result of our observations conducted in this particular study. Nonetheless, the findings demonstrate the feasibility of an approach that can be used by instructors to uncover gender differences in their own makerspaces.

8. CONCLUSION

The current paper examined gender differences in makerspaces and the factors that contributed to students' development of a sense of empowerment and community spirit. T-test results indicate that there are different pathways for male and female students to thrive in makerspaces and regression analyses highlight the quantitative factors that can account for students' development of a sense of empowerment and community spirit. This work presents preliminary steps in designing an automated system for instructional use to support gender inclusion.

ABSTRACT

Recurrent neural network (RNN) achieves state-of-the-art in several researches of the performance prediction. However, accuracy in early time steps is lower than that in late time steps, even though the early detection of at-risk students is important for timely interventions. To improve the accuracy in early time steps, we propose a knowledge distillation method for RNN. Our method distills the time-series information in the RNN model of late time steps into the RNN model of early time steps. This distillation makes the prediction of early time steps closer to that of late time steps. The experimental result showed that our method improved the detection rate of at-risk students compared with traditional RNNs, especially in early time steps.

Keywords

Student performance prediction, Early detection of at-risk students, Recurrent neural network, Knowledge distillation

1. INTRODUCTION

The detection of at-risk students is an essential task to ensure intervention as early as possible. At-risk students are those who may drop out of lecture courses and have low scores (e.g., grade point averages and quiz scores). When potential at-risk students are automatically detected in the early stage of courses, teachers can have sufficient time to encourage them to continue learning.

In recent years, prediction models based on recurrent neural networks (RNNs) have reached high performance [1, 3, 6, 7, 10, 11, 14, 19]. RNNs can handle time-series information such as weekly learning behavior and predict students' performance in each time step. Therefore, RNNs can detect at-risk students in each time step such as after each lecture. However, prediction accuracy in early time steps is lower than that in late time steps because it is difficult for RNNs to extract representative features from only the time-series information in early time steps.

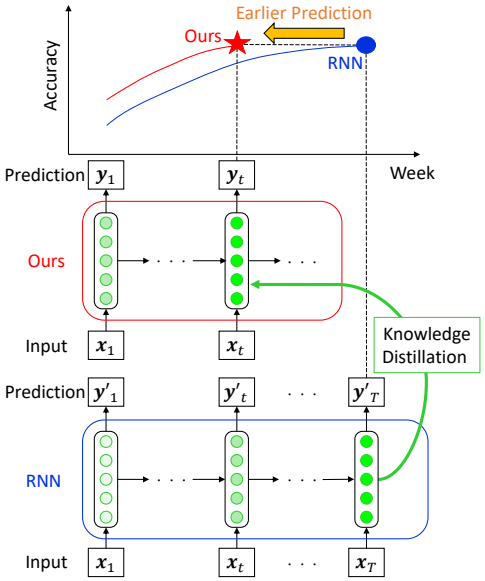

Figure 1: KD for the earlier detection of at-risk students.

To solve this problem, we propose a novel training strategy for improving the prediction in early time steps. Figure 1 shows an overview of our proposed method. Traditional RNNs can extract more representative features in later time steps, and prediction accuracy can also increase because RNNs can use longer time-series information. If RNNs can obtain more representative features from the inputs of earlier time steps, they can detect at-risk students earlier and maintain detection accuracy.

To transfer extracted features, we use *knowledge distillation* (KD) [4]. KD is a compression method for deep neural networks (DNNs), and many methods have been proposed in several fields such as visual recognition [2, 8] and natural language processing [5, 13, 15]. In KD, the model is compressed by training a small DNN model (student model) from a large DNN model (teacher model); that is, the knowledge in the teacher model is distilled to the student model. Further, KD does not require new annotations. In our method, KD is applied to transfer the representative features extracted from

Ryusuke Murata, Tsubasa Minematsu and Atsushi Shimada "Early Detection of At-risk Students based on Knowledge Distillation RNN Models". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 699-703. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

longer time-series information. As shown in Figure 1, this distillation makes the prediction of early time steps closer to that of late time steps, allowing us to detect at-risk students earlier.

The contributions of this study are summarized as follows.

- We introduce KD to predict students' performance. To the best of our knowledge, this is the first study to apply KD to performance prediction.
- We propose the RNN-FitNets model to improve early performance prediction. This model performs as if the learning behaviors in all the time steps are inputted, even though the model only receives the learning behavior in early time steps.
- We evaluate the effectiveness of our model for detecting at-risk students based on the learning logs collected from a higher education course.

2. KNOWLEDGE DISTILLATION RNN MODEL

In this study, we propose RNN-FitNets, which is an integration of RNNs and FitNets [12]. RNN-FitNets distils the well extracted features in the later time step into the RNNs in the earlier time steps by using the architecture of FitNets. Therefore, RNN-FitNets can improve the prediction accuracy in the earlier time steps. For example, as shown in Figure 1, RNN-FitNets can extract representative features in time step 3, whereas traditional RNNs obtain the same feature in time step T.

Figure 2 shows the architecture. The teacher model is pre-trained using all the time steps $(1, 2, ..., T)$, and the student model is trained until time step t $(1 \leq t \leq T)$. During the pre-training of the teacher model and training of the student model, the same ground truth holds (e.g., the final grade is passed to all the time steps). The teacher and student models have the same structure; only the time steps differ between them. Therefore, unlike FitNets, no regressor that transforms the size of the hidden layer of the student model exists.

The student model is trained using two steps in each training epoch as with FitNets. First, it updates its parameter, except for the output layer. Given the t-th time step feature vector of the student model as $\boldsymbol{h}_t$ and T-th time step feature vector of the teacher model as $\boldsymbol{h}'_T$, the parameter is updated by minimizing the following hint loss function L_{HT}:

$$L_{HT} = \frac{1}{2}\|\boldsymbol{h}'_T - \boldsymbol{h}_t\|^2 \quad (1)$$

After updating the parameter, the entire student model, including the output layer, is updated by minimizing the distillation loss. Given the output of the student model as $\mathbf{y}_1, \mathbf{y}_2, ..., \mathbf{y}_t$, T-th output of the teacher model as $\mathbf{y}'_T$, and ground truth as $\mathbf{y}_{\text{true}}$, the distillation loss L_{KD} is calculated as follows:

$$L_{KD} = \frac{1}{t}\sum_{i=1}^{t}(\mathcal{H}(\mathbf{y}_{\text{true}}, \mathbf{y}_i)) + \lambda\mathcal{H}(\mathbf{y}'_T, \mathbf{y}_t). \quad (2)$$

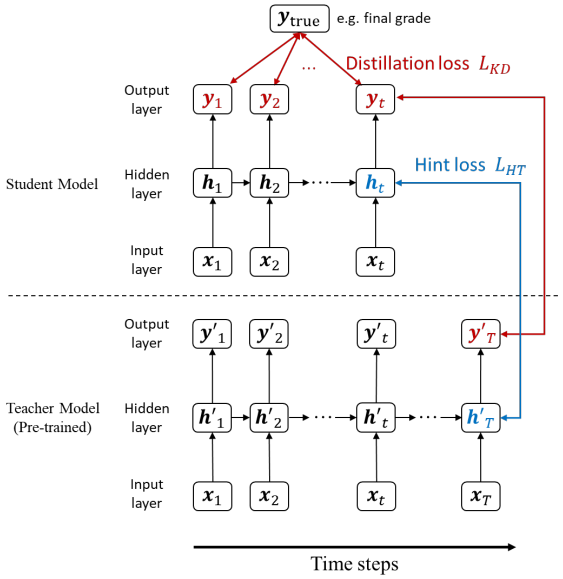

Figure 2: RNN-FitNets.

Table 1: Grade point average distribution.

GPA	A	B	C	D	F
Number of students	25	50	16	12	5

where $\mathcal{H}$ refers to the cross-entropy and λ is a hyperparameter that balances both cross-entropies.

3. EXPERIMENT

3.1 Dataset

We used the same dataset as [10]. The data were collected from the Information Science course at Kyushu University. This course started in April 2016 and 15 lectures were held weekly. Table 1 shows the grade point average of the 108 students that took this course. More than two-thirds of students received an "A" or "B." On this course, the teacher and students used a learning support system called M2B [9]. The M2B system consists of three subsystems: the learning management system, Moodle; the e-portfolio system, Mahara; and the e-book system, BookLooper. Moodle recorded students' attendance, submission of reports, and access to the course. Mahara recorded students' logbook in each lecture on the course. BookLooper recorded students' reading behavior such as turning pages, drawing highlights, and taking notes.

We also applied the feature engineering method used by [10]. The collected data were converted into active learner points, as shown in Table 2. As shown in the table, the learning behavior of each lecture was evaluated on a five-point scale (0–5). Attendance and report submission were evaluated based on whether the activities were on time, late, or not completed. The quiz was evaluated based on the ratio of collected answers. The other behaviors were evaluated by comparing the students in each lecture. Before inputting these features into the prediction model, the evaluated values were divided by 5 (i.e., they were normalized with in the range of 0 to 1).

Table 2: Criteria for active learner points.

Activities	5	4	3	2	1	0
Attendance	Attendance		Being late			Absence
Quiz	Above 80%	Above 60%	Above 40%	Above 20%	Above 10%	Otherwise
Report	Submission		Late			None
Course accesses	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise
Word count in Mahara	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise
Reading time in BookLooper	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise
Highlights in BookLooper	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise
Notes in BookLooper	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise
Total Actions in BookLooper	Upper 10%	Upper 20%	Upper 30%	Upper 40%	Upper 50%	Otherwise

3.2 Evaluation Criteria

We applied 5-fold cross-validation to the 108 students in the dataset. The folds were made by preserving the percentage of samples for each student's grade of "A," "B," "C," "D," and "F." After the separation, we grouped grades "A" and "B" into the "no-risk" class and grades "C," "D," and "F" into the "at-risk" class because more than two-thirds of students received "A" or "B" (see Table 1). Therefore, we conducted a binary classification between "no risk" ("A" or "B") and "at-risk" ("C," "D," or "F"). For the evaluation, we calculated the recall, precision, and F-measure values for detecting at-risk students.

3.3 Comparison Models

To investigate the effectiveness of our model, we compared the evaluation values for predicting the final grades between the following three types of models:

- **RNN baseline model**

  Training the RNN-based prediction model using the learning behavior in all lecture weeks.

- **Week-by-week model**

  Training the RNN-based prediction model using the learning behavior in each lecture week. Therefore, there were 15 independent models (trained by only first-week behavior, trained until the second week of behavior, and so on).

- **RNN-FitNets**

  Training the student model from the RNN baseline model as the teacher model in each lecture week. As with the week-by-week model, there were 15 student models.

The three types of comparison models had the same architecture. We set the batch size to one. The length of time steps took an integer from 1 to 15 when the three types of comparison models predicted students at-risk. When the models were trained, the RNN baseline model used 15 time steps and the other models used the same time steps as the prediction. The input features of the model were the active learner points shown in Table 2; therefore, the number of features was nine. For the hidden layer, we used GRU with 32 units and the activation function was tanh. The output layer had two units and the activation function was softmax. We used RMSprop optimizer [16] for the hint loss and distillation loss. In both the optimizations, we set the learning rate to 0.001. In addition, we applied L2 regularization with a parameter of 0.004 for the optimization of the weights and biases in the hidden and output layers of the RNN baseline and the week-by-week model. λ in the distillation loss (Eq. (2)) was equal to the time step; for example, when RNN-FitNets was trained using the learning behavior until the second week, we set λ to 2. All models were trained for 50 epochs.

3.4 Experimental Result

Figure 3 illustrates the evaluation of the three types of models. We summarize the results as follows:

- In most time steps, the recall values of the RNN-FitNets were higher than the values of the RNN baseline and week-by-week models. In other words, RNN-FitNets detected more at-risk students than other models.

- However, the precision values of the RNN-FitNets were lower than the value of the RNN baseline model, i.e., RNN-FitNets misdetected more no-risk students as at-risk.

- As shown by the F-measure values, the RNN-FitNets' values were higher than that of the RNN baseline and week-by-week models in most time steps. This difference was marked in early time steps. Therefore, the increase in the detection of at-risk students outweighed the increase in the misdetection, especially in early time steps.

- Comparing the evaluation values of the RNN baseline model with those of the week-by-week model, the former was superior in early time steps, although the values of the week-by-week model were close to or outperformed those of the RNN baseline model in late time steps.

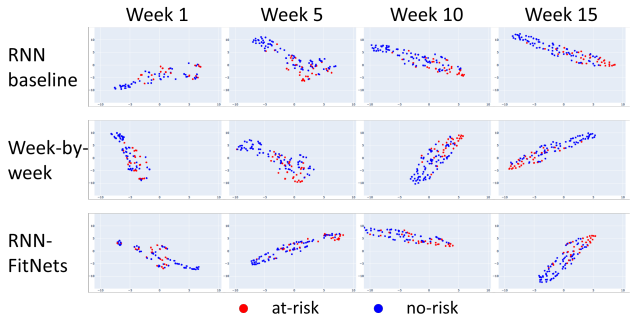

Figure 4: Visualization of the extracted feature vectors in the three types of models by t-SNE.

3.5 Discussion

The experimental result showed that the proposed models improved the detection rate of at-risk students, especially in early time steps. This improvement resulted from the distillation of time-series information. The evaluation values of the RNN baseline model were higher than those of the week-by-week model in early time steps. This result implies that the time-series information obtained by training in all the time steps is effective for early detection. In the RNN-FitNets, the time-series information was expressly passed through KD and that improved the model's performance.

To investigate whether the time-series information was distilled into the models in early time steps, we visualized the extracted feature of the three types of models. Figure 4 shows the visualization results of the feature vectors. Because the models have a 32-dimensional hidden state, we used t-SNE [17] and reduced the 32 dimensions to two dimensions for the visualization. Each point represents each feature vector for the students in the dataset. The red point is at-risk students and the blue point is no-risk students, as defined in Section 3.2. By observing the feature vectors of the RNN baseline and week-by-week models, the more time steps are used, the closer the red points are to each other and the more the shape of the mass of points becomes elongated. This means that the detection of at-risk students becomes easier in the feature vectors of late time steps. In the RNN-FitNets models, the tendency to gather red points and elongate appears in early time steps. This result shows that our KD method properly distills the time-series information extracted in the late time step.

4. CONCLUSION

In this study, we proposed RNN-FitNets, which extends FitNets, a KD method, for application to RNN architecture. RNN-FitNets transfers the time-series information extracted by the later time-step RNN into an earlier time-step RNN. Hence, the earlier time-step RNN learns the method of extracting the representative features in late time steps from short time-series data.

In the experiment, we applied RNN-FitNets to detect at-risk students in higher education. The results show that the proposed distillation model improves the detection rate of at-risk students from the base RNN models. The analysis of feature vectors indicated that our proposed model in earlier time steps extracted similar feature vectors to those of the base model in late time steps. This confirmed that our distillation strategy properly distilled the time-series information in later time steps into the model in earlier time steps.

In future work, we plan to investigate the availability of RNN-FitNets for other datasets. Moreover, we aim to formulate a new distillation method for time-series information for other models such as the Transformer model [18].

ABSTRACT
Sequential pattern mining is a useful tool in understanding learning processes, but identifying the most relevant patterns can be a challenge. Typical sequential pattern mining algorithms and interestingness metrics mainly focus on finding behavior patterns common across all students. However, educational researchers also care about individual differences. This study proposes a method for finding sequential patterns which usage have high variation across students. This method borrows techniques from the field of lag sequential analyses and meta-analyses. It uses the log odd ratio to model the individuals' usage of a sequential pattern and the heterogeneity test to examine the usage variation. We applied this method to analyzing student action logs in a virtual experimental environment and present preliminary results illustrating how the identification of sequential patterns with high usage variation provides interesting information about students' learning behavior. The proposed approach adds a way for understanding individual differences in learning processes.

Keywords
Sequential pattern mining, learning behavior differences, log odds ratio, lag sequential analysis, heterogeneity test

1. INTRODUCTION
Sequential pattern mining (SPM) aims to find the temporal associations between events [1]. For example, whether students read relevant material after answering a question incorrectly. Such sequential behaviors are named sequential patterns. SPM has shown its potentials in helping researchers understand learning behavior [2, 3].

However, there are challenges when applying SPM in education. One important challenge is that SPM algorithms may generate excessive sequential patterns, most of which are uninteresting or irrelevant to the research purpose [2]. This increases the difficulty of making meaningful interpretations and producing actionable pedagogical insights. To address this challenge, researchers select sequential patterns using interestingness metrics, such as the support value e.g., [4, 5]. The support value of a sequential pattern is the proportion of students that shown this pattern. As such, patterns with high support values will reflect similarities in the learners' behavior.

Yingbin Zhang and Luc Paquette "Mining sequential patterns with high usage variation". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 704-707. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Educational researchers also care about differences among students [6]. The understanding of individual differences in learning is essential for providing learners with adaptive scaffolding. To address this need, this study proposes a method borrowing from lag sequential analyses and meta-analyses that uses log odd ratio and the heterogeneity test to select sequential patterns based on their variation in usage across learners.

2. Methodology
Let $E = \{e_1, e_2, \dots, e_p\}$ be a set of p unique events that may occur within a specific learning environment, such as answering a question and asking for a hint. Let $S_m = \{i_1, i_2, \dots, i_n\}$ be a sequence of N temporally ordered items with each i_j being a subset of E. A sequence is a student's learning process data, such as action logs in an intelligent tutoring system. Each i_j usually contains one event because students rarely initiate two different actions simultaneously. Let $e_x \rightarrow e_y$ be a sequential pattern where e_y occurs after e_x (e_x and e_y may be the same event). Let $\overline{e_x}$ denote an event other than e_x. If there are $i_k = e_x, i_l = e_y$, and $k < l$ in S_m, S_m contains $e_x \rightarrow e_y$ [8].

2.1 Using log odds ratio to model sequential pattern usage
If we fix the gap between $e_x \rightarrow e_y$ to a constant c, we may use methods from the field of lag-sequential analyses to quantify students' usage on $e_x \rightarrow e_y$ [8]. Fixing the gap to c means that we only consider $i_k = e_x, i_l = e_y$, and $l - k = c$ as an occurrence of $e_x \rightarrow e_y$. For example, $c = 1$ means that we only count the case where e_y directly follows e_x. Lag-sequential analysis utilizes statistics from contingency table analyses to quantify the usage of $e_x \rightarrow e_y$, such as the odds ratio and the log odds ratio [8].

Let the frequency of pairs of consecutive events where the first event is e_x and the second event is e_y $n(e_x \rightarrow e_y) = a_m$, Let the frequency of pairs of consecutive events where the first event is e_x but the second event is not e_y $n(e_x \rightarrow \overline{e_y}) = b_m$. Let the frequency of pairs of consecutive events where the first event is not e_x but the second event is e_y $n(\overline{e_x} \rightarrow e_y) = c_m$. Let the frequency of pairs of consecutive events where the first event is not e_x and the second event is not e_y $n(\overline{e_x} \rightarrow \overline{e_y}) = d_m$. The odds ratio of $e_x \rightarrow e_y$ in S_m can be calculated as $\frac{a_m d_m}{b_m c_m}$, while the log odds ratio is $log\frac{a_m d_m}{b_m c_m}$. However, there is measurable bias in this expression when the sample is small. A slightly modified version is often used to reduce bias [9]:

$$Y_m(e_x \rightarrow e_y) = log\frac{(a_m + \frac{1}{2})(d_m + \frac{1}{2})}{(b_m + \frac{1}{2})(c_m + \frac{1}{2})}. \quad (2)$$

The log odds ratio of $e_x \rightarrow e_y$ represents the relative likelihood that e_y occurs after e_x during a student's learning, considering the

probability that e_y occurs after an event other than e_x. If a sequential pattern contains more than two events, researchers may segment a sequential pattern into two sub-patterns and represent the sequential pattern as one sub-patterns follows another. For example, $e_x \rightarrow e_y \rightarrow e_z \rightarrow e_w$ may be represented as $e_{x \rightarrow y} \rightarrow e_{z \rightarrow w}$. This preprocessing has been used in computing the confidence value of sequential patterns longer than two events [10]. Then, the above procedure can be used to calculate the log odds ratio.

The variance of $Y_m(e_x \rightarrow e_y)$ is:

$$V_m(e_x \rightarrow e_y) = \frac{1}{a_m + \frac{1}{2}} + \frac{1}{b_m + \frac{1}{2}} + \frac{1}{c_m + \frac{1}{2}} + \frac{1}{d_m + \frac{1}{2}}. \quad (3)$$

$V_m(e_x \rightarrow e_y)$ characterizes the imprecision of the log odds ratio and decreases as the length of S_m increases. The log odds ratio based on a long sequence is more precise than that based on a short sequence [9].

2.2 Ranking sequential patterns by variation across users

We can examine whether the log odds ratio varies across participants via the heterogeneity test used in meta-analyses [11]. One commonly used heterogeneity test is the Q test [12]. In meta-analyses, Q is the weighted sum of the squared deviations of each study's effect estimate from the weighted mean of all studies' effect estimates. The weighting for each study is the inverse of the variance of the study's effect estimate. Thus, in terms of the variation of the log odds ratio of $e_x \rightarrow e_y$, Q can be calculated using the formula:

$$Q(e_x \rightarrow e_y) = \sum \frac{(Y_m - \overline{Y})^2}{V_m}, \quad (4)$$

where $\overline{Y}$ is the weighted mean of log odds ratios, i.e.,

$$\overline{Y} = \frac{\sum \frac{Y_m}{V_m}}{\sum \frac{1}{V_m}}. \quad (5)$$

Q follows a chi-square distribution with $k - 1$ degrees of freedom, where k is the number of sequences or participants. Thus, if $Q(e_x \rightarrow e_y)$ is higher than the critical value for a given significance level (e.g., 0.05), we may conclude that the usage of $e_x \rightarrow e_y$ has statistically significant variation across participants. Moreover, for the same dataset, the number of participants is constant, and thus, the Qs of all sequential patterns follow the same chi-square distribution and are comparable. However, it is difficult to interpret Q because its magnitude is influenced by the number of participants. The I^2 index overcomes this issue [13].

$$I^2 = \begin{cases} \frac{Q - (k-1)}{Q} * 100\%, if\ Q > (k-1) \\ 0, else \end{cases}. \quad (6)$$

$I^2(e_x \rightarrow e_y)$ can be interpreted as the proportion of variation in the log odds ratio of $e_x \rightarrow e_y$ due to true between-participants variance. Ranking sequential patterns by Q and I^2 produces the same results because k is fixed for the same dataset.

3. Example

This section applied the proposed method to a dataset of student action logs collected from a virtual experiment environment called LabBuddy [14].

3.1 Data

3.1.1 Participants

The data were collected from a graduate-level enzymology course at a university in the Netherlands. Participants were 76 graduate students in this course. The average age was 22.91 years old (SD = 1.80). Around 64.47% of the students were female.

3.1.2 LabBuddy

The course helped students prepare for the laboratory classes using LabBuddy. LabBuddy in this course contained a self-directed learning task, which included six research questions offered by a virtual tutor, Professor Kabel. Students start with proposing hypotheses for each question and make an experimental design via a flow chart to test the hypotheses (Figure 1). Each block in the flow chart represents a chemical method and contains details about the method. Each block also contains some closed questions that students must answer correctly before implementing the method and getting the raw data. Students do some calculations based on the raw data to get the results. The details, raw data, and calculations of a method are located in different subblocks of a block. If students are struggling with a closed question, they may request hints or the correct answer. Once students obtain the results, they may consult Professor Kabel to interpret them and either accept or reject their hypotheses. Students used LabBuddy for an average of 7.5 h distributed over three days. Their action logs were used for analysis.

3.2 Analyses

We preprocessed the action logs by removing redundant successive repeated actions (e.g., multiple selections of the same block) and contextualizing some actions (e.g., is the submitted answer to a closed question correct?). The preprocessing resulted in 19 unique events. The average number of events in a student's action log was 995 (SD = 363). Then, we implement our methods via the following procedure:

1. Apply the cSPADE algorithm to find frequent sequential patterns with support no less than 0.5. We used this algorithm because it allows us to fix the gap between events in a sequential pattern, a prerequisite for calculating the log odds ratios. The gap was fixed to 1 in the analysis. For simplicity, we only focused on sequential patterns containing two events. This step generated 81 frequent sequential patterns.
2. For each student, compute the log odds ratio, variance, and the number of occurrences of each frequent sequential pattern.
3. For each frequent sequential pattern, conduct the Q test and calculate the I^2 index, the average log odds ratio, and the average occurrence. As the Q test was run 81 times, we used the Benjamini-Yekutieli correction to control the false discovery rate [15].

Note we only apply our method to frequent sequential patterns because the variation of a sequential pattern across participants would be low if few participants used a pattern (i.e., it was infrequent).

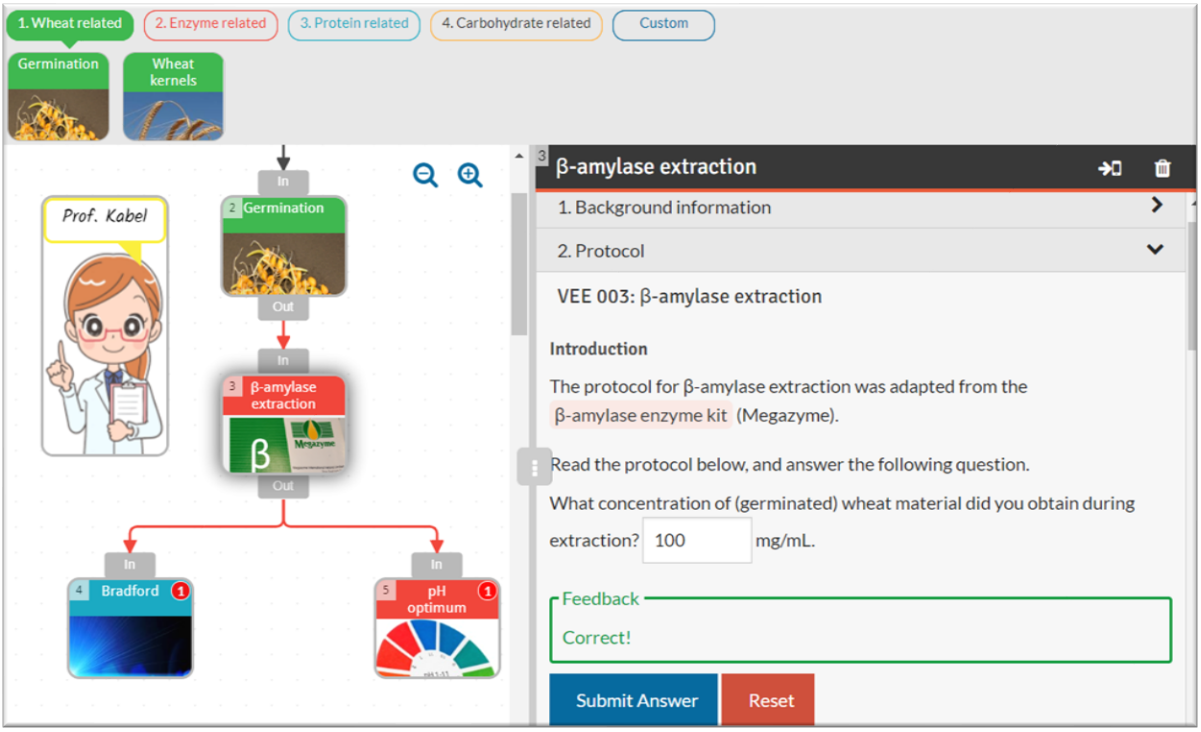

Figure 1. The LabBuddy learning environment.

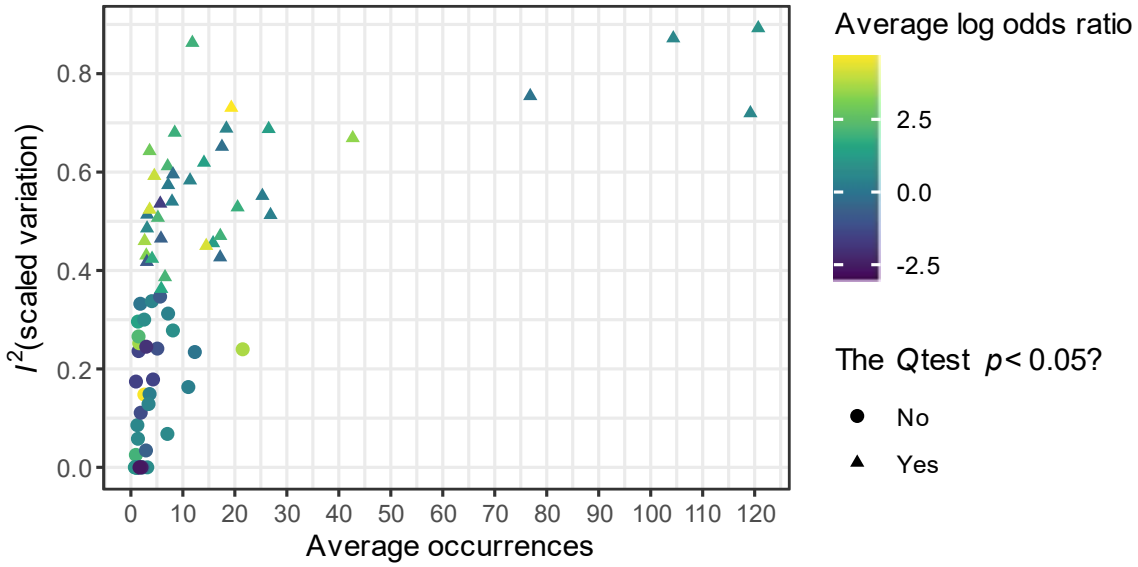

Figure 2. The I^2 indexes, average log odds ratios, and average occurrences of sequential patterns.

3.3 Preliminary results

Figure 2 visualizes the relationships among the I^2 indexes, average log odds ratios, and average occurrences of the 81 sequential patterns. There were moderate positive relationships between the I^2 index and the average log odds ratio ($r = 0.57$, $p < 0.001$) as well as the average occurrences ($r = 0.36$, $p = 0.001$). Nevertheless, ranking sequential patterns by their variation between students results in a different set of selected patterns than ranking them by their similarities (average log odds ratios and occurrences) between students. Some sequential patterns had few average occurrences (e.g., less than 5) or negative average log odds ratios while still being used differentially by students (the adjusted p of the Q test < 0.05). Some sequential patterns had relatively high average occurrences (e.g., larger than 10) or average log odds ratios (e.g., larger than 1) but were used consistently across students (the adjusted p of the Q test > 0.05).

We investigated how I^2 might help us detect behavioral differences by looking more closely at two sequential patterns with distinct I^2: *Submitting an intermedia answer → Submitting an intermedia answer* and *Requesting a hint → Requesting a hint*. Both patterns had high values in average occurrences and log odds ratios (see Table 1). *Submitting an intermedia answer → Submitting an*

intermedia answer had a I^2 of 0.75 ($p < 0.001$), indicating that students had high variations in the usage on this pattern. Further analysis showed that, in 9.54% of all pairs of students (309/3,240), the log odd ratio was significantly different between the two students. This means that among 10 randomly sampled pairs, on average, there was one pair where the two students had significantly different probability of submitting two intermedia answers consecutively. In contrast, the usage on *Requesting a hint → Requesting a hint* was relatively consistent across students (I^2 = 0.24, p = 0.52). Analyses showed that, in only 1.6% of pairs, the log odd ratio was significantly different between two students.

Table 1. The metrics of two sequential patterns

Pattern	I^2	p for the Q test	Log odds ratio	Occurrences
RH.RH	0.24	0.52	3.76	21.51
SI.SI	0.75	0.00	4.81	19.32

Note. RH.RH: *Requesting a hint → Requesting a hint*. SS.WA: *Submitting an intermedia answer → Submitting an intermedia answer*.

4. Discussion

This study proposed a method for mining sequential patterns which usage has high variation across students. We applied the method to a dataset of student action logs in a virtual experimental environment. The preliminary results suggest that ranking sequential patterns by their variation across students results in a different selection of patterns than by their similarities across students. Moreover, the results demonstrated how the proposed method could capture individual differences in sequential behavior patterns. The approach adds a way for understanding individual differences in learning, which is critical in education.

The next step is to examine whether the sequential patterns with high variation are related to students' learning gains. Such investigation would contribute to our understanding of how differences in which sequential patterns may lead to differences in learning outcomes. The insights, in turn, would provide information about how the learning environment might scaffold the learners' interaction with the learning environment by prompting sequential behavior patterns beneficial to learning and discouraging patterns harmful to learning.

Our approach requires fixing the gap between events of a sequential patterns. This requirement limits flexibility. For example, researchers may regard *Submitting an intermedia answer → Requesting a hint → Submitting an intermedia answer* as an instance of *Submitting an intermedia answer → Submitting an intermedia answer*, but fixing the gap to 1 excludes this possibility. On the other hand, if fixing the gap to 2, *Submitting an intermedia answer* directly after *Submitting an intermedia answer* would not be regarded as an instance of *Submitting an intermedia answer → Submitting an intermedia answer*. The limitation is the same as the issue that the lag between the antecedent and consequent events must be fixed in a lag sequential analysis [8]. Addressing this issue is challenging but worthy of effort.

5. ACKNOWLEDGMENTS

We would like to thank the Laboratory of Food Chemistry, Wageningen University & Research for allowing us to use the dataset and access to LabBuddy.

Demonstrating REACT: a Real-time Educational AI-powered Classroom Tool*

Ajay Kulkarni
George Mason University
akulkar8@gmu.edu

Olga Gkountouna
George Mason University
ogkounto@gmu.edu

ABSTRACT

We present a demonstration of REACT, a new **R**eal-time **E**ducational **A**I-powered **C**lassroom **T**ool that employs EDM techniques for supporting the decision-making process of educators. REACT is a data-driven tool with a user-friendly graphical interface. It analyzes students' performance data and provides context-based alerts as well as recommendations to educators for course planning. Furthermore, it incorporates model-agnostic explanations for bringing explainability and interpretability in the process of decision making. This paper demonstrates a use case scenario of our proposed tool using a real-world data set, and presents the design of its architecture and user-interface. This demonstration focuses on the agglomerative clustering of students based on their performance (i.e., incorrect responses and hints used) during an in-class activity. This formation of clusters of students with similar strengths and weaknesses may help educators to improve their course planning by identifying at-risk students, forming study groups, or encouraging tutoring between students of different strengths.

Keywords

Clustering, Decision-support, Educational tool, Explainability, Human-centered computing

1. INTRODUCTION

Instructors play a crucial role in educational institutions, where one of their main responsibilities is effective high-quality teaching. To do so they must stay updated with students' responses, efforts, and outcomes, in order to provide timely feedback to promote students' improvement [9, 29]. One of the ways this can be achieved is by clustering students into groups based on various characteristics such as their learning style preferences, academic performance, behavioral interaction, etc., which can be utilized to explore collaborative learning opportunities and identify at-risk students at an early stage [3]. Thus, this creates a need for tools that will empower instructors to achieve these objectives in the classroom. To this end, the fields of Educational Data Mining (EDM) and Learning Analytics (LA) have emerged with the goal to understand how educational data can benefit the science of learning [7]. One of the ways to promote this understanding is to use AI-powered real-time visualizations. These visual displays summarize large amounts of data in a meaningful way. This is important for humans' sense-making and decision-making [35] as it helps human cognition [12]. An example of these visual displays are dashboards which may contain various data indicators [20].

Furthermore, applications of Artificial Intelligence (AI) in the domain of education for predicting student performance, detecting undesirable student behavior, or providing feedback for supporting instructors and students, are becoming more common [8]. This creates a need for incorporating interpretability, explainability, and, ultimately, trustworthiness in AI for supporting human teaching and learning [39]. The simplest way to include explainability in AI is by using model-agnostic explanations that consist of textual and visual explanations [4]. Interpretability can be achieved by including humans in the process of decision making (HitAI) i.e., decision power is given to the specialized professionals who utilize machines/tools as advisors [41].

This paper presents a demonstration of REACT, a **R**eal-time **E**ducational **A**I-powered **C**lassroom **T**ool, which utilizes the principles of HitAI and model-agnostic explanations to support educators in their decision-making. REACT clusters students based on their responses during in-class activities, and provides context-based recommendations for course planning. It also provides personalized feedback about individual students. REACT is a real-time data-driven decision-support tool that incorporates explainability, interpretability, and portability. It presents different indicators of students, their learning processes, learning contexts, and recommendations for increasing efficiency in course management. Based on the Learning Analytics Process model [38], REACT may directly help educators in awareness, reflection, and sense-making while it can indirectly create impact and motivate to take actions. This functionality can support educators in making decisions concerning their course planning and instructional goals setting, by consistently monitoring students' activities (tests, quizzes, and exercises) to inspect the their learning process.

Ajay Kulkarni and Olga Gkountouna "Demonstrating REACT: a Real-time Educational AI-powered Classroom Tool". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 708-712. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

The remainder of this paper is structured as follows. Section 2 presents the background of EDM and how clustering can be useful in this context. Section 3 describes the architecture of our tool and explains how clustering is utilized in REACT. Section 4 presents the details on the design of the user interface and details of the demonstration. Finally, Section 5 concludes the paper discussing directions of future research.

2. BACKGROUND

EDM enhances the decision-making of teachers, students, and educational institutes by utilizing data mining techniques in an educational context [31]. A variety of methods, including cluster analysis, outlier detection, text mining, recommendation systems, and visualizations can be applied in the EDM domain [32]. *Cluster analysis* or *clustering* is the most well known unsupervised machine learning task [24]. In the context of EDM, identifying meaningful clusters of students can be useful in understanding their learning behavior [14, 13, 10, 5, 26, 22]. Clustering consists of four steps [40]: (1.) *Feature extraction and selection* – Relevant features are selected from the data and transformed into an appropriate format. (2.) *Algorithm design* – A suitable clustering algorithm and (dis)similarity measure are selected. (3.) *Evaluation* – Different clustering results can be evaluated using different metrics such as external, internal and/or relative indices. (4.) *Explanation* - The main purpose of clustering is to generate knowledge, useful for decision-making. This is conveyed to the user in different ways such as visualizations, textual feedback, or statistical metrics.

Hierarchical clustering organizes the data points in a taxonomy tree of clusters and sub-clusters [37]. Thus, it is suitable for detecting clusters of arbitrary shape, type and hierarchical relationships [40]. Hierarchical clustering has been shown to provide good results for small datasets [1], which is useful for typical class sizes. Furthermore, the entire clustering process can be visualized by plotting a *dendrogram*, which shows the cluster-subcluster relationships, similarity between clusters, and the order in which they are merged [37]. This results in an informative visualization of the data clustering structures [40], fulfilling the goal of explainability. There are two basic approaches to Hierarchical clustering – agglomerative and divisive [25]. The agglomerative hierarchical clustering is a bottom-up approach that starts with each points being an individual cluster, and merges the closest pair of clusters at each step. The divisive method is top-down approach that starts with points being in one large cluster and progressively divides them. This is computationally expensive [15] and not commonly used [40]. Thus, agglomerative hierarchical clustering makes a suitable choice for implementing cluster analysis on REACT.

3. REACT ARCHITECTURE

REACT is developed using the `R Shiny` framework which incorporates the principles of reactive programming [6] that are suitable for interactive applications. REACT is portable in a sense that it can be connected to any Learning Management System (LMS), like Moodle or Blackboard, as well as different database management systems, including MySQL, Oracle, Salesforce, etc. This can be achieved by using different packages such as DBI[1] (for databases), bRush[2] and rcanvas[3] (for the Canvas LMS) which are available in R. Additionally, many other LMSs offer REST APIs which can be connected with REACT using httr[4] and jsonlite[5] packages.

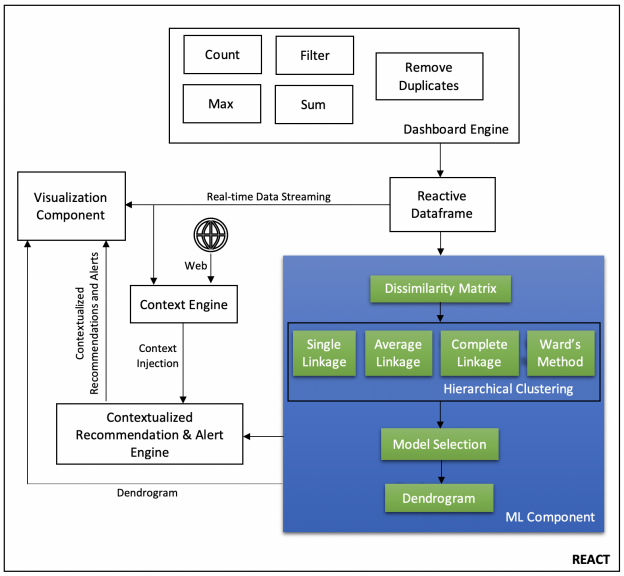

Figure 1: Architecture of REACT

The architecture of REACT is motivated from RAED [23] and it is shown in Figure 1. It consists of five main components: the Dashboard Engine, the Machine Learning (ML) Component, the Context Engine, the Contextualized Recommendation & Alert Engine, and the Visualization Component. Due to space limitations, we focus on the component that implements clustering as an EDM technique, i.e., the ML component.

The ML component receives input from a reactive data frame that contains the input features of each student and initiates the clustering process by first calculating all the pairwise distances (i.e., dissimilarities) of students. We use the Gower distance [18] as the dissimilarity metric for the clustering, as it can be applied to mixed data (i.e., a mix of numerical and categorical variables) in general [33]. However, for the purposes of this demonstration, we use as input features of each student the numbers of incorrect responses and the number of hints used per learning concept. For these numerical features, Gower uses Manhattan distance to calculate dissimilarity. The Dissimilarity Matrix sub-component calculates the pairwise distances between all n observations (i.e., students) in the data set organized in an $n \times n$ matrix, using the `daisy() R` function. This dissimilarity matrix then becomes the input of the Hierarchical Clustering sub-component.

The Hierarchical Clustering sub-component trains four different hierarchical clustering models using the same dissim-

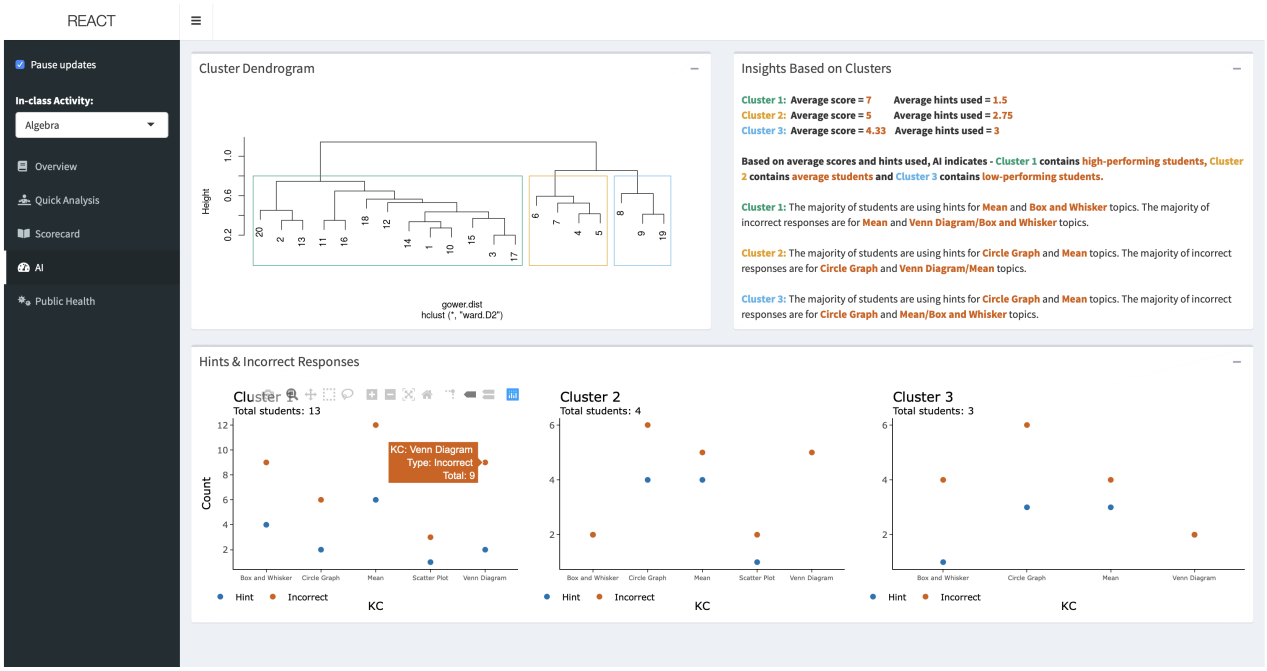

Figure 2: The AI tab provides real-time insights of clustering to instructors with visual explanation (dendrogram - top left) and textual template-based recommendations (top right)

ilarity matrix. These models are based on four different linkage methods: Single linkage, Average linkage, Complete linkage, and Ward's method. The `R` function `agnes()` is used for building these models and computing their agglomerative coefficients.

The Model Selection sub-component ensures robustness and acts as an internal index for evaluations. It compares the four clustering results based on their agglomerative coefficients. Their values lie between 0 to 1, and describe the strength of the corresponding clustering structure [21]. This sub-component selects the model with the highest agglomerative coefficient.

The Dendrogram sub-component creates a visualization of the hierarchy of clusters and sub-clusters that are the result of the selected model. This visualized hierarchy is called a *dendrogram*. The dendrogram provides a diagrammatic representation of the hierarchical cluster analysis. It can help to understand the clustering process which may help to incorporate explainability. An example of a dendrogram is shown in Figure 2 and discussed in the next section.

4. DESIGN AND DEMO

A dashboard can be defined as "an easy to read, often single page, real-time user interface, showing a graphical presentation of the current status (snapshot) and historical trends of an organization's key performance indicators (KPIs) to enable instantaneous and informed decisions to be made at a glance" [11]. It is also common for decision-makers to use KPIs for understanding the performance or the deviation from the set target at a glance [28]. Thus, the user-interface of REACT is designed as an interactive dashboard, displaying KPIs to help teachers monitor and understand their student's learning performance. These KPIs include the minimum, maximum, median and mean scores of the class, as well as the number of students who have completed all the questions of the in-class activity thus far.

4.1 Design Elements

A dashboard's visual attraction significantly affects its perceived usefulness and its potential to bring change in users' behavior [27]. The design choices of REACT were made with this consideration in mind. The selection of visualizations is based on the chart suggestions provided by Abela [2] and a review provided by Schwendimann et al. [34]. Further, its color palettes were selected so that it is colorblind-friendly [17]. REACT contains interactive visualizations and tables. Interactive applications need to ensure that they are easy to learn, and effective as well as enjoyable to use [30]. To ensure this, we aimed to follow the 'golden rules' of interface design proposed by Shneiderman et al. [36] – strive for consistency, permit easy reversal of actions, keep users in control, and reduce their short-term memory load.

The user interface of REACT currently has five tabs:
Overview – presents the KPIs, an interactive plot for monitoring students' performance, and textual alerts & recommendations for the instructors.

Quick Analysis – presents an interactive plot that monitors the progress of students in real time, and bar charts that count the incorrect responses, and hints used for each KC.

Scorecard – displays a histogram of the score distribution, and a dynamic table with students' information and scores, both updated in real-time.

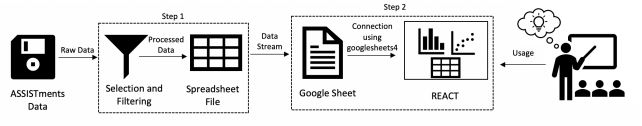

Figure 3: Creating a real-time demo of REACT

AI – provides insights of the cluster analysis and textual template-based recommendations. Figure 2 shows a screenshot of this tab. An instructor may use this tab to see on the dendrogram (top left) how different groups (i.e., clusters) of students are formed, based on their performance in in-class activities. Textual explanations about each of these groups are provided on the top right. Finally, to enhance interpretability, each of the different clusters is also visually explored at the bottom of the tab. The counts of incorrect answers and the counts of hints used are displayed per Knowledge Component (KC) for each group of students.

Public Health – provides context based on the COVID-19 outbreak. It displays infection rates in the surrounding counties and counts of students who may live in high risk areas, to inform educators, who may opt to transition online.

4.2 Demo

Holstein et al. [19] note the importance of using real-world datasets to understand the behavior of LA tools. We use the 2009-2010 Skill-builder ASSISTments data set [16]. The raw data consists of more than 100,000 rows representing details of 4217 students and 111 Knowledge Components (KCs). To achieve the objective of this demonstration, we randomly selected a sample of 20 students. Due to privacy, this data set includes only pseudo-ids. In real-word uses of REACT, authenticated instructors will be able to see students' names, as memorising their ids would be troublesome. Our approach to create a demonstration of REACT is shown in Figure 3 and can be summarized in the following steps:

- **Step 1 (Filter):** We selected 20 students and two questions from five KCs from the topic of statistics (Mean, Circle Graph, Venn Diagram, Box and Whisker Plot, and Scatter Plot). This filtered data set is first stored in a spreadsheet on a local hard disk.
- **Step 2 (Stream):** The filtered data from *Step 1* are then streamed on a Google sheet that acts as a database for this demonstration. It is connected to REACT using the `googlesheets4`[6] package.
- **Step 3 (Use):** REACT receives live updates from the streaming data. These concern hints that each student uses during the simulated in-class activity, as well as if they provided a correct or incorrect response to each question, as time progresses. These data are processed on the fly and used to update the visualisations, alerts, and recommendations displayed on the user interface.

A live version of REACT[7] is deployed using the `Shiny Server` and it can be accessed using a web browser on any desktop, laptop, tablet, or smartphone.

5. CONCLUSIONS AND FUTURE WORK

We presented REACT, a data-driven, visual, decision-support tool that incorporates model-agnostic explanations. This paper provides details on demonstrating a use-case scenario by utilizing the ASSISTments dataset. Our next step is to evaluate our proposed tool with the help of domain experts, using a combined approach of think-aloud testing and questionnaires. This approach will help us to understand the usability and user experience while interacting with REACT. The results from this combined approach can help us to identify directions of improvement in the interface design and to propose the addition of new features. In the future, we aim to answer *how the integration of AI and visualizations in real-time can impact the instructors' decision-making process, and to what extent they do trust it.* The answers to these questions will play a crucial role in making REACT a deployable tool that can enhance data-driven decision-making in education.

dgerrits@andrew.cmu.edu

ABSTRACT

This research presents a process for simplifying video labeling and feature generation when building classification systems from real classrooms. Using video from a single, wide-angle recording of a live classroom, we create a low-level feature set of posture primitives built on keypoints from OpenPose. We use that feature set to build a posture recognition model of "natural labels" built from a scripted posture video using the same classroom. This model provides automatic labels for the real classroom data. We then derive a set of interpretable descriptors to characterize student-specific posture pattern dynamics. We show that those descriptors are able to discriminate between subtle differences in learning activities in a real college classroom.

Keywords

classroom analytics, posture analysis, student activity recognition

1. INTRODUCTION

The field of research into classroom sensing technologies and data mining is growing. One goal of this work is to provide automated feedback to instructors about anything from latent states of the students to overt actions by the teacher [15]. The motivation for this work is usually to empower teachers and scaffold instructional development without always relying on human consultants [13].

The promise of this field is high, but so are the costs. Technical staff and software development are all expensive. Additionally, labeling video data in order to derive insights about student interactions is particularly time-consuming and difficult. This study describes an attempt to reduce that cost. We used a freely available posture analysis tool (OpenPose) to produce keypoint data for human postures which we then used to build a generic set of labels for a class of students. Our goal was to simplify both the application and interpretability of data labels.

Lujie Karen Chen and David Gerritsen "Building Interpretable Descriptors for Student Posture Analysis in a Physical Classroom". 2021. EDM '21 June 29 - July 02 2021, Paris, France

2. RELATED WORK

Emerging technologies for sensing pedagogical events in live classrooms include the detection of overt student behaviors (e.g., hand raising and gaze direction [1]), latent states (attention and engagement [16, 12]), and instructor actions (e.g., questions, activity sequences, gestures, and physical location in the room [3, 7, 11, 14]). Each approach has its own trade-offs in terms of reliability and effort required, but the models all require a dictionary of human-labeled body postures. Data annotation is time-consuming work requiring special expertise. For example, one must choose between coding in real-time [9, 10] or post-hoc [12, 16], and whether or not to use assisted label production [17].

Feature generation is a related but different concern. Education researchers may want to build models on comprehensible features, such as the words used during teachers' questions [3, 14], or the gestures students and teachers exhibit during interactions [5, 4, 7, 12, 16]. While it is possible to use a "kitchen sink" approach to quickly assess the success of an algorithm and its inputs, education researchers may prefer to use features that can be observed and understood by the end-user. This way the instructors using their systems might be able to make changes based on the model output, e.g., [2].

3. MOTIVATION

High-quality video cameras are ubiquitous. Researchers in education and machine learning can quickly generate large volumes of dynamic, rich data from the classroom. When turning video into data, education researchers traditionally code classroom videos using any number of methodologies [8]. Each approach for annotating and interpreting video data takes a significant amount of training and time.

To this end we present the following case study in which we demonstrate a pipeline that requires only minimal resource investment on the part of the experimenter, including the time it would normally take to define, identify, and verify student gestures. We propose that this savings is possible without sacrificing the interpretability of a human-coded feature set. To test the pipeline, we designed an easy and accessible feature generation strategy which we then tested against the most difficult in-class dataset we could imagine.

Figure 1 illustrates our workflow, broken into the following stages: (1) We collect a video recording (scripted posture data, section 4.2) with synchronized, scripted posture pat-

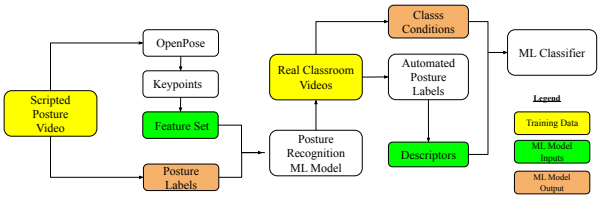

Figure 1: Workflow

terns commonly observed in classrooms; (2) We fit supervised machine learning models to automatically recognize the scripted posture patterns (section 5.1); (3) Using video from a real classroom (section 4.1), we demonstrate the utility of those auto-estimated posture patterns by applying the posture detection models to the real classroom dataset to discriminate between class conditions (section 5.2).

4. DATA SOURCES & AUTO-LABELING

Here we describe our data collection and analysis. We conducted the study at Carnegie Mellon University in the Spring semester of 2019. We generated model data from a group of volunteers, and target data from a class of real students. All students signed IRB-approved consent forms.

4.1 Real Classroom Data

In selecting a use-case for our approach we chose a class that embodied a traditional lecture-based class. We worked with a semester-long graduate level course on "Applied Data Science" (ADS) in Spring 2019. There were 22 enrolled students, all of whom could fit in a single frame of a wide-angle camera (Marshall CV505). The camera faced the rows of students, and the instructor was not in frame. We recorded throughout the entire semester of bi-weekly, 75-minute session. We collected 22 sessions for a total of about 30 hours of class time.

The format of the class was almost completely dominated by professor lecture. Halfway through the semester the students were put into groups for their final projects. During that second half of the semester, student groups took turns giving short presentations throughout the second session of each week. We used this naturally occurring difference in class format to inspire our classification problem. We thus generated two main class conditions: those led by the professor (i.e. *Professor-Lead*), and those led by groups of students giving project presentations (i.e. *Peer-Lead*). In the *Professor-Lead* condition (16 sessions), students listened to the professor lecture and were permitted but never required to ask questions. In the *Peer-Lead* condition (6 sessions), students listened to groups of peers take turns giving a short presentation describing their progress on an ongoing class project. After each presentation, all students were allowed to ask questions, and a random selection of students were required to ask questions for participation points.

Our goal was to model generic student posture patterns as descriptors to discriminate between *Professor-Lead* and *Peer-Lead*. From a naive perspective, the postures of the students in each condition were virtually indistinguishable. We chose this objectively difficult classification problem in order

Figure 2: A snapshot of scripted posture video in which volunteers were performing one of the scripted action of *Checking Phone*

to stress-test our approach. Our proposition was that students in either condition might have different internal states related to their expectation of learning useful information (*Professor-Lead*) vs. their potential requirement to ask a question (*Peer-Lead*), but that we would not have predictions about which gestures might reveal those latent states. This is a "good enough" test of our goal of building a practical process that could eventually be of some potential use to researchers who are likely to test less fuzzy classification problems.

4.2 Generic Student Posture Descriptors

To address our goal of helping researchers create descriptors without deep, costly annotation, we designed an approach that would create a catalogue of possible postures students exhibit in a typical class. We began by creating a 7-minute video of 11 volunteers arranged in the same seats as the students from the ADS class. Using the same equipment as would be used in the real class, we led the volunteers through a series of scripted movements. The "Scripted Posture Video" section of our workflow (Figures 1 and 2) comprises these data. The volunteers did not know what the prompts would be in advance, and their behaviors appeared natural. We guided them through 13 generic posture patterns: *Checking Phone*, *Looking at Computer*, *Looking Down*, *Looking Up*, *Looking at front-left*, *Looking at front-right*, *Looking Left*, *Looking Right*, *Performing Q&A*, *Talking to neighbor*, *Raising hand* (left and right) and *Writing*. We chose this list as a comprehensive representation of observable posture patterns in real classrooms when students listen to lectures. There are additional gestures we could have included, such as sleeping, eating, or drinking. However, this seemed outside of the scope of training on only the most frequent and probable behaviors rather than trying to include every conceivable movement that might exist.

Our next step was to produce an underlying set of low-level features for defining these generic posture patterns. Table 1 is a partial list of the 24 frame-by-frame features we created from OpenPose keypoints [6]. OpenPose[1] is a freely available toolkit for identifying physical landmarks, or "keypoints," on human figures in a picture, as shown in Figure 3 (left). Each keypoint is part of a 2-D array of real-valued numbers (Figure 3, right plot). In this analysis we only use upper body keypoints, including head, neck, and arms.

[1]https://github.com/CMU-Perceptual-Computing-Lab/openpose

Feature Name	Description
neck_nose	neck nose distance
Lshoulder_nose	left shoulder nose distance
Rshoulder_nose	right shoulder nose distance
rHand_nose	right hand nose distance
lHand_nose	left hand nose distance
nose_neck_h	nose neck horizontal displacement
nose_neck_v	nose neck vertical displacement
nose_shoulder angle	nose neck angle w.r.t shoulder
rElbow_angle	right elbow angle
lElbow_angle	left elbow angle

Table 1: A partial list of low-level features used in the posture recognition machine learning model

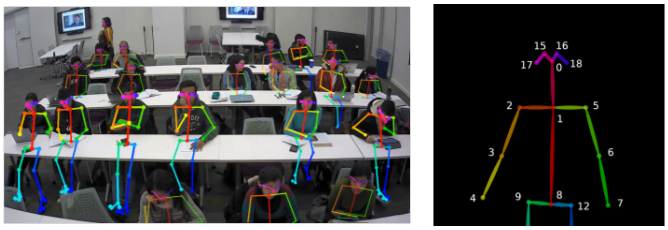

Figure 3: An example of OpenPose toolkit keypoints for a given frame of real classroom data (left); and the upper body keypoints used in our analysis (right)

We designed the features from Table 1 based on our professional experience performing student observation and an analysis of how groups of keypoints move together to produce gross postures. For example, the features *rHand_nose* and *lHand_nose* each measure the vertical distances between the nose and the hand. These distances can indicate vertical hand movements, e.g., as seen in hand-raising. "Nose-neck" related features (e.g. *nose_neck_h* or *nose_neck_v*) can indicate left/right head movements. With these low-level features in hand we then applied them to the scripted posture data and train a random forest classifier for recognizing posture patterns. We compiled a training set with each data point representing a person-frame pair and labeled each data point with labels naturally available from scripted posture data. We then fit several independent binary classifiers, each predicting the binary label of whether a given posture pattern occurred.

Our hope was that by having 11 different people perform the scripted movements in their own unique fashion, the model would be exposed to a sufficient amount of variability—such as one would expect to see in a the real world. We worked from the assumption that this would at least reduce the need for building and applying a precise annotation manual. This allowed us to quickly compile a posture-recognition model.

5. RESULTS

In this section, we present the frame-by-frame posture recognition model (section 5.1) using our generic behavior labels from the scripted posture dataset (4.2). We then applied that model to the ADS dataset (4.1), automatically labeling the posture patterns frame-by-frame. We derive descriptors from each 5-min segment of classroom video based on those machine labels, and built a classifier to discriminate between the two class conditions. The *Peer-Lead* segments of video did *not* include periods of question-asking after student presentations. This was meant to maximize surface similarity between the two conditions and provide a challenging test.

5.1 Posture Patterns Recognition

Table 2 summarizes the Area Under Curves scores (AUCs) for binary classifiers predicting whether a given posture pattern occurred in the appropriate position. An AUC rating of 0.50 is equivalent to chance, which means that *check-phone*, for example, does not have a reliable posture pattern as a composition of its keypoint structures. However, the model is able to identify head movement in left, right and up directions somewhat more reliably than other types of subtle head movements, such as *look-down*, *look-front-left* or *look-front-right*. Hand-raising postures and *writing* are also found to be relatively easier to identify. Similar to *check-phone*, actions without clear movement patterns exhibit low performance, i.e., *look-at-computer*, *Q&A*, and *talking-to-partner*.

Posture Patterns	AUC Scores	Posture Patterns	AUC Scores
check-phone	0.51	look-up	0.80
look-at-computer	0.63	look-left	0.84
look-down	0.53	look-right	0.88
look-front-left	0.67	writing	0.81
look-front-right	0.75	raise-left-hand	0.81
Q and A	0.63	raise-right-hand	0.84
talk-to-partner	0.60		

Table 2: Area Under Curve (AUC) scores from binary classifiers each predicting whether or not a given posture pattern has occurred, from leave-one-person out cross-validation experiment.

5.2 Discriminating Class Conditions

In this section we report the results from testing the hypothesis that there are discernible differences in students' posture patterns between the *Professor-Lead* and *Peer-Lead* class conditions. To answer this question, we formulated a machine learning classification task in which we used the descriptors derived from videos of the ADS class as input (right part of Figure 1). For output labels we used the class conditions. In creating the training dataset, we extracted a series of non-overlapping 5-minute segments from the real classroom videos and computed a list of statistics based on predicted student-by-student, frame-by-frame probabilities of posture patterns from the generic behavior model described in section 4.2. For each 5-minute video segment we derived five statistical values (*mean*, *standard deviation*, *min*,*max*, and *median*) summarizing the predicted probabilities of each of the 13 posture patterns. As a result, we have a training dataset with 65 features (13 posture patterns by 5 statistics) with each row representing a student-segment pair. We use random forest to fit the model. For comparison, we also derived an independent set of low-level features using only the keypoint structures described in Table 1.

We conducted two types of cross-validation experiments: *random split* and *leave-one-session-out*. In *random split* mode, the training and test datasets were constructed by random selection from the pool of 5-minute video segments,

irrespective of the class sessions to which they belonged. This design can yield relatively optimistic performance because of the likelihood that the segments from the same session can appear both in training and testing. In the second experiment, the split is based on class session, which results in a more conservative measurement of discrimination.

Table 3 shows the AUCs for model discrimination between *Professor Lead* vs *Peer Lead* using two different sets of input variables and under two different experimental conditions. The AUCs for each experimental design is beyond a random chance of 0.5. Specifically, we note that AUC decreases when using model-based descriptors compared to using a low-level, less interpretable feature set derived directly from the key points. The drop of AUC from *random split* to *leave-one-session-out* cross-validation suggests that certain predictive features are session specific and therefore make it difficult to predict labels for an unseen session. Future work will be of interest to identify those session specific features and investigate their roles in predicting class conditions.

Input Variables	Random Split	Leave-One Session Out
Posture-Model-based descriptors	0.72	0.64
Keypoint-based features	0.82	0.68

Table 3: Area Under Curve (AUC) scores for experiments to discriminate between *Professor-Lead* and *Peer-Lead* class conditions, comparing *random split* and *leave-one-session-out* cross-validation designs.

In order to understand the features that contribute to discriminating between the class conditions, we reviewed the feature importance from the random forest model that used interpretable posture-model-based descriptors as well as the low-level keypoint features. Figure 4 shows a selection of important and unimportant features from each approach. As noted in the upper portion of Figure 4, the most important input variables in the posture-based model are those describing the variation of left and right head movements. Other posture patterns, such as looking to the front, raising hands, and looking down did not play an important role in the model. The bottom portion of the figure shows that some of the important features were the distances between students' eyes and the angles between their nose and shoulders. Some of the less important keypoint structures included the relative angles of the left shoulder and elbow, as well as the distance between the left shoulder and the nose.

6. DISCUSSION

In this project we explored methods for extracting posture-related descriptors from videos of students in a real classroom. We derived the posture labeling model from a video of volunteers following scripted prompts. We extracted keypoint data from the videos using OpenPose, a freely available general purpose posture keypoints detection tool. We then showed that this method of automatic labeling could distinguish between two highly similar class conditions.

Large body movements such as hand raising and left/right head shifting were the easiest for the model to detect, and the most important descriptors in the posture model. In terms of using labels that are easy to interpret, these types

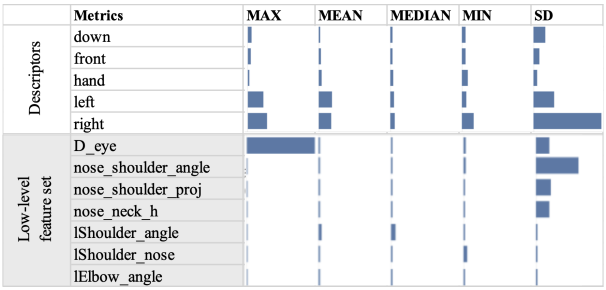

Figure 4: A selection of posture-based descriptors (white) and low-level features (gray) and their importance in a Random Forest model for discriminating between class conditions.

of movements seem like a promising start. Without trying to interpret those movements at this time, they were at least important to the posture model. It maybe the case that simply informing an instructor about these movements could be a productive starting point for reflection.

Given that there were a number of features that did not contribute to the models, and that the raw keypoint model performed better than the derived model, we note that there is a trade off between the accuracy of this approach on the one hand, and its interpretability and transferability on the other. When we look at the variance in Figure 4, we see indications that the importance of some features (and the *lack of importance* of others) is more interpretable than the power of different keypoint angles and vectors. These higher level features say something about what students do differently in different scenarios. Our point here is not to deduce what those meanings are, but to show some of the student behaviors that are worth noticing. In terms of transferability, the fact that we built these labels from a 7-minute session of non-student volunteers shows that this approach may have some potential as a one-to-many label generation method, at least when the volunteers use the same classroom as the target students.

Finally, we propose that the pipeline we explored in this project, from feature generation to auto-labeling and from data prepossessing to feature extraction, can all be generalized to other teaching and learning scenarios in physical classrooms. For researchers in this space, i.e., developing classroom-based technologies for sensing behavior and providing automated feedback, our study may help simplify and accelerate their work by simplifying annotation and anticipating features that the end-user can understand.

ABSTRACT

Cross-validation is a wide-spread approach to understand how well a prediction model performs with unseen data. While this is the state of the art, machine learning is often used for educational purposes in educational data mining. Whether a system is applicable and generalizable in practical settings is based on the cross-validation accuracy. One major problem is that the quality of annotated data is often worse due to different raters that score equal tasks differently, even if they were trained before. In this paper, we did an experiment where 1.200 texts of three difficulty levels in an open writing task for language learning were scored by two tutors independently to get the inter-rater reliability score for measuring the similarity across their grades. We used the existing scorings of other tutors of the system to train a random forest regressor for predicting scorings based on the texts. We found out that the accuracy has a strong relationship to the inter-rater reliability score and propose a new measurement that combines both metrics for scenarios where data was annotated by tutors, that could principally be diverse.

Keywords

Tutoring systems, scorings, data labeling, inter-rater reliability, cross-validation

1. INTRODUCTION

As long as tutor scorings are used as a basis to train machine learning systems, there is a bias of subjectivity. Research has shown that the agreement among scores given by tutors often varies [1]. Depending on the task and scale, tutors reach different inter-rater reliability scores. Practical settings have shown that even when teachers were trained for grading, there is a gap. Thus, formal exams are often graded twice and in case that there is a huge gap, a third grader needs to be taken into account. For the field of machine learning, we need thousands of scored tasks, e.g. for automated essay grading. From the practical point, it is understandable that scorings cannot be done by the same tutor all the time. Tutors' time is a limited resource and thus there is the need to score tasks by different experts. If we consider machine learning approaches, there are many examples of prediction tasks, where researchers try to imitate teacher scorings, based on different features. As the reduction of a text or task to features removes information that could be important for a good evaluation, automatic scorings cannot be perfect. Using data gathered by tutors where even scorings for the same texts or tasks are not always equal we think, that it is not fair to compare the prediction accuracy in education in general if we use tutors' labeled datasets.

In machine learning, the proper way to decide whether a system generalizes well is to do cross-validation [2]. Therefore, the data is split into several pieces. The model will be trained on all the data, except from one piece. This piece is used to evaluate the model as we know features and the concrete label. Based on the features, the system creates a prediction using the trained model. The predicted label can be compared with the known one. With every piece, the leave-one-out method (or alternative ones) can be applied to get an averaged accuracy. The main advantage of this method is to create a prediction on previously unseen data. Thus the evaluation shows whether a model generalizes well. Observing this value in detail, we often notice that the accuracies are between 0.6 and 0.8, e.g. 0.6 for 8 classes and 0.78 for 4 classes in [3] or 0.7 in for 4 classes in [4]. From the perspective of machine learning, these are bad values as it means that 3-4 of 10 predictions are wrong.

To have a good and fair measurement for comparison it is necessary to take the inter-rater reliability of human raters into account as in general, the prediction cannot be better than the ratings among raters that have been used for training the machine. The inter-rater reliability is a score of consistency among raters. According to McGraw & Wong [5], the minimum value should be 0.6 as the cut-off for acceptability. Wang & Michelle [6] did a comparative study to compare human essay scoring and reached an inter-rater reliability score (IR score) of 0.62, using the Intraclass Correlation Coefficient. Williamson proposes that an IR score lower than 0.7 is not applicable [7].

The accuracy of predictions is often measured as the comparison of the prediction of the machine and the rater annotations. But the machine itself was trained based on the raters scores, which could differ among raters [8] [1]. It is not surprising that the predicted scorings by machines correlate with the human rater scorings as they are the training base [6]. In contrast, Williamson has shown statistically significant differences between human and machine rating scores [7]. The question remains: comparing all the systems, what is the best and most applicable one? Using the accuracy only fails as the major problem is the quality of the training data – and not the resulting accuracy in cross-validation.

In this paper, we propose an extension of the cross-validation to have a fair measurement for comparing educational predictions, where training data was gathered from tutors. We focus on language learning and examine two research questions:

Sylvio Rüdian and Niels Pinkwart "Using Data Quality to compare the Prediction Accuracy based on diverse annotated Tutor Scorings". 2021. RQ1: What is the correlation of the inter-rater reliability score in essay scoring for language learning, compared to the prediction accuracy?

RQ2: Combining the cross-validation with the inter-rater reliability score, what is a fair interpretable measurement taking both metrics into account?

2. METHODOLOGY

To address RQ1, two tutors had the task to score open text submissions of three tasks. All tasks had a different difficulty level, easy (1), medium (2), and difficult (3). For every task, we had 400 user submissions, in sum 1.200. Both tutors got access to the tasks and they got 10 typical scorings for a pre-training. Then, all submissions were scored by both instructors independently of each other, using scores of 1 (very good) to 4 (bad/not acceptable). The scoring procedure lasts 1 week for every tutor.

Then we prepared a random forest regressor [9] as a classifier to train a prediction model for essay scoring based on at least 1.200 scorings for each task, that are already existing in the learning system, independently of the scorings from the previous step. These scorings are created by different tutors, where each text was scored only once. So we did not use the data of the previous step for a comparison to avoid training with the new labeled dataset. From practical settings we know that intermediate grades are quite subjective, thus we concentrate on grades 2 and 3 only, which represent "good" and "satisfactory" that are used as labels for the classification problem. The accuracy for prediction in cross-validation (CV) was gathered for each task separately.

Within the next step, we compared the similarity among both tutors of the first step with the accuracy of the second step to examine a possible relation. Finally, we propose a combination of both metrics that allow a fair comparison of the prediction accuracy with the IR Scores to address RQ2.

3. RESULTS

Figure 1 shows all IR scores and the prediction accuracy in a 10-fold CV. We can see that there is a good correlation between these metrics (correlation 0.88). We used the same approach for all tasks, but the IR-scores vary from 0.45 to 0.74, and the accuracies in 10-fold CV range from 0.47 to 0.64. The results show that the accuracy, as well as the IR-score, vary depending on the task. But, there is a strong positive relationship between the maximal achieved prediction accuracy and the IR score.

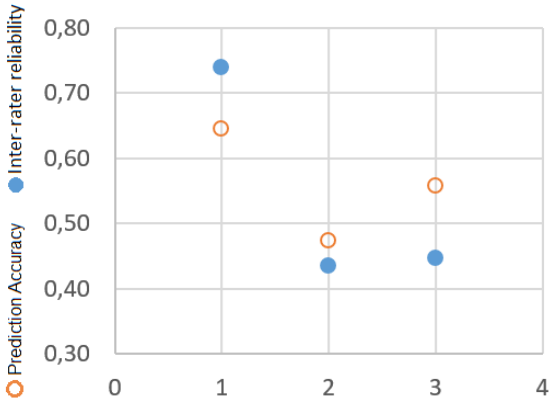

Figure 1. Inter-rater reliability score of two tutors for three tasks, separated by increasing difficulty level and prediction accuracies in cross-validation.

4. NEW MEASUREMENT

The main idea is to combine the classical cross-validation with the inter-rater reliability score. The CV addresses the accuracy of a trained prediction model. As there are multiple versions of the CV, e.g. leave-one-out or leave-p-out (where p is a range of the dataset), we use CV as a general concept and do not limit our approach to a specific version.

The similarity of tutor scorings can be measured by using a correlation coefficient. We chose the Pearson correlation coefficient (PCC) for applying to a sample [10]. It is not outlier resistant [11], but in the area of learning, large gaps can principally occur in ratings, e.g. the score from one rater is "very good / 1" and from another, it is "very bad / 4". This will impact the resulting correlation coefficient. For our new measurement, this is important as this gap influences the training data as well and thus, it influences the prediction accuracy negatively due to a large bias.

We propose a combination of both metrics, namely CV_{PCC}, defined by the following formula:

$$CV_{PCC} = 1 - |CV - PCC^{+}|$$

under the constraint $0 \leq CV, PCC^{+} \leq 1$. The CV accuracy is defined as a number between 0 and 1 [2] and $PCC^{+} = |PCC|$ as we only consider the similarities, not whether the PCC is positive or negative. The CV_{PCC} is a new value where $CV_{PCC} \in [0,1]$, similar to the CV. In the following paragraph, we show that CV_{PCC} cannot be smaller than 0 and never more than 1. Let CV and PCC^{+} be defined as above. Then we examine whether $\exists CV, PCC^{+}$: $1 - |CV - PCC^{+}| < 0$ or $1 - |CV - PCC^{+}| > 1$.

$$1 - |CV - PCC^{+}| < 0 \iff 1 < |CV - PCC^{+}|$$

With $PCC^{+} \geq 0$ we set $PCC^{+} = 0$ to maximize the value for $|CV - PCC^{+}|$. As $0 \leq CV \leq 1$, the maximum value for CV is 1. This follows: $1 < |1 - 0| \iff 1 < 1$, which is a contradiction.

$$1 - |CV - PCC^{+}| > 1$$
$$\iff 1 > 1 + |CV - PCC^{+}|$$
$$\iff 0 > |CV - PCC^{+}|$$

The absolute value x is defined as $\forall x \in \mathbb{R}: |x| \geq 0$ [12]. Thus, with $x = CV - PCC^{+}$: $0 > |x| \iff |x| < 0$. According to the definition of the absolute value, this is not existing in $\mathbb{R}$. Finally, we showed the second contradiction and can conclude that $CV_{PCC} \in [0,1]$. □

In Figure 1 we can see that the CV accuracy, as well as the IR scores, range from 0.44 to 0.74. If we just compare the CV accuracy, we can conclude that there is a high fluctuation. Using the new CV_{PCC}, the scores range from 0.89 to 0.96. Here, the fluctuation is much lower and we now can compare this value with other tools and different datasets.

5. DISCUSSION

In general, we know that having a low inter-rater reliability score is an indicator of a bad quality of training data. Although we used the same amount of data to train the classifier for each task we can observe that it is not fair to compare the achieved accuracy in prediction only. As there is a strong positive relationship between the accuracy and the inter-rater reliability score we propose to combine both metrics when comparing the result with other datasets. Otherwise, that is what our results show, the accuracy differs across tasks, and results are based on the task selection.

In an optimal setting, where all scorings are the same for equal texts across different raters ($PCC^{+} = 1$), follows $CV_{PCC} = \text{CV}$. Observing the other "extreme" side, where the PCC^{+} and the CV values are very low, we can still achieve a high CV_{PCC}, as the

accuracy will be low if labels are diverse for equal feature values. The higher the range between PCC^+ and CV is, the lower CV_{PCC} will be, which means that the relation between both metrics is low. With that information we address RQ2. Thus, this is an indicator of whether the model needs improvement or whether the accuracy cannot become better as the training base has a low quality due to diverse labeling based on different quality expectations of tutors. This interpretation of the value can be helpful to optimize the model. As we use cross-validation as a general metric, our approach is not limited to specific classification methods. We used the random forest regressor, but we can use other classification-based methods like neural networks, support vector machines, or others as long as we get access to the CV score.

We need to emphasize that our method requires a further labeling step to get the inter-rater reliability score across at least two tutors, where each text needs to be labeled twice. This increases the labeling costs. To reduce the amount of work, we could principally use a subset of already labeled texts that has to be labeled by a new tutor to understand the data quality. If a low value will be detected, we know that the resulting accuracy will differ from experiments with other datasets due to the low agreements. We can argue that knowing the problem of diverse scorings is a good fundament to optimize further scorings by a better pre-training of raters. But in praxis, often thousands of labels are existing based on the data that was collected over the last years. Thus, only for future data collection, there can be optimization. If we want to use existing datasets, we propose to use the CV_{PCC} for a fair comparison in relation to other datasets.

In our experiments, we used two separate datasets, one that contains the scorings of the two tutors and one much larger set, where more texts were scored by other tutors. The first was used to get the PCC^+ score and the other to train the classifier based on the maximum achievable CV score. To benefit from the extra labeling, we could enhance the training dataset by the data where the two tutors had equal scorings for the same texts.

Our proposed metric is limited to datasets that were annotated manually. If we have labels that are automatically processed (e.g. the achieved scores in interactive tasks in an online course or whether a student drops out), normally we do not have a diverse annotated dataset. Thus we recommend using the CV_{PCC} in all scenarios where tutors are involved and where diverse annotations (e.g. in scorings) play a role. This is early-stage research, limited to three difficulty levels of specific open-writing tasks. To generalize our findings, the next step is to compare more tasks and the resulting CV_{PCC}. Besides, further studies in other learning domains are required to verify the found relations of the metrics. Our first findings are promising.

6. CONCLUSION

In this study, we examined the relation of the inter-rater reliability of tutor scorings and the accuracy that can be achieved to predict two concrete ratings. In our setting of language learning, we focused on three open writing tasks of different difficulty levels, those accuracies in prediction differ. Based on our results, we observe that there is a strong relationship between both scores, even though both metrics were derived using datasets from multiple raters. Thus we can see that datasets, labeled by tutors, can differ. This infers the data quality and the maximum achievable accuracy in prediction. To use possibly diverse annotated data by tutors and for comparing the prediction results, we propose a new method of combining both metrics to allow fair comparison across different datasets. This new metric can help scientists in educational data mining to compare results of different tutor-based labeled datasets and it helps to understand whether a model or the dataset needs improvement.

ABSTRACT

Automatic Question Generation seeks to generate questions about a given text for educational purposes such as testing students' comprehension processes while reading. This paper focuses on the task of predicting the next sentence as a way to exercise and assess a crucial skill that comprehension questions often fail to test, namely relating sentences to the context preceding them. We train a BERT-based model of text coherence to estimate the probability that a given sentence will come next in a story. It achieves 68.4% AUC on a held-out test set, significantly above chance. We define an easiness score as the difference between the estimated probabilities of the next sentence and (the likelier of) two distractors, namely the two subsequent sentences. We evaluate our model on data from Project LISTEN's Reading Tutor by correlating the easiness scores of 1,023 questions against the percentage answered correctly by 274 children. A strong correlation would make it possible to filter such questions by difficulty for children at a specified reading level. Unfortunately, the easiness scores of the questions did not correlate with the correctness of children's answers to them.

Keywords

1. INTRODUCTION

A crucial skill in reading comprehension is inter-sentential processing – integrating meaning across sentences. It involves analysis of cohesive relationships such as coreference, indirect reference, and ellipsis [3]. Inter-sentential processing is hard for young readers partly because it requires assimilation from short-term memory to mid-term memory [12]. Unfortunately, reading comprehension questions often fail to assess inter-sentential information integration [1, 13, 14].

Next-sentence prediction questions are a natural way to test inter-sentential processing and are easy to generate. They are also easy to score, because by definition the correct answer is the next sentence. One form of such questions is true/false, i.e., "Does this sentence come next?" Another form is multiple choice, i.e., "Which sentence comes next?" This form has a higher cognitive load because it requires considering multiple sentences, but may be easier than judging a single candidate sentence by itself. Figure 1 shows both.

Context: Everyone knows that the elephant has a very long nose. But a long time ago, the elephant's nose was short and fat. Like a shoe in the middle of its face.

Does this sentence come next?
− She had a question for every animal.

Which sentence comes next?
− She was curious about everything.
+ One day a baby elephant was born.
− She had a question for every animal.

Figure 1: Two forms of next-sentence prediction questions. Answers in green are correct and answers in red are incorrect.

Although easy to generate and score, next-sentence prediction questions can be hard to answer correctly. For example, one study [2] randomly inserted "Which sentence comes next?" questions in children's stories, with the next three sentences of the story in random order as the choices. Children answered only 41% of these questions correctly, barely above chance and frustratingly low.

Good questions should be challenging but not frustratingly hard. Therefore, difficulty control is important in automatic question generation. However, despite the rapid development of question generation, little work has analyzed the difficulty of automatically generated questions [9], especially for reading comprehension [6, 7, 16], and none of it addresses next-sentence prediction questions.

This paper addresses the difficulty of such questions, and is organized as follows. Section 2 describes how we trained a coherence model to estimate the probability that a sentence comes next given the preceding context, and how we used it to score question easiness. Section 3 evaluates this model on a corpus of children's stories. Section 4 correlates the easiness scores of the questions against the percentage of children who answered the questions correctly. Section 5 concludes.

2. COHERENCE ESTIMATION

To estimate the coherence between a given context and sentence, we fine-tuned a BERT-based binary classification model.

Jingrong Feng and Jack Mostow "Towards Difficulty Controllable Selection of Next-Sentence Prediction Questions". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 721-725. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

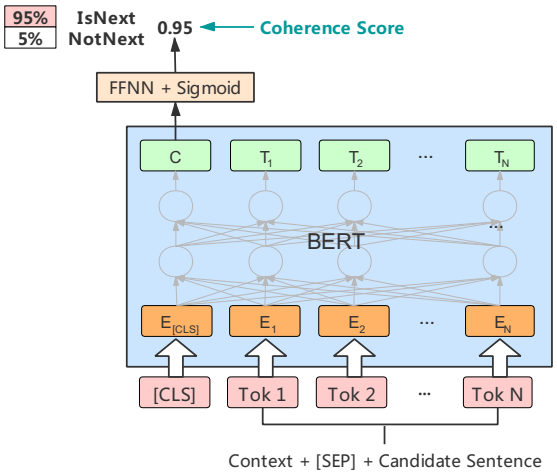

Figure 2: Architecture of the BERT-based model for coherence estimation.

BERT [5], a widely used Transformer-based language model, has achieved state-of-the-art performance on a large suite of natural language processing tasks. The blue box in Figure 2 shows the architecture of the pre-trained BERT model. To do classification, it appends a 2-layer feed-forward neural network (FFNN) to the BERT model, followed by a sigmoid function to scale the FFNN's output between 0 and 1.

BERT was pre-trained on BooksCorpus (800M words) [17] and English Wikipedia (2,500M words) with two objectives. First, randomly masking various words in a text and predicting the masked words from the surrounding text forced BERT to embed each word based on the surrounding words. Second, predicting whether one sentence follows another sentence in the original text forced BERT to learn inter-sentential coherence. Thus these two objectives prompted BERT to learn both intra- and inter-sentential semantic structure.

The effect of the next-sentence prediction task in pre-training has recently been questioned [4, 8, 15]. Some researchers believe that BERT actually learns inter-sentential topic similarity rather than coherence, because its negative instances are sentences sampled randomly from the entire text corpus, which are likely to be topically unrelated to the context.

We now describe how we adapted the BERT-based model to estimate inter-sentential coherence in children's stories.

Input: We fine-tuned the pre-trained BERT-based model on input token sequences of the following form:

- a special token `[CLS]` used for classification tasks
- three sentences of context, which we assume suffice to capture the semantically relevant content. Any more might include irrelevant information or exceed BERT's input length limit of 512 word pieces (i.e., roots and morphemes).
- a special separator token `[SEP]`
- a candidate next sentence; for positive instances, the sentence immediately following the context.

Selection of negative instances: We wanted the task to test children's judgment of inter-sentential coherence, not merely topical relevance. Therefore, rather than sample negative instances randomly from the entire corpus, we selected them from the same story, specifically the 2 sentences immediately following the correct sentence, which are likelier to be topically relevant to the local context than sentences from later in the story. Using the 3 sentences following the context as the multiple choice candidates also matched the task performed by the children in our evaluation dataset, to be described in Section 4.

Human experts could presumably pick contexts and distractors more judiciously to test children's judgements of inter-sentential coherence. However, such manual selection is neither economical nor scalable. One goal of this work was to identify requirements for choosing better contexts and distractors so as to improve automated selection.

Positive-negative ratio of training instances: BERT was pre-trained on equal numbers of positive and negative instances. In contrast, the 3 candidate sentences after the 3-sentence context included one positive instance and two negative instances.

Training labels: To fine-tune BERT and train the FFNN, we set the output of the combined model to 1 for positive instances and 0 for negative instances.

Easiness scores: To measure each candidate sentence's coherence with the given context, we used the probability output by the sigmoid function. Given this measure of coherence, we used a simple heuristic to rate the easiness e of answering a 3-choice question:

$$e = c_{pos} - max(c_{neg_1}, c_{neg_2}) \quad (1)$$

Here c_{pos} is the coherence of the correct answer, and c_{neg_i} is the coherence of distractor neg_i. This formula assumes that the difficulty of the question depends on whichever distractor is more coherent with the context. (As a reviewer suggested, we also tried the log ratio of the two coherence scores instead of their difference, but it performed the same in the evaluation reported in Section 4.)

Figures 4 and 5 show example questions with easiness scores of 0.244 and -0.262, respectively (see Appendix). A negative easiness score occurs when a distractor has greater coherence than the correct answer.

3. EVALUATION OF COHERENCE MODEL

We now evaluate how accurately our coherence model classified the 3 sentences following a 3-sentence context as $IsNext$ or $NotNext$.

3.1 Text Dataset

We constructed a dataset for fine-tuning and evaluating our coherence model from a corpus of English-language children's stories from two sources:

Table 1: Examples of Cases Removed by Data Cleaning

Type	Context	Correct Answer	Choices
two identical choices	...Did the frog slip?	Yes.	<Yes.> <Yes.> <The frog swam fast.>
one choice appearing in the context	...Yes.	Yes.	<Yes.> <The frog swam fast.> <It went past Pat.>
very short context	Pop can twist and bend. Pop slips! Pop stops.	Pop sits.	<Pop sits.> <Pat slaps Pop's hand.> <Pop must rub his feet!>
unfinished sentence in the context/content about phonics instruction	real meat peak	What sound do the letters e a make in the words real, meat, and peak?	<What sound do the letters e a make in the words real, meat, and peak?> <near> <leap>

- 337 stories from Project LISTEN's Reading Tutor [2], totalling 39K words with a vocabulary of 8K distinct words, at grade levels K-7.
- 354 stories from www.africanstorybook.org totalling 91K words with a vocabulary size of 11K, with page lengths ranging from one word to multiple paragraphs.

For fine-tuning and evaluation, we split the 337 LISTEN stories into three subsets, with 60% for training, 20% for hyper-parameter tuning, and 20% for testing, so as to ensure that stories in the test set were not seen during training. We used the African Storybook stories to augment the training set.

For every story in the corpus, we used a 6-sentence sliding window to generate next-sentence prediction items of the form ([`3-sentence context`; `IsNext sentence`; `NotNext sentence`; `NotNext sentence`]), with the correct (IsNext) sentence and two (NotNext) distractors to be presented in random order.

To clean the data, we filtered out several cases (illustrated in Table 1):

- **Cases with two identical choices or a choice appearing in the context:** typically caused by repeated sentences in a conversation.
- **Cases with context or a candidate sentence exceeding 125 words:** might cause the input sequence to exceed BERT's input length limit of 512 word pieces.
- **Cases with very short context:** typically caused by short sentences in a conversation that provide too little information to predict which sentence belongs next.
- **Cases with an unfinished sentence in the context:** for some poems or phonics instructions, sentences were not segmented according to sentence separators.
- **Cases about pronunciation or spelling:** are not relevant to semantic coherence.
- **Cases with the same context followed by different sentences:** may confuse the model during training.

As a result, we got a dataset consisting of 10,761 instances for training, a development set of 1,716 instances for hyper-parameter tuning, and a test set of 2,340 instances for evaluation.

3.2 Training

To fine-tune our coherence model, we used BERT$_{base}$ [5] as the backbone, and the AdamW optimizer [10] with a initial learning rate of 1e-3 and a ReduceLROnPlateau scheduler[1]. We used a ReLU [11] activation in the hidden layer of the FFNN, and set the dropout probability of this hidden layer to 0.5. We trained the model with a standard binary cross-entropy loss function weighted by the positive-negative sample ratio of 1:2.

In contrast to pre-training BERT's hundreds of millions of parameters from scratch, fine-tuning the BERT-based coherence model was inexpensive. It took only about 5 minutes on a single Tesla-V100 GPU to optimize the parameters on the training set.

3.3 Evaluation Results

Table 2 evaluates the coherence model on the development and test sets using various metrics: accuracy, weighted-average precision, recall and F1-score, and area under the ROC curve (AUC). To evaluate metrics other than AUC, we set the classification threshold to 0.5 and compared the predicted label with the ground truth label. In other words, we classified an instance as $IsNext$ if the output probability (coherence score) exceeded this threshold, otherwise as $NotNext$. AUC measures the entire area beneath the ROC curve, which plots true positive rate vs. false positive rate at different classification thresholds. AUC evaluates the overall performance of a classification model by aggregating across all possible classification thresholds.

Table 2: Evaluation of the Coherence Model

Dataset	Accuracy	Precision	Recall	F1-score	AUC
Dev	0.608	0.663	0.608	0.620	0.662
Test	0.609	0.679	0.609	0.619	0.684

4. EVALUATION ON CHILDREN'S DATA

We evaluated our easiness scores by correlating them against 274 children's performance on next-sentence prediction questions. These questions were inserted randomly by the spring 2003 version of Project LISTEN's Reading Tutor into 179 English-language stories ranging from grades 3-7. None of these stories were in the dataset used to train the coherence measure used to score easiness. The questions asked "Which will come next?" and presented the next three story

[1] https://pytorch.org/docs/stable/optim.htmltorch.optim.lr_scheduler.ReduceLROnPlateau

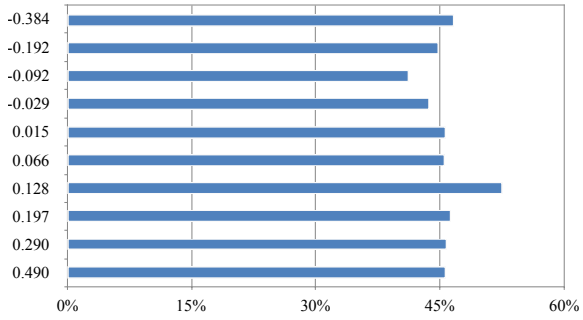

Figure 3: Percentage correct binned by easiness score.

sentences in random order. After data cleaning, we got 1,023 distinct questions with 1,626 responses, of which 45.7% were correct.

344 of these questions had choices with differences in capitalization, as illustrated in Figure 6 (see Appendix). Children might conceivably have used these differences as a clue to eliminate incorrect choices. However, their 622 responses to choices capitalized differently had virtually the same (in fact slightly *lower*) percentage correct (45.5%) as their 1004 responses to choices capitalized the same (45.9%). Evidently children did not make use of this clue. Accordingly, we did not exclude these 622 responses from our dataset.

The questions averaged only 1.59 responses each, far too few to reliably estimate the percentage correct for individual questions. Instead, we split questions by easiness scores into N bins with equal numbers of questions. For N=10, % correct ranged from 41.2% to 52.5%. Figure 3 shows a bar chart with a bar for each of the 10 bins, its average easiness score to its left, and its % correct as its width. The % correct was similar across all 10 bins and unrelated to easiness score. We tried various values of N, ranging from 3 to 128 questions. For each value of N, we correlated the average easiness score of the questions in each bin against their percentage of correct responses. The correlations got weaker as N increased, and were not statistically significant.

To explore why, we regressed response correctness against several features of questions, namely the length and contextual coherence of the correct answer and the two distractors, the length (in characters) of the context, the position of the question in the story (the number of sentences preceding it), and the grade level of the story. We normalized the value of each feature x as $(x - x\_min)/(x\_max - x\_min)$. We performed logistic regression with the normalized feature values for each question as numerical inputs and the correctness of the child's response as binary output. None of the regression coefficients differed significantly from zero. However, their general pattern makes qualitative sense. The contextual coherence of the correct answer was the strongest positive predictor, which makes sense because it measures how well the answer fit the context. The coherence of the harder distractor was the strongest negative predictor, which makes sense because it measures how well that distractor fit the context. The length of the correct answer and the number of preceding sentences in the story were positive predictors, which makes sense because they measure the amount of information provided for selecting the correct answer. Context length and the grade level of the story were negative predictors, which makes sense because reading longer sentences and higher level stories was harder (though better readers read harder stories).

5. CONCLUSIONS

This paper addresses two hypotheses regarding the use of next-sentence prediction questions in assessing children's inter-sentential processing during reading comprehension.

Hypothesis 1: An automated measure of text coherence can predict which of the next 3 sentences will come first. To test hypothesis 1, we trained a BERT-based model of a sentence's coherence with the preceding context to predict whether it comes next. It achieved 61% accuracy on a held-out test set.

Hypothesis 2: An easiness metric based on this measure can predict children's accuracy in selecting the next sentence. To test hypothesis 2, we scored the easiness of the 3-way choice as the coherence of the correct next sentence minus the coherence of the strongest competitor. We then related this score to children's performance on 1,023 such questions presented by Project LISTEN's Reading Tutor to the children while they were using it. There was virtually no correlation. Children answered approximately 45% of the questions correctly regardless of their easiness scores or whether the BERT-based model answered them correctly.

5.1 Limitations and Future Work

If hypothesis 2 were true, we could use a BERT-based coherence model to estimate the difficulty of deciding whether a given sentence will come next in a story context. We could then control question difficulty by using this estimate to help decide which sentence prediction questions to ask. Unfortunately, our results did not support hypothesis 2, which raises the issue of why they did not. The predictor coefficients in our regression analysis to explore this issue made qualitative sense but were not statistically significant.

Perhaps children's performance was affected by the added memory load of considering three sentences as choices. Future work could kid-test the simpler question "Is this next?".

Another possibility is that our coherence model was too impoverished to reflect children's inter-sentential processing. A richer model could capture other aspects such as causal relations, world knowledge, and inference important in story understanding. Or perhaps our BERT model merely needed better adaptation to the domain of children's stories.

An IRT model predicts probability of correctness based on student proficiency minus question difficulty. We did not take direct account of children's differing proficiency, but the Reading Tutor gave children stories at their own reading level, accounting for their proficiency indirectly. Future analyses may need to account for proficiency explicitly.

6. ACKNOWLEDGMENTS

We thank the reviewers for their insightful comments, the children who used Project LISTEN's Reading Tutor, and the team that implemented it and collected our dataset.

Kun Xu
Spark EdTech
xukun04@huohua.cn

ABSTRACT

The aim of the present study was to examine the rarely studied existence of sex-related behavior difference in online mathematics classes in China. Epistemic Network Analysis (ENA) was utilized in this study to explore the connection of students' classroom behaviors, and the differences in connection patterns for boys and girls. The class monitoring videos of a sample of 64 students (32 male, 32 female) was coded for microscopic categories of in-class behaviors, and all the codes were organized in the format of adjacent matrix. ENA model showed significant results that girls were more likely to engage in social activities in class, while boys exhibited more disruptive behaviors. There was also a relatively stronger connection between disruptive behaviors and call-out behaviors, and a slightly stronger connection between off-task behaviors and disruptive behaviors, and between disruptive behaviors and direct-no volunteer interactions for boys, compared with girls. This study provided an insight into the connection of different categories of classroom behaviors varied by gender, implying a future direction to examine the relationship between different behavioral connection patterns and students' math achievement in online math classes.

Keywords

sex-related behavioral difference, math achievement, teacher-student interaction, Epistemic Network Analysis (ENA), online math class

1. INTRODUCTION

1.1 Background

Previous studies examining sex-related differences in mathematics performance have reached inconsistent conclusions: while some reported a male advantage in math achievement, other studies only found sex-related differences in certain age groups and certain areas of mathematics ability, or even a female advantage in math exams [5][9][25][15][33].

On the other hand, although various research has been conducted to identify the specific contexts and factors that correlated with the difference in mathematics achievement of female and male students [7][11][14][21], the specific classroom behaviors and level of engagement, which have been linked by previous research to varying levels of mathematics achievement, have rarely been studied [10][26][17][22]. In a study conducted by Hart [13], boys were found to be more involved in public interactions in class with their teachers than girls, and the study indicated significant main effects of gender of students on two sub-categories of public teacher-student interaction: open volunteer interactions, and call-out interactions

1.2 Online Math Classes in China

During the past few years, China has witnessed an explosion of different online education platforms, which provides students with easy access to high-quality learning materials regardless of their geographical location. The bloom of online education also provides researchers with opportunities to conduct observational studies on teacher-student interactions without having to set up a camera or be physically present in the classroom. In this case, online learning platform provides a great opportunity for researchers to examine the behaviors of students of different sex in the online classes without influencing or interrupting how teachers and students behave and interact in class. Thus, the present study utilized the classroom monitoring videos from Spark EdTech, a Chinese K-12 online education platform that aims to cultivate mathematics thinking among mandarin-speaking children, to examine whether sex-related behavioral differences exist in online settings adopting the coding rules used in Hart's framework [13][19][8].

1.3 Epistemic Network Analysis

Epistemic Network Analysis (ENA) is a quantitative ethnographic technique designed to address questions in learning analytics and model the structure of connections in the dataset. Major assumption of ENA includes: 1) a set of meaningful features, which is defined as *codes*, can be identified systematically in the data; 2) the data has local structures, which are referred to as *conversations*; and 3) the way in which *codes* are connected to each other within the *conversations* is an important feature of the data [27][28][29].

ENA models the connections between *codes* by quantifying the co-occurrence of *codes* within *conversations*, generating a weighted network of co-occurrences and visualizations for each unit of analysis in the data accordingly. Since all the networks of units are analyzed simultaneously, ENA could ideally produce a set of networks that can be compared visually and statistically alike. Such a method has been used to not only analyze learning data, but also in other context where structure of connections in the data is meaningful, such as communications among health care team and gaze coordination during collaborative work [31][1]. Having recognized the unique power of ENA in analyzing

Yufei Gu and Kun Xu "Sex-Related Behavioral Differences in Online Math Classes: An Epistemic Network Analysis". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 726-730. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

connections within the data, this study adopted ENA for exploring the connections of students' behaviors in mathematics classes, and the differences between connection patterns for students of different sex.

1.4 Goals

The present study aims to: 1) examine the existence of sex-related behavioral differences in online math classes in China; 2) explore the connections of students' in-class behaviors and engagement in classroom activities; 3) compare both visually and statistically the structure of connections of mathematics classroom behaviors for students of different sex.

2. METHODS

2.1 Participants

In order to control for the influence of class content and teaching style on students' classroom behavior and engagement, 12 math classes taught by 2 teachers (1 male, 1 female) of the same topic were randomly drawn from all Level 6 mathematical thinking classes of Spark EdTech. Each class consisted of 5 or 6 students of different sex, making up a sample of 64 students (32 male, 32 female). Teachers from both sexes were selected in order to control for the potential interaction effect of students' sex and teacher's sex on students' behavior. The average class duration for Teacher 1 was 49.13 (SD = 2.49) minutes, and the average class duration for Teacher 2 was 45.43 (SD = 0.84) minutes. Since students went through placement exams that determined their math ability before being assigned to different levels of classes, it can be assumed that students of the same level have similar level of mathematics ability. Level 6 class was primarily designed for third-grade students around eight years old. In this sample, students have the average age of 7.46 (SD = 1.63) years old.

2.2 Procedure

Class monitoring videos were viewed and coded by an experienced coder based on the definition of different types of classroom behaviors proposed in Hart's study (1989). Each students' classroom behavior and interactions with teacher was viewed and coded individually, following an event sampling or episodic approach, which has been widely used in the field of developmental psychology [16][18]. Microscopic categories of behaviors were coded in order to demonstrate the initiations and responses of the students and the teacher. When a behavior lasted for more than 20 seconds, such a behavior was coded again in order to indicate the continuity of that behavior. All the codes were organized in the format of adjacent matrix (see Table. 1 for an example) required by Epistemic Network Analysis (ENA), a sample of which can be found below. Then ENA will be applied to the data using the ENA Web Tool (Version 1.7.0) [20].

Student ID	Sex	Teacher ID	social activity	call out	open volunteer	off task	disruptive behavior
001	1	teacher 0	0	1	0	0	0
001	1	teacher 0	0	0	0	1	1
002	0	teacher 1	1	0	0	0	0
002	0	teacher 1	0	0	1	0	0

Table 1. Illustration of Coding Sheet

2.3 Measures

Several subcategories of students' public interaction with teachers were identified in Hart's study [13]. Two sub-categories of public teacher-student interaction which were found to be significantly correlated with students' sex were: *open volunteer interaction*, and *call-out* interaction. Meanwhile, since another category of public teacher-child interaction, direct-no volunteer interaction, is pretty common in online classes, we decided to also include it as a type of behavior to be examined in our study.

An *open volunteer* interaction was coded when the student indicated in some way other than by calling out a desire to respond to a teacher question or to initiate a public interaction with the teacher. A *call-out* interaction was coded when a target student called out the answer to a teacher question before the teacher gave permission for that student to respond. A *direct-no volunteer* interaction was coded when the teacher asked a question and requested that a target student answer who had not indicated in some way a desire to answer the question. The students usually indicated a desire to respond by raising a hand or calling out.

In addition, we combined two types of behaviors that indicated a lack of engagement in mathematics activities in class which were found to be differently correlated with mathematics achievements for boys and girls in a study conducted by Peterson and Fennema [24]. *Off-task behaviors* were defined in this study as behaviors that are irrelevant to class activities. *Social activities* were defined in this study as the engagement in an activity in which the content of the activity involved a social topic, socializing or discussion of personal information or problems. Another category of behaviors – *disruptive behaviors*, which boys and girls differ drastically in the classroom settings was also included in our measure [4][6]. *Disruptive behaviors* were coded in this study when a student was engaged in behaviors that were likely to substantially or repeatedly interfere with the conduct and discipline of the class.

3. DATA ANALYSIS AND RESULTS

3.1 Definition of ENA Elements

In the present study, the *units of Analysis* were defined as all lines of data relative to a single value of student' sex subsetted by student ID. For instance, one unit included all the lines that represented the occurrence of each category of behaviors for one single student.

In our ENA model, the following codes, which corresponded to the aforementioned five categories of classroom behaviors, were included: social_activity, direct_no_volunteer, off_task_behavior, open_volunteer and disruptive_behavior.

Conversations were defined as all lines of data related to a single value of Teacher Name. For instance, one *conversation* consisted of all the lines associated with one of the two teachers.

3.2 Procedure of ENA

The ENA algorithm adopts a moving stanza window to generate a network model for each line in the data, showing how *Codes* in the current line are connected to codes that appear within the recent temporal context [30], defined as 4 lines (each line plus the 3 previous lines) within a given conversation. The corresponding networks are aggregated for all lines for each *unit of analysis* in the model. In this model, we aggregated the resulting networks using a binary summation where the networks for a given line reflect the presence or absence of the co-occurrence of each pair of *codes*.

The networks for all *units of analysis* in the present model were normalized before being subjected to a dimensional reduction, in order to account for the different amounts of coded lines of different *units of analysis* in the data. In terms of dimensional reduction, a singular value decomposition was utilized, which produces orthogonal dimensions that maximize the variance explained by each dimension [2][28][31].

3.3 ENA Model

Networks were visualized using network graphs where nodes correspond to the *codes*, and edges reflect the relative frequency of co-occurrence, or strength of connection, between two *codes.* The result is two coordinated representations for each unit of analysis: 1) a plotted point graph, which represents the location of that unit's network in the low-dimensional projected space, and 2) a weighted network graph. The positions of the nodes in the network graph are fixed and determined by an optimization routine minimizing the difference between the plotted points and their corresponding network centroids. Because of this co-registration of network graphs and projected space, the positions of the network graph nodes—and the connections they define—can be used to interpret the dimensions of the projected space and explain the positions of plotted points in the space. Our model had co-registration correlations of 0.92 (Pearson) and 0.92 (Spearman) for the first dimension and co-registration correlations of 0.97 (Pearson) and 0.97 (Spearman) for the second. These measures indicate that there is a strong goodness of fit between the visualization and the original model according to the rule-of-thumb by Shaffer, Collier & Ruis [28].

Mean networks for boys' and girls' behaviors in online math classes were constructed by averaging the connection weights across individual networks, and were compared using network difference graphs. These graphs are calculated by subtracting the weight of each connection in one network from the corresponding connections in another (See Figure 3 for a comparison ENA Model for student behaviors in online math classes by sex).

According to Figure 3, the network centroids for boys and for girls differ along the x-axis. There is a relatively stronger connection between disruptive behavior and call out behaviors in online math classes for boys compared with girls. In addition, there is a slightly stronger connection between off-task behaviors and disruptive behaviors, and between disruptive behaviors and direct-no volunteer interactions for boys, compared with girls.

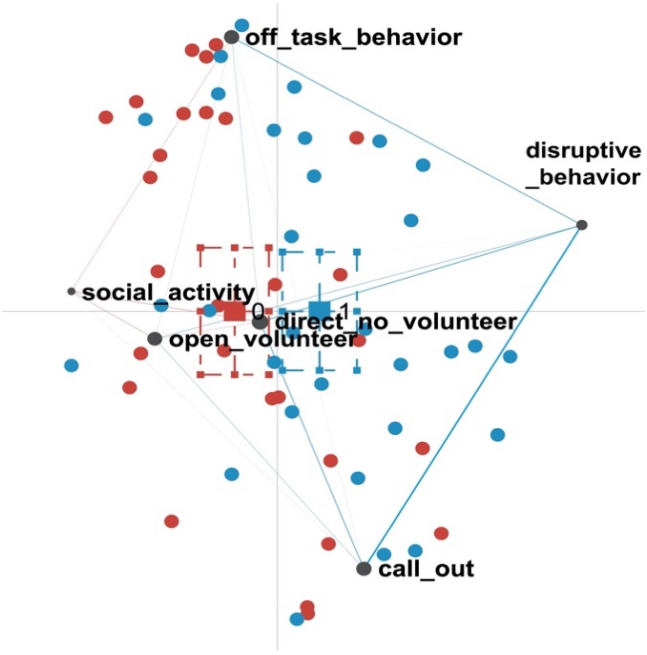

Figure 3. Comparison ENA Model for Student Behavior in Online Math Classes by Sex

4. CONCLUSIONS AND IMPLICATIONS

The present study examined the differences in the structure of connections of classroom behaviors for boys and girls in online mathematics classes in China using Epistemic Network Analysis (ENA). The results indicated a significant difference along the x-axis of the model, suggesting that in our sample, girls were more engaged in social activities and open volunteer interactions with the teacher, while boys exhibited more disruptive behaviors during the class. The difference in off task behavior and call out interaction for boys and girls were not significant. Such a finding is largely consistent with the study conducted by Hart [13], except for we did not find a significant effect of sex on call out interactions. Such an inconsistency might be due to the unique characteristics of online classroom settings, where girls tend to experience higher influence of social presence on their satisfactory level in class, and thus are equally, or even more active in online discussion than boys [32][23].

Thus, in order to elevate their level of satisfaction in online math classes, girls might be more motivated to engage in interactions with their teachers by calling out their answers to teachers' questions than they would normally do in traditional classrooms. Another possible explanation to this phenomenon is the reward system designed by Spark EdTech, a leading online education technology company in China, for its online mathematical thinking classes, where students could receive "little stars" from their teachers by answering questions and participating in classes. Such a reward system could encourage students to participate in classes, and to become the first to respond to the questions by calling out the answers.

Another conclusion we could reach according to the comparison graph is that there is a relatively stronger connection between disruptive behavior and call-out behavior for boys compared with girls. Such a connection indicates that while boys call out their answers to teachers' questions more often, they are more likely to also become disruptive in class by interrupting teacher's lecture or interaction between other students and teacher. It could be implied that boys are more expressive and active in classes, yet such behaviors could become disruptive if they could not regulate their level of activeness in class or if they disregard class disciplines.

In addition, there is a slightly stronger connection between off-task behavior and disruptive behaviors, and between disruptive behaviors and direct-no volunteer interactions. Such connections indicate that boys are more likely to violate discipline in class and be disengaged in class activities at the same time, and teachers are more likely to call on disruptive boys to answer questions, compared with girls. Such findings were consistent with the findings of research conducted in face-to-face classroom settings, that teacher tended to attend more to boys because they were more likely to exhibit disruptive behaviors in class [8][6]. All the findings mentioned above implied the necessity to recognize the

difference in boys' and girls' behavioral patterns in online math classes, and to call for the development of a more gender-sensitive guidance for online teaching, which had been pointed out recently by several researchers [3].

One major limitation of this study is the relatively small sample size. However, since each student's behaviors during a full-length class were coded, we still obtained statistically significant results. At the meantime, due to the time constraint, all the videos were coded by only one coder, which might lead to biased data. The fact that the coder had more than 1000 hours experience of video coding and maintaining an inter-rater reliability of more than 0.9 might, to some extent be able to account for such a limitation. Another limitation of the study arises from the nature of class monitoring videos, which might not always be able to fully capture students' behaviors in class. Scarcely, when students wrote on a notebook or scratch paper, coder was unable to distinguish whether they were taking notes or engaging in off-task behaviors such as sketching. These ambiguous behaviors were not coded, and thus might lead to a slight underrepresentation of students' off-task behaviors.

Overall, the present study is mostly consistent with existing research on sex difference in students' behaviors in traditional in-person classrooms. The novel findings of an insignificant sex-related differences in call-out behaviors could be attributed to the uniqueness of online class settings and the reward system adopted by Spark EdTech. To our knowledge, this study is the first of its kind to employ Epistemic Network Analysis (ENA) to examine the structure of connections of students' classroom behaviors in online math classes in China and conduct a comparison of such connection patterns between boys and girls. Thus, the findings of this study could serve as the first step to examine the relationship between different behavioral patterns in online math classes and math achievement, and to develop a gender-sensitive guidance for online teaching.

5. ACKNOWLEDGMENTS

Our sincere thanks to Spark EdTech for their generous help on providing data for this study.

ABSTRACT

We introduce a new readability tutoring system, Read & Improve, a freely available online resource aimed at supporting learners of English and English Language Teaching (ELT) professionals by improving English learners' reading proficiency. Using a combination of machine learning approaches and natural language processing techniques, Read & Improve detects learning needs of every student and makes sure no learner is left behind by identifying reading content at an appropriate level of *readability* and helping learners acquire new words through accessible dictionary definitions and content exploration functionality.[1]

Keywords

Distance Learning, Student Assessment, Natural Language Processing

1. INTRODUCTION

Reading is one of the fundamental language skills. Developing this skill is an essential part of language acquisition, both for native speakers and second language learners [9, 13]. At the same time, developing reading ability takes a considerable amount of time, and, as any learning process, it gets interrupted if readers lose motivation [8, 15]. Such factors as not having a range of engaging reading content offered and being presented with reading material at the wrong level of readability are some of the major contributors to the decreased motivation in readers [11]. In addition to language learners themselves, English Language Teaching (ELT) professionals face similar problems, as finding engaging reading content at the right level of readability is a challenging and a time-consuming task. In this paper, we present Read and Improve (*R&I*), a freely available, open-access educational system that is aimed at both language learners and teachers.[2]

To ensure that the reading content provided to a learner is at an appropriate level of readability, *R&I* uses machine learning methods described in [18] to automatically label texts with readability levels corresponding to the Common European Framework of Reference for Languages (CEFR) [6]. The CEFR is an international standard that describes language ability on a six-point scale from A1 for beginners level up to C2 for advanced level of language proficiency.

To ensure that the reading content presented to a learner is engaging, *R&I* employs news articles that are sourced from news websites in real time. To source news content, *R&I* monitors both RSS Feeds from news websites and the publicly available Common Crawl News (`CC-NEWS`) Dataset.[3] A fully automated *Indexing Pipeline* (RIIP, herein) processes news articles and automatically labels the *readability* of each article's text. News articles are generally available for learners on *R&I* within 10 minutes of publishing on an RSS news feed and in 3-6 hours of the article's publishing time if sourced from `CC-NEWS`. As compared to other domains, news articles have the additional benefit of being generally free of grammatical and spelling errors, which allows us to achieve more reliable linguistic analysis and to provide learners with high quality reading content. *R&I*'s user interface (UI) enables learners to not only read the latest news articles but also to perform keyword search to find articles on topics that they are interested in at their desired CEFR level(s).

A number of applications for various groups of readers, including native and non-native speakers, readers with cognitive impairments, and children, to name just a few, have been developed in recent years. In contrast to the previous work [13, 16, 17], our platform is aimed specifically at developing reading ability in non-native speakers of English. Our approach bears similarities to the Read-X [14] and REAP [10] systems, while also being actively developed and supported as an open-access educational platform available online. *R&I* is markedly different from other available applications, as in addition to providing text search functionality (as in [5]) and vocabulary acquisition help (as in [4]), it supports comprehension testing and personalisation.

[1]This work has been done while the second author was a Senior Research Associate at the University of Cambridge. We thank Cambridge English for supporting this research via the ALTA Institute. We are also grateful to the anonymous reviewers for their valuable feedback.

The rest of this paper is structured as follows: Section 2 provides an overview of the system's architecture, Section 3 describes the current UI functionality, and finally Section 4 concludes the paper and describes future work.

2. SYSTEM ARCHITECTURE

Figure 1 illustrates the system architecture of *R&I*. We do not describe the full details of system components here,as this is outside the scope of the paper. Instead, we provide a general overview of the components and their use of natural language processing (NLP).

2.1 API

The API connects to an information retrieval index ('IR Engine'), a database ('DB Engine'), and several APIs to provide the data and search functionality required by the UI. The IR Engine employs Elasticsearch[4] (ES) and includes several distinct indices that facilitate search over news articles and other data.

2.2 RIIP

RIIP is responsible for processing articles into the ES article index. In order to prevent duplicate processing, the pipeline modules first check whether the output file(s) already exist in the 'Data Lake', a single store of all data processed. The API monitors the set of URLs listed in RSS feed(s) and the set of `CC-NEWS` files for new items, and if found, these are sent to RIIP for processing. Therefore, ingestion of new articles through the system requires no manual effort, and up-to-date news content is continuously processed and made available to learners via the UI.

RIIP modules include: the *Extractor*, that extracts text and other information from news articles (i.e. HTML); *RASP*, that parses the text to provide linguistic information [2];[5] the *LevelMarker* module, that labels the text for readability (on the CEFR scale); and finally the *ES* module that indexes text and other linguistic information.

2.3 LevelMarker Module

For RIIP's LevelMarker module we follow Briscoe et al. [3], and define the task of learning readability levels as a discriminative preference ranking task. We employ their machine learning (ML) software and use linguistic features outlined by Xia et al. [18] that represent a text's readability.

2.3.1 Data

We have crawled three publicly available news websites to create datasets: Breaking News English (BNE)[6] (2771 articles), News in Levels (NIL)[7] (6373 articles) and Tween Tribune (TT)[8] (7768 articles). These websites have news articles labelled in terms of their readability however each website's readability levels are based on different scales as shown in Table 1.[9] Each of these datasets are considered to be *parallel* as they contain multiple versions of the same articles simplified across different levels. While the BNE and NIL datasets are designed for L2 English learners, the TT is designed to help L1 learners (early and school-aged readers).

Table 1: Dataset levels and distributions.

(a) BNE

BNE level	CEFR level	Count
0	A2	386
1	A2	386
2	A2	386
3	A2-B1	418
4	B1-B2	392
5	B2	392
6	C1-C2	412

(b) NIL

NIL level	Count
1	2126
2	2124
3	2123

(c) CER

Exam	CEFR level	Count
KET	A2	64
PET	B1	60
FCE	B2	71
CAE	C1	67
CPE	C2	69

(d) TT

TT level	Count
Grade K-4 (0)	1965
Grade 5-6 (1)	2029
Grade 7-8 (2)	1771
Grade 9-12 (3)	2003

Table 2: 5-fold cross-validation tests for each dataset.

Source	Pearson's	Spearman's	Kendall's
BNE	0.8338	0.8368	0.6873
NIL	0.9217	0.9164	0.7880
TT	0.9055	0.9250	0.8071
CER	0.9155	0.9185	0.8015

2.3.2 Evaluation

RIIP employs a model trained on the full BNE dataset as this dataset can be reliably mapped to the CEFR scale (Table 1). Based on this mapping we determined the ranges of ML scores that corresponded to each CEFR level (using observed score range from training data). We tested our model on the Cambridge English Readability (CER) dataset,[10] a publicly available dataset of 331 texts spanning CEFR levels A2 to C2 [18]. On this test set, our model achieves 0.83 Pearson's, 0.85 Spearman's and 0.71 Kendal's correlation coefficient. We also ran 5-fold cross-validation for each dataset[11] and present the results in Table 2.

2.4 ES index

In addition to article index, we create 'WordInfo' and 'CALD' indexes. The CALD indexing system processes definitions from the Cambridge Advanced Learner's Dictionary (CALD) to populate the CALD index. The LexDoop system employs Hadoop[12] to process the Data Lake files (currently around 1 million articles) to produce raw frequency counts of linguistic properties for every word lemma.[13]Following this step, these lemma statistics are collated and added to the 'WordInfo' index.

[10] `https://ilexir.co.uk/datasets/index.html`
[11] We split the data randomly into training and test sets, ensuring an even distribution of class labels.
[12] Apache Hadoop: `https://hadoop.apache.org/`
[13] LexDoop is also used to process `CC-NEWS` files in parallel.

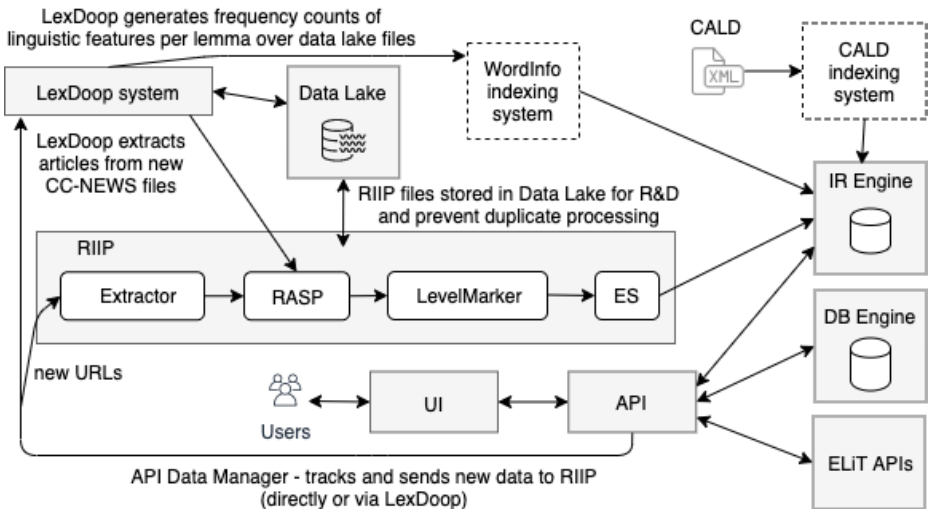

Figure 1: Overview of *R&I* architecture. *R&I* is hosted within, and relies upon, cloud computing services from Amazon Web Services (AWS). Components that use cloud AWS services are shown with grey backgrounds.

2.5 Sanitisation

To make sure the content provided on the platform is acceptable for a wide range of readers across various ages and cultures, we apply content *"sanitisation"* strategy, whereupon we automatically filter out news articles that contain words pertaining to the topics that might be considered offensive in some cultures or inappropriate for younger readers. The list of around 1600 such taboo words was curated using the lists of taboo words from social media. Sanitisation is run within RIIP and the API and, in case the sanitisation system makes an error, the UI enables admin users to mark articles as 'unsafe' (or vice versa).

3. READING ON THE PLATFORM

We define the *R&I* functionality in terms of four major aspects, which cover the tutoring system's ability to provide learners and teachers with engaging reading content at the appropriate level of readability (§3.1); help learners develop their vocabulary in English (§3.2); run comprehension tests (§3.3); and allow learners to revisit texts they read, words they clicked on and tests they submitted (§3.4).

3.1 Finding engaging reading material at an appropriate level

The first step for learners accessing *R&I* is to define their language proficiency level. Learners can log in to *R&I* using their account credentials from Write & Improve,[14] a freely available system linked to the reading platform, that is able to assess and provide feedback on a learner's writing proficiency. Once logged in, *R&I* defaults reading proficiency to current writing proficiency, but a learner can change their CEFR reading level.

Figure 2 contains a screenshot of the *search page*'s results showing the latest news articles at the learner's CEFR level (currently B1). The search page provides learners with snippet(s) of the article text, and they can click on any of the titles listed on this page in order to load the *article view page* where they can read the article itself. In addition, search by keywords is enabled on *R&I* to allow learners to find articles not only at their level of readability, but also on the topics of their interest.

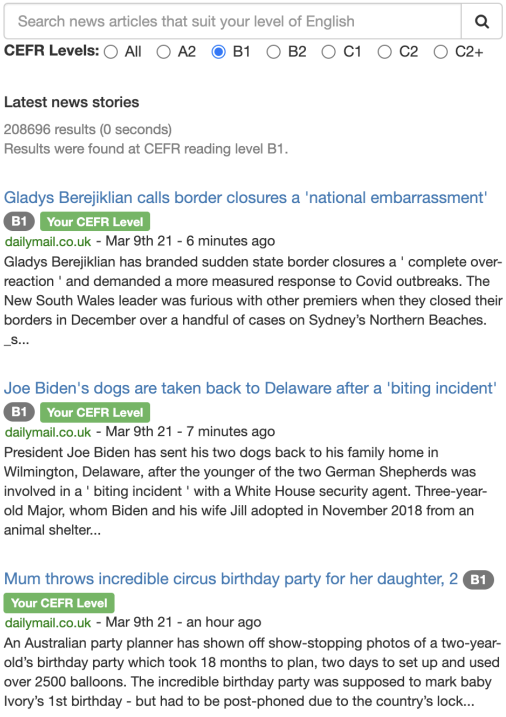

Figure 2: Screenshot: search results.

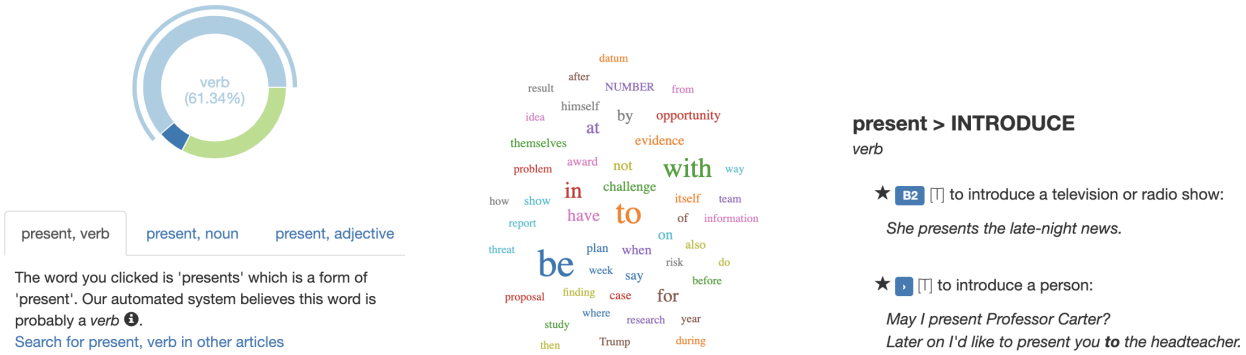
3.2 Developing one's vocabulary

Vocabulary is very important in language learning to the point that language learning itself would sometimes be equated with knowing language vocabulary [12]. To help learners

[14] `https://writeandimprove.com/`
R&I employs Write & Improve APIs developed by ELiT: `https://englishlanguageitutoring.com/`



(a) Part of speech (PoS) statistics (b) Word cloud (c) CALD word sense 'INTRODUCE'

Figure 3: Screenshots of the sections of the 'Word Information' and 'English Dictionary' panels on the UI. Here, the user clicked on the word *presents*, used as a verb. The pie chart in (a) illustrates the relative frequency of all PoS categories for the lemma *present* across all articles. The word clouds in (b) contain the 50 lemmas most frequently co-occurring with *present* as a verb in grammatical relations (where font size reflects relative frequency), and (c) shows the dictionary definition.

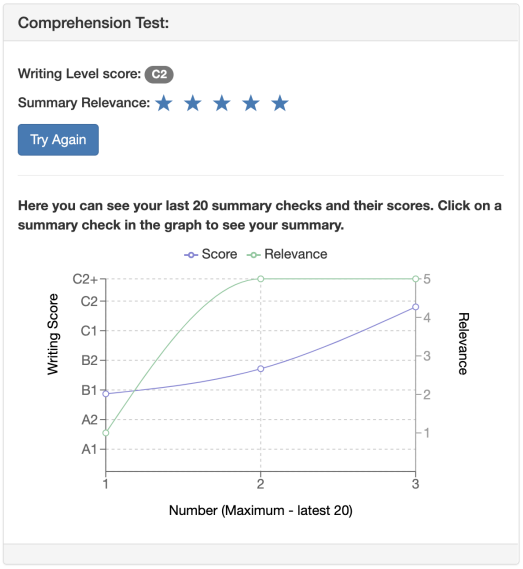


Figure 4: Screenshot: Comprehension Test panel. Learners are able to click on the graph to view previous summaries, which they can refine and re-submit.

with vocabulary acquisition and development, *R&I* allows them to select any words they do not recognise or wish to learn more about within the article view page. When a learner clicks on an unknown word, *R&I*'s UI launches two side panels for *Word Information* and *English Dictionary* (shown in Figure 3) to display information available for the word in the 'WordInfo' and 'CALD' index, respectively(§2.4).

Several searches can be performed by clicking on links within the *Word Information* panel and words within the co-occurrence word cloud. These links to search results shown in *R&I*'s search page enable learners to perform advanced, linguistically motivated searches intuitively and learn how vocabulary is used in context.

3.3 Running comprehension tests

R&I allows users to submit a summary of the article as a *comprehension test* in the *Comprehension Test* panel on the article view page (Figure 4). *R&I* automatically scores these summaries and returns a *writing score*, determined by a mature feature-based automated essay scoring (AES) model [1, 3, 20], graded on the CEFR scale via the Write & Improve API, and a *relevance score* based on the maximum sentence-level cosine similarity value, which is then converted to a score in the range 0–5 using the lexical overlap between the article and the summary [7] that shows whether the learner captured the main salient topics in the article.

3.4 Accessing reading history

All history of learner interaction with the *R&I* platform, including texts, vocabulary items and submitted summaries is available to the learners on the personal *My Reading* pages.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we presented Read & Improve, a freely available, open-access reading tutoring system that is aimed at language learners and teachers. Currently, it is a prototype system, and thence most of its components will benefit from further research on the platform. For instance, we are planning to improve our Indexing Pipeline using quality human annotated training data and user analytics that we are collecting via the *R&I* platform.

R&I records learners' actions on the UI, which in turn, will provide valuable data for use in further research and development. For example, [19] employed the comprehension test data collected by the platform to develop a new automated comprehension test (summary assessment) marking system suitable for use in *R&I*. Further, each learner's data may be useful in directly improving their learning experiences. For example, analysis of an individual learner's history could be used to tailor custom content and testing.This symbiotic relationship, developed in an ecosystem of freely available educational system benefiting from cutting-edge research, will ultimately produce a state-of-the-art ELT resource.

ABSTRACT

We present Generate, a AI-human hybrid system to help education content creators interactively generate assessment content in an efficient and scalable manner. Our system integrates advanced natural language generation (NLG) approaches with subject matter expertise of assessment developers to efficiently generate a large number of highly customized and valid assessment items. We utilize the powerful Transformer architecture which is capable of leveraging substantive pretraining on several generic text corpora in order to produce sophisticated, context-dependent text as the basis for item creation. We present early results from experimental studies demonstrating the efficiency of our approach.

Keywords

NLP, Transformer Networks, Domain Knowledge Modeling

1. INTRODUCTION

The COVID-19 pandemic has accelerated the push towards remote delivery of formative and summative assessments and with it have arisen heightened security concerns of item pool exposure. Moreover, there is growing adoption of highly personalized and adaptive learning and assessment experiences [25] that require regularly replenished assessment item pools. These twin factors among others are placing ever growing demands on traditional processes of creating assessment content that are based in large part on manual labor, highly dependent on subject matter expertise and challenging to scale up. Furthermore, the manual generation of content and assessment items heightens the risk of incomplete, duplicate and/or redundant content. We believe advances in AI, particularly natural language generation (NLG) can help mitigate this bottleneck and open new possibilities for personalized learning experiences.

Classical natural language processing (NLP) work in this area dates back to John Wolfe's seminal work [17] that demonstrated the feasibility of automatically generating natural language questions. In recent years there has been a revival in interest, spurred in part by advances in dialogue systems such as Amazon Alexa. While traditional approaches to NLP-based assessment item generation involve a pipeline of modules such as content selection, template design and item realization [18], these have been criticized for being rigid and too reliant on arbitrary heuristic rules and having limited novelty and psychometric variability [19]. There is growing interest in developing end-to-end deep neural network based approaches that do not require customized, hand crafted rules and are better equipped to generalize across content areas [20]. A key element of such approaches is leveraging large text content databases and well annotated datasets such as BookCorpus [21], SQuAD [22] and Wikipedia. For further details on related work, readers are directed to the survey of state of the art by Kurdi et al. [26].

In this paper we present Generate, a NLG system that efficiently and in real-time creates lexically and semantically appropriate item content, dramatically speeding up assessment item authoring, freeing item writers and subject matter experts (SMEs) from unnecessary work, and can enable personalized learning and assessment experiences. At the core of Generate's content generation capabilities is the Transformer architecture [4] that leverages substantive pretraining on several generic text corpora to produce sophisticated, context-dependent text as the basis for item creation. From a small number of representative items as training samples to learn lexical and semantic structure, Generate is able to produce a wide variety of draft item content. Users utilize an intuitive graphical interface that allows selection of item stems, keys (correct answers) and distractors from a number of generated options.

In the following sections we provide technical details of our system starting with a brief review of Transformers, system implementation and architecture. Following that we present analysis from experimental studies and share thoughts on future directions.

2. TECHNICAL APPROACH AND SYSTEM DETAILS

2.1 Transformers and NLG

In order to capture the subtlety and breadth of lexical patterns necessary to faithfully generate novel assessment content, we opted to base our NLG engine on the Transformer architecture, which is capable of leveraging substantive pretraining on several generic text corpora in order to produce highly sophisticated, context-dependent token embeddings for a variety of NLP tasks. First proposed in 2017 by Vaswani et al. [4], the Transformer architecture has since revolutionized NLP research, with state-of-the-art performance on benchmarks like the broad GLUE suite of NLP tasks [5] being set by Transformer-based models such as Google's BERT [6] and OpenAI's GPT series [7, 8, 9].

The central idea of the Transformer architecture is to do away with sequential processing of text altogether, as was done traditionally with deep-learning architectures like LSTMs [10] and GRUs [11], and instead process the tokens (words, subwords, and punctuation) of text simultaneously using an operation called *attention*. The variant of attention used in the original formulation of the Transformer architecture, *scaled dot-product attention*, is defined as follows:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d}})\ V$$

Saad Khan, Jesse Hamer and Tiago Almeida "Generate: A NLG system for educational content creation". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 736-740. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

The matrices Q and K are called the *queries* and *keys*, respectively, and each have column-dimension d, while the matrix V, called the *values*, has column-dimension d'. We consider the case when Q, K, and V are all the same matrix X, and the resulting operation is known as *self-attention*. Each row of X corresponds to a context-independent dense embedding of a single token with a small *positional encoding vector* added so that the model can take into account the position of the token in the input text. Thus, self-attention recomputes every token as a linear combination of every other token, where the weights in the linear combination depend on a scaled dot-product similarity (the $\frac{QK^T}{\sqrt{d}}$ term). In order to allow the Transformer to learn several different patterns of lexical interaction, several matrices of weights are used to compute *multi-head self-attention*:

$$\text{MultiHead}(X, X, X) = \text{Concat}(\text{head}_1, \text{head}_2, \ldots, \text{head}_h)W^O,$$

where

$$\text{head}_i = \text{Attention}(XW_i^Q, XW_i^K, XW_i^V),$$

and all of the W matrices consist of learnable weights. After multihead attention is computed, the results are aggregated and resized using a simple single-hidden-layer feedforward neural network, which has its own learnable weights. This combination of multihead attention followed by a feedforward neural network constitutes the fundamental building block of the Transformer architecture: the *Transformer block*. A *Transformer model*, then, is built by chaining together several Transformer blocks, each potentially with its own set of weights.

For its NLG engine Generate utilizes a Transformer model pre-trained for the task of next-token prediction. The Transformer architecture processes the conditioning input text in order to produce a probability distribution over all tokens in the vocabulary. We sample from the vocabulary according to this distribution, and then proceed *auto-regressively*: we process the newly sampled token and use it to produce a new probability distribution and sample a new token. We continue in this way until a maximum token limit is met, or until a stop sequence is produced (such as a newline character '\n').

2.2 How Generate Works

As illustrated in figure 1 Generate has five main system architectural components. The first is a React Javascript-based graphical user interface. Through the interface, users can select pre-uploaded AI models, generate an item, visualize and edit the item and visualize the metrics generated by the AI, allowing the user to create a complete item generation flow, from creation to validation. The user interface is linked to the second component which is the Auth0 authentication platform, a third party service specialized in secure authentication and authorization workflows. Once the user is authenticated, the GUI will connect with the third component, Hasura [2]. Hasura serves mainly as a GraphQL API to connect the GUI with the database and the serverless services. The fourth component is the item generation services (SQS Queue and Lambda Worker), which are responsible for interfacing with the NLG engine API with all the advantages of a serverless architecture [3]. The NLG engine API forms the last core component and is responsible for generating content based on the model provided.

Users begin their interaction with Generate by providing specifications of desired content including: a content map of item types and topics to be generated; user-specific writing guidelines

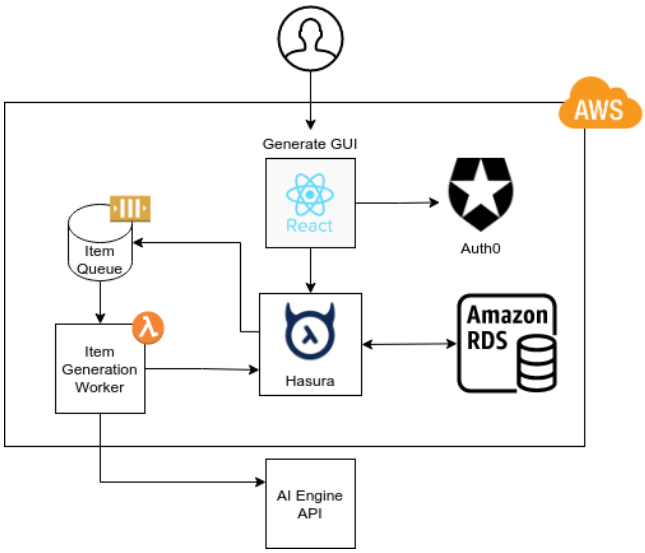

Figure 1: Generate system architecture is designed to be modular with distributed services hosted on AWS.

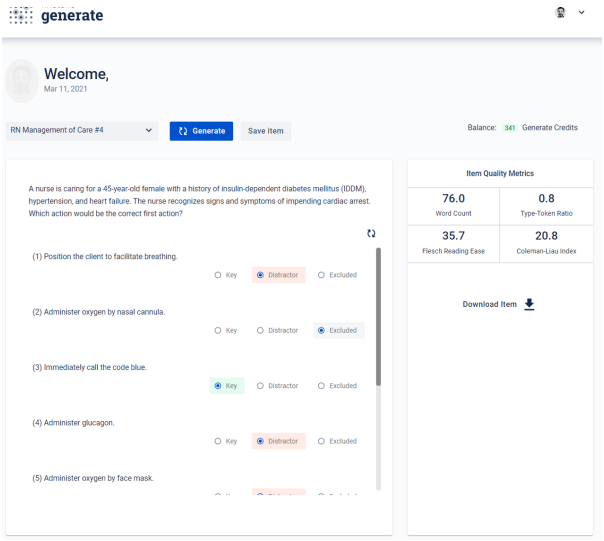

Figure 2: Generate item authoring interface. Users can select from a number of item generation models and create items on-the-fly with the click of a button.

so that domain semantics and formatting can be tailored to best practices; and specification of admissible lexical metric ranges, such as type-token ratio, Flesch Reading Ease, and the Coleman-Liau Index. These specifications constitute what is called a *project*. Along with these specifications, users must also supply a set of representative items. The number of such items is usually between 100-200 items total, although it will depend on the complexity of the content map specified in the project and the number of different types of items to be generated. At a baseline, all that is needed is the raw item, though users may supply their own item metadata to help improve the performance of our AI engine. Features such as item topic categorization, key and distractor labels, item cognitive type (recall, application, etc.), and difficulty metrics like p-value and point biserial [12] may all be used to further hone our AI models' performance.

After supplying content specifications and representative items, the *k*-means clustering algorithm [13] is applied to produce several groups of 8-10 representative items each. The clustering algorithm is predicated on a combination of user-supplied metadata, as well as numeric item features produced by the Transformer-based Universal Sentence Encoder (USE) model [14]. The goal of this clustering procedure is to produce groups of items which are semantically and stylistically homogeneous, which in turn improves the reliability of our AI engine to produce items which are coherent, semantically and factually relevant to the content domain, and stylistically appropriate according to the user's writing guidelines. Each group of representative items corresponds to a different string of conditioning input text for our AI engine, which we refer to as a *model*. Each model produces a different "flavor" of content. By building several models, we ensure that a user's content specification demands are met, and a wide diversity of items is produced while doing so.

Given a model, raw content is generated by our NLG engine and then undergoes several automated quality checks before being presented to the user. First, the raw content must pass a parse check to ensure that desired item formatting has been captured. Next, we perform an overlap check to ensure that no part of the generated content overlaps too heavily with the representative items, or with any other part of the generated content (e.g. to prevent duplicate options in a multiple choice item). For multiple choice content, users are able to specify a range of options to generate and so we also check that a sufficient number of unique options are produced. Finally, previously specified lexical metrics are computed, and we check that the generated item lies in the user-specified admissible ranges for these metrics.

As shown in figure 2, Generate offers a graphical user interface where item writers interact with our NLG engine directly to produce content. With this interface, item writers can select one of several item generation models and generate items on-the-fly with the click of a button. The item writer can then refine and annotate generated items before saving a finalized version. Generate's content generation interface allows item writers the ability to save an intermediate version of a promising item and regenerate unwanted parts. For example, with multiple choice content, one can select a key and one distractor from the list of available options, and then regenerate the remaining options to produce a fresh list to choose from. In this way, item writers can use Generate to help them rapidly ideate additional options, leading to significant speedups to the item-writing process.

Users can review generated content at any time using Generate's content dashboard. This dashboard allows users to review project-level information such as lexical metric distributions, as well as review individual items and their SME annotations. Once a selection of items has been made, users can download their content either as raw text or in QTI format.

2.3 SME Usability Experiment Results

For the content domain of nursing professional licensure, we performed two experiments with a subject matter expert (SME)/item writer in the domain. In the first experiment, the SME was asked to perform a quality review of a set of 40 items purely created by Generate NLG spanning four topic areas including biotechnology, medical assisting, nursing assisting, and practical nursing (see figure 3 for an item from this set). For a baseline of comparison, we mixed in a "calibration set" of 40 representative items produced by a separate human item writer spanning these same four topic areas. The SME was not told which items were

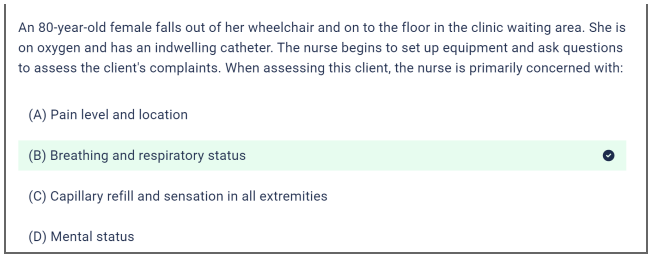

Figure 3: Sample item created by Generate. A user/SME is able to select the key/correct answer and make any edits required.

from the calibration set, and which were created by Generate. To perform the quality review, the SME was asked to check factual accuracy and topic relevance, make any necessary edits, estimate the difficulty of the item on a subjective easy/medium/hard scale, give any general comments and feedback, and assign a subjective overall quality rating on a 1-7 Likert scale (with 1 being poor and 7 being excellent). The median quality rating for Generate items was 5.5, compared to a median quality of 6 on the calibration set, with 70% of Generate items rated 5 or higher. There was also considerable overlap in the difficulty distributions, as shown in table 1. It took the SME an average of 3.75 minutes/item to perform this quality review. Compared to the SME's estimated 20-30 minutes/item to write an item manually, Generate demonstrates clear improvements to SME item writing throughput.

In the second experiment, the same SME was asked to interact directly with the Generate content generation interface to produce 50 more items in the domain of nursing professional licensure. We gave the SME five models ranging over a single nursing topic and requested that they produce ten items for each model. We captured data on generation time as well as item survival rate. For each item, the SME used Generate's content generation interface to first generate a multiple choice item with eight possible options. The SME was then asked to select the best combination of key and three distractors from these available eight options, and then perform necessary fact checking and editing. Using the Generate system, it took the SME an average of 2.7 minutes/item, including latency necessary for the system to generate the raw item. According to SME testimony, a similar exercise with a conventional item writing approach would have taken roughly 30 minutes/item, not including slowdowns due to SME fatigue and burnout. We are currently working on a number of follow-on experiments with item writers in a variety of domains including K-12 education, higher-ed and professional licensure.

Table 1: Comparison of difficulty distributions

	Easy	Medium	Hard
Generate	42.5%	40%	17.5%
Calibration	37.5%	45%	17.5%

3. DISCUSSION AND FUTURE DIRECTIONS

Our early investigations with item writers indicate a significant increase in assessment authoring throughput, which if borne out in

future and ongoing studies would mitigate bottlenecks in producing easily accessible high quality assessment items. We believe this would help enable innovations in formative assessment, personalized learning, and building customized and efficacious classroom activities.

In addition to assessment content generation, we plan to implement the following functionality to Generate over time.

3.1 Item Difficulty Estimation

Content creators must ensure that assessments adhere to a desired difficulty distribution, where we take difficulty to be measured by *p*-value (the proportion of examinees that answered a question correctly). Current methods for estimating *p*-values involve manual field-testing of provisional items, which is both time-intensive and risks item exposure, reducing the lifespan of the item. While previous work in automated difficulty estimation has employed techniques of first-order-logic [15] as well as a machine learning-based word embedding approach [16], we are exploring a blended approach which leverages structured item metadata with Transformer-based processing of unstructured item text. In this way, users can quickly recycle items which do not adhere to required difficulty specifications, thereby increasing the survival rate of items produced by Generate.

3.2 Automated Content Tagging

Tagging educational content with the most relevant learning and assessment standards such as CCSS [23], NGSS [24], etc. is one of the most critical elements in creating highly efficacious content. This enables the tracking of student skill gaps, recommendation of remediative learning resources and mastery of discipline topics, skills and cross cutting capabilities. We are currently developing a text content classification approach that can be used to delineate skills, learning objectives and core disciplinary ideas in the generated assessment items.

4. CONCLUSION

In this paper we have introduced Generate, a system that utilizes an NLG approach to significantly increase productivity of assessment content creators. Generate is built on a language modeling architecture that understands the deep semantic and lexical structure of assessment content that allow us to handle a variety of assessment domains and item types. Our system's content dashboard integrates elegantly with existing item writer workflows for item review, editing and approval. To the best of our knowledge Generate is the first NLG content authoring system designed for use in education and we believe can enable innovations in personalized learning, formative assessment and efficacious classroom activities.

ABSTRACT

We present Catalog, an educational content classification and alignment system that tags learning and assessment content in a semantically meaningful and accurate manner. Unlike other approaches that rely on keywords or search terms and crosswalks between knowledge taxonomies, Catalog utilizes powerful NLP, specifically language models based on the Transformer architecture, to encode content in a context attentive fashion. This allows us to capture deep conceptual and contextual relations in content to classify it against a wide variety of educational standards and taxonomies. We present results from empirical studies demonstrating efficacy of our approach in classifying learning content to the Next Generation Science Standards (NGSS).

Keywords

Content tagging/classification, NLP, Transformer Networks

1. INTRODUCTION

Tagging educational content with the most relevant learning and assessment standards and education search terms is one of the most critical elements in creating highly efficacious content. This enables the tracking of student skill gaps, recommendation of remediative learning content and mastery of discipline topics, skills and cross cutting capabilities. With the ever growing volume of digital learning content and educational standards [12] the demands on tagging content are not being met by current solutions.

Current processes to tag content typically starts with raw untagged content that has to be manually reviewed, understood and analyzed by subject matter experts (SMEs) and then classified against a particular education standard e.g. the NGSS [10] resulting in the first set of foundational standards tags. Typically, these standards are hierarchical and utilize a taxonomic knowledge representation to capture the knowledge structure including core disciplinary knowledge, skills and/or cross cutting capabilities. Given the foundational tags one can transfer onto any number of desired taxonomies, for instance the Common Core State Standards [11], using taxonomy crosswalks [13]. Crosswalks are essentially mappings from one standard's taxonomy to another that have for the most part been developed by SMEs and are many times proprietary limiting their applicability.

Saad Khan, Joshua Rosaler, Jesse Hamer and Tiago Almeida "Catalog: An educational content tagging system". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 741-744. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

While in theory this process seems to offer a relatively scalable solution to the content tagging problem, in practice it is inefficient and has significant limitations. Firstly, the initial step of creating the foundational tags is manually executed and highly subjective, making it expensive and error prone. But even when that is done well the taxonomy crosswalks do not offer a perfect solution, because these crosswalks are not one-to-one mappings between the tags of one taxonomy and the other. Due to the hierarchical nature of the standards taxonomies and how they are designed and crafted by SMEs, oftentimes there are vast differences in the levels of knowledge abstraction, resulting in many-to-many mappings for the crosswalks connecting them. The end result is that for a given unit of content even when there is a foundational tag available and using an associated crosswalk, SMEs still have to make the final adjudication of the most appropriate tag in the target standard's taxonomy.

To address these challenges we have developed Catalog, an automated content classification system that leverages recent advances in NLP, specifically the Transformer architecture. This allows us to analyze educational content with richer context-aware text embeddings and pre-trained language models. We have evaluated the accuracy of our approach with promising results on an OpenStax Biology textbook [14] with ground truth NGSS tags (human experts labeled). We believe Catalog can significantly help streamline and accelerate manual workflows around content tagging and curation. These are applicable for both existing or new content, enriching existing content tags for more targeted search, discovery and recommendation as well as maintaining content alignments as educational standards evolve.

2. TECHNICAL APPROACH AND SYSTEM DETAILS

2.1 Transformers and Text Embeddings

At the core of Catalog's content classification tagging system is the Transformer architecture, first proposed by Vaswani et al in 2017 [2]. Catalog utilizes a series of pre-trained Transformer models [5, 6] to encode text-based content in vectorized features which are then further used to analyze the probability that the content is related to a textual description of the target taxonomy. Further details of this approach are presented in the following subsections. Here we present a brief overview of the Transformer architecture.

By eschewing the sequentially-processed nature of previous deep-learning NLP architectures (like LSTMs [3] and GRUs [4]) in favor of *multi-head attention*, the Transformer architecture is highly parallelizable and scalable, allowing for richer context-aware text embeddings and a substantial pre-training capacity which allows for a transfer learning approach to NLP tasks. Since its inception, research into the Transformer architecture has exploded, with variants such as Google's BERT

[5] and OpenAI's GPT series [6, 7, 8] topping several NLP benchmarks, such as the multitask GLUE suite [9].

As indicated above, Transformers are a deep-learning architecture based on the *attention mechanism*. The original formulation of the Transformer architecture used a variant known as *scaled dot-product attention*, defined as

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d}})\, V,$$

where the matrices Q and K are called the *queries* and *keys*, respectively, and each have column-dimension d, while the matrix V is called the *values* and has column-dimension d'. When the queries, keys, and values are all equal to some matrix X, the resulting operation is called *self-attention*. The rows of this matrix X correspond to context-independent feature vectors of the tokens of the input text, each with a small *positional encoding vector* added so that the model is aware of each token's position within the input sequence. Self-attention can be thought of as an operation which recomputes each token as a linear combination of the other tokens, where the weights of the linear combination correspond a scaled dot-product similarity score (the $\frac{QK^T}{\sqrt{d}}$ term).

In this way, (potentially long-range) interactions between tokens are captured. To allow the Transformer to learn different patterns of interaction, several matrices of learnable weights are used to compute *multi-head self-attention*:

$$\text{MultiHead}(X, X, X) = \text{Concat}(\text{head}_1, \text{head}_2, \ldots, \text{head}_h)W^O,$$

where

$$\text{head}_i = \text{Attention}(XW_i^Q, XW_i^K, XW_i^V),$$

and all of the W matrices consist of learnable weights. After multi-head self-attention is computed, the resulting feature vector is fed to a single-hidden-layer feedforward neural network for aggregation and resizing. These two consecutive operations, multi-head self-attention followed by the feedforward neural network, constitute the core of a *Transformer block*. A *Transformer model*, then, is built by chaining several Transformer blocks together, each potentially with their own set of weight matrices.

2.2 How Catalog Works

Catalog's AI-powered content tagging system utilizes a Transformer-based semantic matching engine to rank taxonomic categories by their semantic similarity to given educational content. The semantic matching algorithm works as follows. We are given a collection of textual descriptions of taxonomic categories (e.g. NGSS [10]), which we refer to as "documents," and the raw text of educational content, referred to as the "query" that needs to be classified. For each document, we produce a string of input text by combining it with the query along with a small amount of connective text. Using a Transformer model pre-trained for next token prediction, we then process the input string to convert the query tokens into feature vectors. These feature vectors are then further processed to produce probabilities for each query token, conditioned on the document text. Additionally, we process the query text by itself in order to determine unconditioned probabilities for the query tokens. Finally, a match score is produced for each document by comparing the conditioned vs. unconditioned query token probabilities and then aggregating these into a single real-valued score. Documents are then ranked according to these scores, with a higher score indicating a higher match similarity.

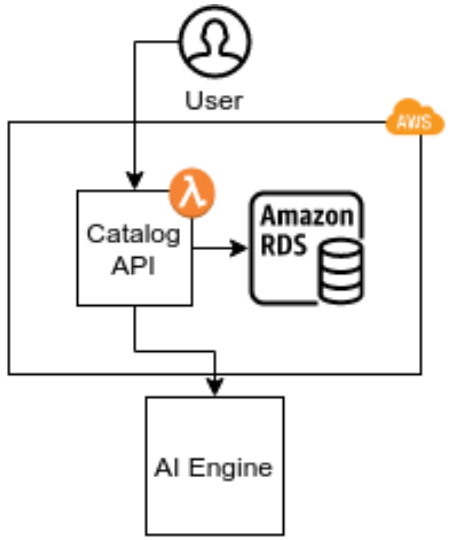

Figure 1: Catalog system architecture is designed to be modular with disturbed services hosted on AWS.

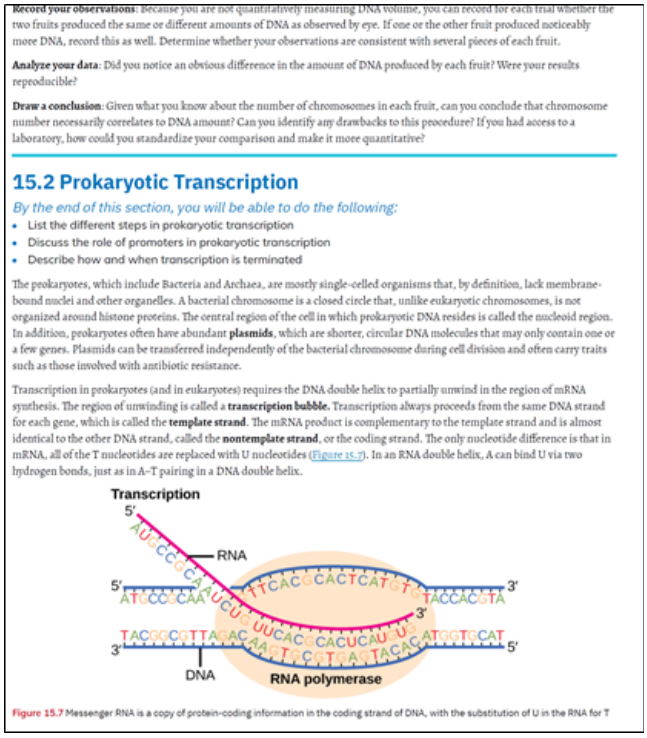

Record your observations: Because you are not quantitatively measuring DNA volume, you can record for each trial whether the two fruits produced the same or different amounts of DNA as observed by eye. If one or the other fruit produced noticeably more DNA, record this as well. Determine whether your observations are consistent with several pieces of each fruit.

Analyze your data: Did you notice an obvious difference in the amount of DNA produced by each fruit? Were your results reproducible?

Draw a conclusion: Given what you know about the number of chromosomes in each fruit, can you conclude that chromosome number necessarily correlates to DNA amount? Can you identify any drawbacks to this procedure? If you had access to a laboratory, how could you standardize your comparison and make it more quantitative?

15.2 Prokaryotic Transcription

By the end of this section, you will be able to do the following:

- List the different steps in prokaryotic transcription
- Discuss the role of promoters in prokaryotic transcription
- Describe how and when transcription is terminated

The prokaryotes, which include Bacteria and Archaea, are mostly single-celled organisms that, by definition, lack membrane-bound nuclei and other organelles. A bacterial chromosome is a closed circle that, unlike eukaryotic chromosomes, is not organized around histone proteins. The central region of the cell in which prokaryotic DNA resides is called the nucleoid region. In addition, prokaryotes often have abundant **plasmids**, which are shorter, circular DNA molecules that may only contain one or a few genes. Plasmids can be transferred independently of the bacterial chromosome during cell division and often carry traits such as those involved with antibiotic resistance.

Transcription in prokaryotes (and in eukaryotes) requires the DNA double helix to partially unwind in the region of mRNA synthesis. The region of unwinding is called a **transcription bubble.** Transcription always proceeds from the same DNA strand for each gene, which is called the **template strand**. The mRNA product is complementary to the template strand and is almost identical to the other DNA strand, called the **nontemplate strand**, or the coding strand. The only nucleotide difference is that in mRNA, all of the T nucleotides are replaced with U nucleotides (Figure 15.7). In an RNA double helix, A can bind U via two hydrogen bonds, just as in A–T pairing in a DNA double helix.

Figure 2: Sample page from the OpenStax Biology 2e textbook used in our experiments.

System architecture and implementation wise, Catalog has two core architectural components as shown in figure 1. The first is a Lambda API Endpoint that leverages the serverless architecture and serves mainly as an interface between the user and the Transformer-based semantic query process, the "AI Engine". It authenticates users' requests, manages requests and accesses the system database. The second major component, "AI Engine"

manages content processing and returns the match scores from classification.

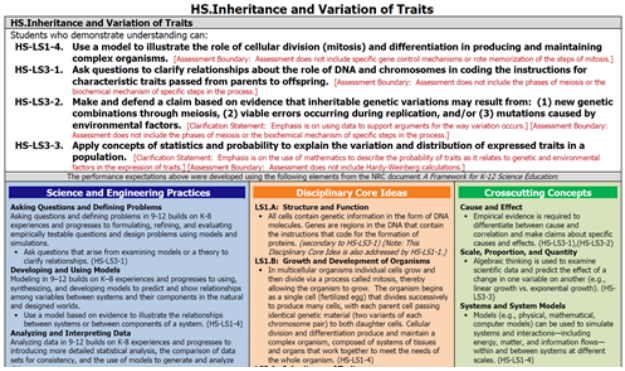

Figure 3: Sample from NGSS High School Life Science Biology performance expectation (PE) standards. Image shows 4 of the 24 unique PE standards used in our experiment.

2.3 Experimental Results

We tested the accuracy and performance of our approach on a learning content dataset extracted from the OpenStax Biology 2e high school textbook [14]. The dataset consists of approximately 500 pages of content spanning 98 chapter/subchapter sections that ranged from 410 to 545 words each. Each of the book's 98 sections is annotated with NGSS High School Life Sciences (HS-LS) performance expectation (PE) tags [10], also provided by OpenStax [14] and served as the ground truth labels in our experiment. There are a total of 24 unique Biology NGSS PE standards applicable to our dataset, essentially rendering this a 24 class classification problem. Figure 2 shows a sample from the OpenStax textbook and in figure 3 we include sample PEs from the 24 NGSS standards used in our experiment. We note that these ground truth labels are not necessarily unique: each section is associated with one to three NGSS tags.

Topic documents for the 24 PE standards were assembled from the Topic Arrangements of the NGSS that includes descriptions of PEs, Science and Engineering Practices, Disciplinary Core Ideas, Crosscutting Concepts. Because our model predicts NGSS tags for a given OpenStax section by ranking them, we assess performance by computing the *top-n overall accuracy*, that is, the proportion of predictions which have at least one ground truth label in their top-*n* ranked predictions (note that for $n = 1$, this is just the traditional overall accuracy measure). For comparison, we had an SME perform this classification exercise manually i.e. provide up to three suggested NGSS PE tags for each of the 98 book sections in our dataset. This SME is a high-school science teacher in a New York city school district and is highly experienced with the NGSS standards.

Before examining the results of this experiment, we note that one NGSS standard, HS-LS1-2, was severely overrepresented in our dataset, accounting for nearly 42% of all ground truth tags, more than 5 times the next-most-represented tag. To account for this in our accuracy computations, we decided to take 1000 random subsamples of this class, and then average the top-*n* accuracy over these subsamples. Figure 4 shows the resulting NGSS tag distribution of such a subsample.

Figure 5 shows the top-*n* accuracy averaged over the 1000 subsamples as a function of *n*. When compared to ground truth, the semantic query model achieved 51%, 73%, and 77% top-1, top-2, and top-3 overall accuracy, respectively, among the 24 NGSS PE standards. In contrast, the SME achieved 48%, 68%, and 70% top-1, top-2, and top-3 overall accuracy, respectively. It should also be noted that it took the SME 520 minutes to complete the manual classification of the dataset, whereas our system completed processing in only approximately 2 minutes.

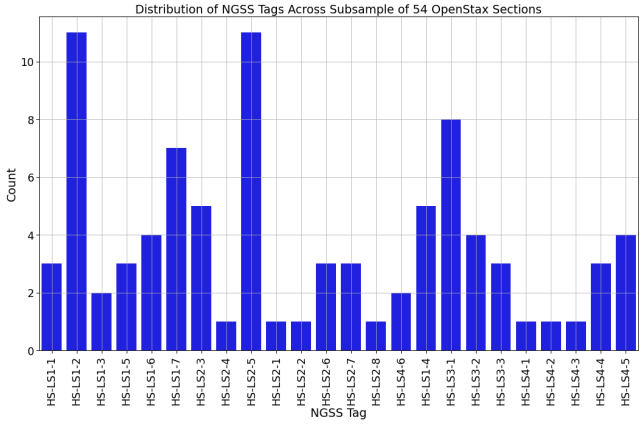

Figure 4: Distribution of NGSS tags across subsample of data. In all, 55 OpenStax sections are associated with tag HS-LS1-2, whereas each subsample randomly selects only 11 of these to be commensurate with the next most represented tag, HS-LS2-5.

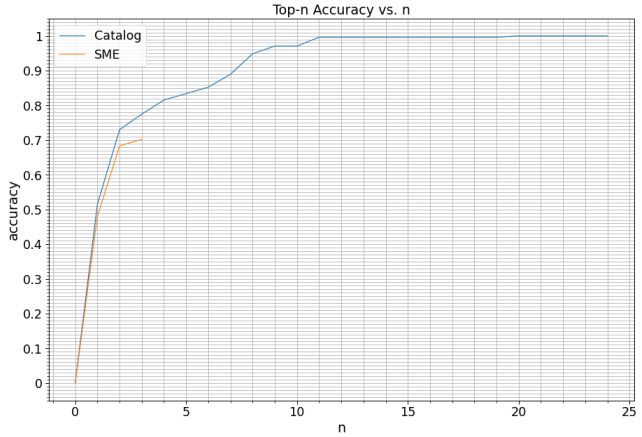

Figure 5: Top-*n* Accuracy vs. *n* for 98 items of section text from the OpenStax Biology 2e textbook, tagged against the NGSS High School Life Sciences performance expectation standards (as above, *n* is the number of top predictions within which at least one ground truth label must fall for the prediction to be counted as correct).

3. CONCLUSION

In this paper we have introduced Catalog, a NLP based content classification system that utilizes recent advances in transfer learning approaches to deeply and accurately tag educational content against popularly used learning standards. Unlike other approaches that rely on keywords or search terms and crosswalks between knowledge taxonomies, Catalog is built on a language modeling architecture that understands the deep semantic structure and relationship between concepts, topics, learning objectives and other attributes of content. We have presented early results from empirical studies demonstrating efficacy of our

approach in classifying learning content to the Next Generation Science Standards (NGSS).

4. ACKNOWLEDGEMENTS

We would like to thank Sara Vispoel for reviewing our results and insightful discussions and comments on the NGSS standards and taxonomic representations used in K-12 life science education and high school biology in particular.

ABSTRACT

As the use of social media increases in daily life, it has also increased for institutions in the field of education. While there may be benefits for schools to use this media outlet, the privacy of students within those schools may be at risk when their names and photos are shared on such a publicly accessible domain. In this study, we analyzed the extent to which students' privacy is protected by qualitatively coding a random sample of 100 Facebook posts made by U.S. school districts from a population of over 9.3 million photo posts that we collected. Using inferential techniques, we found that students are somewhat protected compared to teachers and community members, with only 2.67% of students' detected faces able to be identified by name. The same measure for staff and community members were 4.6% and 16%, respectively. These numbers at first appear small, but if applied to the entire population, this could potentially leave between 153,218 and 1,153,844 students identifiable to anyone on the internet. We discuss the severity and scale of these privacy threats and make recommendations for research on student privacy in social media and other informal education-related contexts.

Keywords

Privacy, Social Media, Facebook, Educational Institutions, Facial Recognition

1. INTRODUCTION & PRIOR RESEARCH

As the number of people using social media has increased, the risks to the privacy of social media users have also increased [23], and this is particularly true since social media use expands into areas of our lives that it did not previously occupy. Education is one such domain in which social media use is now widespread [2, 10, 11, 13, 21, 22]—and is one domain for which the privacy risks from social media use, in general, may be compounded because of the centrality of a particularly vulnerable population, minors at school.

For students in any given school district, the use of their name or face for social media may present notable privacy concerns. As many social media posts are made publicly available, they may be accessed by unexpected sets of individuals, even by those without an account on the corresponding social networking site. Such use may pose a legitimate threat, which may be unknown to (or under-acknowledged by) teachers, administrators, and parents.

Macy Burchfield, Joshua Rosenberg, Conrad Borchers, Tayla Thomas, Benjamin Gibbons and Christian Fischer "Are Violations of Student Privacy "Quick and Easy"? Implications of K-12 Educational Institutions' Posts on Facebook". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 745-749. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

There is past research on the intersection of privacy and social media. For example, Fiesler and Proferes [6] examined what participants in social media studies thought of their data being used by others—particularly, by academic researchers. Only around one-quarter of participants in their survey study reported being comfortable with their data being used without being informed of such use.

Related lines of research explored the intersection of privacy and social media data for students. For instance, Ifenthaler and Schumacher [9] surveyed students about what they thought of their data being used in learning analytics systems. They found that while students expressed comfort with sharing some types of data (i.e., data on their course enrollments, for which less than 20% of students reported reluctance with sharing such data), for others, students were much less comfortable. Notably, highly-personal data, such as medical records, data on one's personal income, and externally-produced data, including social media, were among those that students were the least willing to share. Less than 10% of students reported being willing for externally-produced data to be used within learning analytics systems. Other scholars have shown that pre-service teachers are highly-uncomfortable with how social media companies use students' social media data, with more than two-thirds of teachers expressing discomfort with such uses [16].

While past research has explored the willingness of social media participants and students to share their data for research, a different—institutional rather than personal—context for social media use presents potentially notable privacy risks. Namely, past research has shown that both post-secondary [13] and K-12 educational institutions use social media extensively; particularly, Twitter and Facebook [10, 11]. However, to this point, no research has yet investigated privacy in the context of social media use by K-12 educational institutions.

This topic—K-12 institutions' use of social media from a privacy perspective—is relevant and timely for a number of reasons. Recent research has shown that institutions are very active on both Twitter and Facebook, being associated with more than 300,000 posts/month from the accounts of K-12 districts and schools [11]. As a consequence, there could be hundreds of thousands of students with their identities being posted in a highly-public, searchable, persistent record, and in a way that could be misused in the future. In addition, these posts may contain information that would typically be thought of as information which should not be shared publicly and widely, but which may be shared because of limited understanding of how widely such posts (on public pages) can be viewed. The audiences of institutions are likely much

greater than that of individual educators, meaning any potential privacy concerns may be much larger than that of independent users' accounts. Raising awareness of this issue may prompt some reflection on the part of those sharing this information.

This study involves an initial investigation into the extent to which students' privacy is protected through analysis of Facebook posts made by public schools and school districts. In doing so, we ask a question about the nature of Facebook. Facebook claims that its site is "quick and easy," [5] but the expediency and facility with which K-12 administrators and educators may use the platform may mean that it is also easy for school districts and schools to violate the privacy of students—with potentially difficult-to-anticipate negative ramifications at present and in the future. In particular, we aim to explore the degree to which the privacy of students might be compromised through public Facebook posts guided by the following research questions:

1. To what extent can students be identified by name and photo on public Facebook pages of schools and school districts?
2. How does the identifiability of students compare to that of staff and community members?

2. METHOD

2.1 Sample

We used a *public data mining* methodology, one that draws from *educational data mining* techniques [1, 7], but which is distinguished by the use of (largely unstructured) publicly available data, such as data from websites and social media platforms [12]. Specifically, to obtain our sample of 100 schools' and school districts' Facebook posts, we used CrowdTangle, Facebook's platform for providing academics and journalists access to data about public content on Facebook, including the content of posts and links to associated media as well as their timestamps and number of comments and likes (and other interactions) [4]. This content includes historical data from public Facebook pages with more than 50,000 likes and verified profiles. In addition, individuals with access to CrowdTangle can access public pages—but not individual users' pages.

We accessed all of the posts from K-12 institutions' public Facebook pages in the United States, having obtained the URLs to 15,728 educational institutions' Facebook pages. We did so by using the statistical software R [20] to programmatically access (or, to webscrape) their homepages using data provided by the Common Core of Data [19], and recording all links to Facebook pages from their home pages. When schools linked to the same page as the district, we considered the page as a district page. The total study population included roughly 18 million posts shared from 2005-2020, with about 9.3 million of these posts including at least one photo.

Carrying out a privacy-focused study ourselves, we took steps to protect the privacy of the individuals represented in our data. First, while we accessed and structured the data in a PostgreSQL database, we did not save the images themselves, instead using the Facebook posts and links therein to access the images through our web browser. More broadly, we determined early in our process that we were not prepared to analyze the photos algorithmically/automatically in a safe and ethical manner (e.g., using machine learning methods); we were concerned about uploading the images to a server, where they might be scanned and indexed. While we did not store the images in our database, we nevertheless took steps to protect this data, including permitting access only to authenticated members of the research team.

From the population of approximately 18 million posts, we randomly sampled 100 posts with photos for this analysis. Our random sample of posts and related coding data were stored in a private Google Sheets file stored within a University Google Account (in part because Google is less likely—based upon past legislation, lawsuits and company policies—to programmatically search the contents of educational accounts) to which only project contributors had access; this ensured that any data that could potentially be used to identify individuals was protected.

2.2 Measures

We analyzed the data qualitatively using a combination of two commonly-used qualitative analysis techniques [8], the use of priori codes that we developed based upon prior research and our research questions as well as an exploratory process that allowed us to elaborate on and to substantiate those codes and to train as coders on the use of the coding frame. In particular, we analyzed the data in two ways, as we describe next.

First, to determine *whose privacy was at risk* using our sample of 100 posts, we accessed the images from each post through photo-specific URLs that are included along with information for each post in the data. Each image was accessed and analyzed individually. When there were more than ten images included in a post, we analyzed the first ten, reasoning that these first 10 were the most likely to be seen by viewers of the post. Each post of our sample was analyzed by two trained coders to evaluate the levels of identification for all names and faces included. Upon analysis of 15 posts, we drew three categories from similar research to distinguish individuals included in posts based on their role in the school or school district community [18]:

- *Students*: Any minor assumed to be enrolled in a school and/or participating in a school hosted event or activity.
- *Staff*: Any known employee of the school or school district; including but not limited to teachers, administrators, paraprofessionals, and communications directors.
- *Community Members*: Any member of the school community who is not a verifiable student or staff member, including but not limited to parents, school board members, local business owners, and volunteers.

Second, to determine *how individuals' privacy may be threatened*, we developed a coding frame that we used to assess whether individuals' names and/or photos of individuals were shared in posts, and whether it was possible to readily connect individuals' names and photos of them. We will next describe our qualitative coding process for applying this coding frame.

2.3 Qualitative Coding

Coding proceeded by first determining the classification (student, staff, or community) of each individual detected by name or photo in a post, and then identifying the number of different first and last names included in the text of the post, as well as the number of individual faces shown in the posts' images. In particular, the following four elements were recorded for each category of individuals:

- *Number of First and Last Names in Post*

First and last names were recorded separately within each category due to the fact that staff and community members are often mentioned using their professional prefix (Mr., Mrs., Dr. , etc.) and only their last name.

- *Number of Faces in Images*

For identifying the presence of individuals' faces, a detectable face was considered to be one for which three out of four of the following features were visible without enlarging the image: 1) eyes, 2) nose, 3) ears, and 4) mouth. Any faces appearing in more than one photo within the entire post were only counted once.

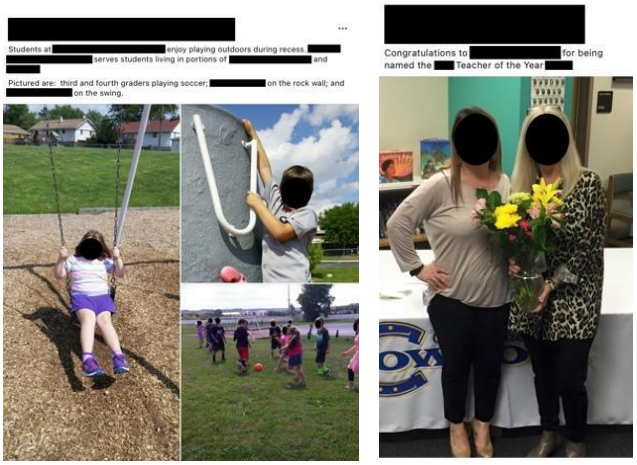
- *How many Names and Faces Connected*

We looked in posts for specific indicators of an individual's location in an image, including the order in which individuals appear in an image or labels on images. In general, identifiability criteria appeared as any text that explicitly stated which name matched with which face in which image.

Our coding included an interrater reliability check for 15 posts. Two coders coded these 15 posts individually using the coding process outlined above. Agreement percentages for detecting names, detecting faces, and identifying faces were 100%, 77.77%, and 93.33% respectively. Total agreement between coders across all codes was 92.34%.

2.4 Illustration of the Coding Process

Image 1. Example Posts



To illustrate the coding process, we provide two example posts and how we coded them above (Image 1). In the image for the first example, two student names, both first and last, are included in the text of the post, and multiple student faces are included in the three images of the post. The "third and fourth graders playing soccer" are not named individually and cannot be distinguished from each other. The two listed student names, which have been covered along with their faces for their protection, are identified by their locations in the images, thus making their faces identifiable by name as well. In the second image, the post included the name of a staff member, as well as detectable faces of two staff members. Without clarification, neither of these faces could be identified with the name mentioned.

2.5 Inferential Analysis

To analyze data to answer our first question, on how students can be identified by name and photo on public posts by K-12 educational institutions, we evaluated the percentages of student faces that were able to be identified by name; for example, if, across the 100 posts, we detected 50 student faces in images, and one was identifiable by name, then the percentage of identifiable students would be 1% (rather than 2%, because we were interested in making inferences on the basis of the number of identifiable students per post). We refer to this value in our results as the *percentage of identifiable faces per post.* Then, based on the observed frequencies (from which we calculated these percentages), we calculated binomial 95% confidence intervals for the ratio of identifiable faces and categories of faces. We did this to present an initial set of estimates for how many faces in our population of 9.3 million photo posts may be identifiable.

To answer our second research question on relative differences in identifiability of individuals from different groups, we carried out the same analysis as above (for students) for teachers and community members. Then, to compare the percentages of photos with identifiable individuals across categories, we calculated a different percentage than for RQ #1, one based not upon the number of posts (i.e., one identifiable face across 100 posts; 1%), but, rather, one based upon the total number of faces detected for people in each category. For instance, if there were 50 faces of students detected, and one was identifiable, then the percentage would be 2%; we refer to this in our results as the *percentage of identifiable faces per category sum*. This number—and comparing the confidence intervals between groups—would allow us to speak to whether individuals were differentially identifiable when photos of them were detected, even if there were, for example, far more photos of students than community members detected.

3. RESULTS

Our coding resulted in the detection (but not identification) of 299 faces in the images from the 100 posts in our sample. Of these 299 faces, only 13 (4.35% of all detected faces [2.33%, 7.32%]) were able to be identified with the individuals' name from the text of the post.

RQ #1. These 13 identifiable faces were identified within 12 individual posts from schools or districts. Student faces comprised 5 of those 12 and thus, for every 100 posts, we estimated that there were 5 identifiable student faces, representing the rate of a single identifiable student face for every twenty posts. Put another way, we estimated that 5% ([1.64%, 11.28%]) of these posts contained identifiable student faces. While this rate is relatively low, if used to make an inference about the population of photo posts we collected, this would suggest that between 153,218 and 1,053,844 students could potentially be identified via their inclusion in school or school districts' posts.

RQ #2. For students, 187 faces were detected in photos and only 5 of those 187 faces were able to be identified by their names, meaning that 2.67% ([0.87%, 6.13%]) of student faces were identifiable by name. Similar percentages are given below for each of the other categories. These numbers indicate that students and staff had a much smaller percentage of identifiable faces than that of community members. The rest of our results are shown in the table below (Table 1).

Table 1. Identifiability Percentages by Category

Category	Total # of Faces	# of ID Faces	Percentage of Identifiable Faces per Post (RQ #1)	Percentage of Identifiable Faces Per Category Sum (RQ #2)
Student	187	5	5% [1.64%, 11.28%]	2.67% [0.87%, 6.13%]

Staff	87	4	4% [1.10%, 9.92%]	4.6% [1.27%, 11.36%]
Community	25	4	4% [1.10%, 9.92%]	16% [4.54%, 36.08%]

4. DISCUSSION

4.1 Key Findings

Upon the completion of coding our sample and numerical analysis for each category, we are able to make a few important claims about the protection of student privacy. First, students comprised a majority of the faces detected in images; however, compared to the large number of student faces, less than 3% of those faces were able to be identified by their names. While this low proportion may seem to indicate that students' privacy is well-protected, the massive scope of this data (more than nine million public posts by schools or school districts) nevertheless means that many students are at-risk to be identified by both face and name by anyone with internet access if expanded to the entire data set. In short, K-12 institutions' uses of social media could introduce very widespread threats to students' privacy.

How serious are these privacy threats? An identifiable photo presents a relatively low risk compared to, for example, one's address or grade-related information being shared. However, the risk of doing so is not zero: These posts could be used to identify information about individuals, and when accessed, could potentially be used to predict their personal characteristics, even those that require making strong inferences, such as those about individuals' political identities [14]—and, potentially, other identities. Adding to the problem, we note that each of these posts not only associates a name with a photo, but also an identifiable photo to a particular location (a school or district) at a specific time. In summation, what seems like a low-risk form of identification, can reveal quite a bit of information on students, leaving their privacy vulnerable.

In addition to the number of photos of students that were able to be identified, the level of protection attached to the privacy of students was intriguing when compared to that of students and staff. More specifically, while students had the highest number of faces detected in images, their isolated level of identifiability was the lowest of all three categories. We can also note that students and staff members together have drastically lower isolated levels of identifiability compared to that of community members: Community members were generally easier to distinguish between than our other categories.

Taken together, these findings speak to concerns about privacy on social media, revealing that not only individuals' actions and posts (e.g. [6, 9, 23]), but also those of educational institutions may pose risks for the privacy of a vulnerable societal group: minors at school. They suggest that the wide use of Facebook and ease of accessing posts coupled with identifiable posts of students may make this particular use of social media a key avenue through which students' privacy is compromised. In this way, these findings add to prior research pointing out that young people may view privacy differently [17]. In addition, this research suggests to the educational data mining community that privacy risks to students may appear in unexpected contexts—and in contexts for which schools may, technically, not be violating the United States' Family Educational Rights and Privacy Act (FERPA), but which may be deserve greater scrutiny.

4.2 Limitations and Recommendations

This study represents an initial exploration of a topic that has been investigated extensively using other data sources and populations [6, 9]—and which could be investigated much further to better understand the nature of how students' privacy may be threatened due to the increasingly widespread use of social media by K-12 educational institutions. Due to the small size of our sample (compared to that of the population of photo posts), while we made some inferences from our sample to the population, these were associated with very wide ranges of plausible values: for example, we estimated that the number of identifiable students ranges from between 150,000 and more than one million, a range that makes it difficult to inform other researchers as well as administrators, educators, parents, and students about the scale of the threat to students' privacy. In addition, there are certain statistical inferences that we are unable to make at this time: For instance, with a small number of posts from varying years, we must code a larger sample to be able to model change in privacy risk over time.

It is important to consider the issue of parent consent in the context of student photos via public pages of schools and districts. While our sample data does not include specific information on each educational institution's privacy policies, there has been past research performed regarding actions such as consent forms [3]. Students' parents or legal guardians typically act as their agents of consent, which may appear to legitimize the publicizing of student faces. However, those making these crucial decisions may not have all of the necessary information to make these choices on behalf of their students.

Future research may expand on the findings presented in this study by not only coding a greater number of posts, but also coding for different features of them. For instance, we noted that because many images in the latter part of 2020 included students wearing masks, there may surprisingly be a decrease in the number of identifiable faces during the COVID-19 pandemic. Future research that aims to mitigate risks may also note some of the features of posts which protect the privacy of students, and posts by schools or districts that achieve some of the benefits of educational institutions' social media use. How accessible the posts we accessed via both the CrowdTangle [4] platform and other (authorized or unauthorized--e.g., through web-scraping) means is another topic future scholarship can explore in greater depth, as the extent to which others can reproduce our analysis has a bearing on how extensive the threats to students' privacy are. Limiting risks to students' privacy may serve as a model to inform or prompt reflection on the part of the administrators and educators using their school's or school districts' Facebook account. Finally, future research might investigate what key stakeholders--students, parents, and teachers--think of the potential privacy risks around social media use. While past research has reported that teachers are uncomfortable with how social media platforms use student data [16], our results suggest that key individuals in schools may not draw connections between this lack of comfort and how their school or district uses social media, and survey research methods may compliment our public data mining approach.

ABSTRACT

Collaboration is identified as a required and necessary skill for students to be successful in the fields of Science, Technology, Engineering and Mathematics (STEM). However, due to growing student population and limited teaching staff it is difficult for teachers to provide constructive feedback and instill collaborative skills using instructional methods. Development of simple and easily explainable machine-learning-based automated systems can help address this problem. Improving upon our previous work, in this paper we propose using simple temporal-CNN deep-learning models to assess student group collaboration that take in temporal representations of individual student roles as input. We check the applicability of dynamically changing feature representations for student group collaboration assessment and how they impact the overall performance. We also use Grad-CAM visualizations to better understand and interpret the important temporal indices that led to the deep-learning model's decision.

K-12, Education, Collaboration Assessment, Explainable, Deep-Learning, CNN, Grad-CAM, Cross-modal Analysis.

1. INTRODUCTION

Collaboration is considered a crucial skill, that needs to be inculcated in students early on for them to excel in STEM fields [24, 6]. Traditional instruction-based methods [14, 7] can often make it difficult for teachers to observe several student groups and identify specific behavioral cues that contribute or detract from the collaboration effort [20, 15, 25]. This has resulted in a surge in interest to develop machine-learning-based automated systems to assess student group collaboration [17, 11, 12, 8, 1, 9, 26, 23, 21, 4, 27, 22].

In our earlier work we developed a multi-level, multi-modal conceptual model that serves as an assessment tool for individual student behavior and group-level collaboration quality [2, 3]. Using the conceptual model as a reference, in a different paper we developed simple MLP deep-learning models that predict student group collaboration quality from histogram representations of individual student roles [22]. Please refer to the following papers for more information and for the illustration of the conceptual model [2, 3, 22]. Despite their simplicity and effectiveness, the MLP models and histogram representations lack explainability and insight into the important student dynamics. To address this, in this paper we focus on using simple temporal-CNN deep learning models to check the scope of dynamically changing temporal representations for student group collaboration assessment. We also use Grad-CAM visualizations to help identify important temporal instances of the task performed and how they contribute towards the model's decision.

Paper Outline: Section 2 provides necessary background on the different loss functions used, dataset description and the temporal features extracted. Section 3 describes the experiments and results. Section 4 concludes the paper.

2. BACKGROUND

2.1 Cross-Entropy Loss Functions

The categorical-cross-entropy loss is the most commonly used loss function to train deep-learning models. For a classification problem with C classes, let us denote the input variables as $\mathbf{x}$, ground-truth label vector as $\mathbf{y}$ and the predicted probability distribution as $\mathbf{p}$. Given a training sample $(\mathbf{x}, \mathbf{y})$, the categorical-cross-entropy (CE) loss is defined as

Table 1: Coding rubric for Level A and Level B2.

Level A	Level B2
Effective [E]	Group guide/Coordinator [GG]
Satisfactory [S]	Contributor (Active) [C]
Progressing [P]	Follower [F]
Needs Improvement [NI]	Conflict Resolver [CR]
Working Independently [WI]	Conflict Instigator/Disagreeable [CI]
	Off-task/Disinterested [OT]
	Lone Solver [LS]

Table 2: Inter-rater reliability (IRR) measurements.

Level	Average Agreement	Cohen's Kappa
A	0.7046	0.4908
B2	0.6741	0.5459

$$\text{CE}_{\mathbf{x}}(\mathbf{p}, \mathbf{y}) = -\sum_{i=1}^{C} \mathbf{y}_i \log(\mathbf{p}_i) \tag{1}$$

Here, $\mathbf{p}_i$ denotes the predicted probability of the i-th class. Note, both $\mathbf{y}$ and $\mathbf{p}$ are of length C, with $\sum_i \mathbf{y}_i = \sum_i \mathbf{p}_i = 1$. From Equation 1, it's clear that for imbalanced datasets the learnt weights of the model will be biased towards classes with the most number of samples in the training set. Additionally, if the label space exhibits an ordered structure, the categorical-cross-entropy loss will only focus on the predicted probability of the ground-truth class while ignoring how far off the incorrectly predicted sample actually is. These limitations can be addressed to some extent by using the ordinal-cross-entropy (OCE) loss function [22], defined in Equation 2.

$$\begin{aligned} \text{OCE}_{\mathbf{x}}(\mathbf{p}, \mathbf{y}) &= -(1+w)\sum_{i=1}^{C} \mathbf{y}_i \log(\mathbf{p}_i) \\ w &= |\text{argmax}(\mathbf{y}) - \text{argmax}(\mathbf{p})| \end{aligned} \tag{2}$$

Here, $(1+w)$ represents the weighting variable, argmax returns the index of the maximum valued element and $|.|$ returns the absolute value. When training the model, $w = 0$ for correctly classified training samples, with the ordinal-cross-entropy loss behaving exactly like the categorical-cross-entropy loss. However, for misclassified samples the ordinal-cross-entropy loss will return a higher loss value. The increase in loss is proportional to how far away a sample is misclassified from its ground-truth class label.

2.2 Dataset Description

We collected audio and video recordings from 15 student groups, across five middle schools. Out of the 15 groups, 13 groups had 4 students, 1 group had 3 students, and 1 group had 5 students. The student volunteers completed a brief survey that collected their demographic information and other details, e.g., languages spoken, ethnicity and comfort levels with science concepts. Each group was tasked with completing 12 open-ended life science and physical science tasks, which required them to construct models of different science phenomena as a team. They were given one hour to complete as many tasks possible, which resulted in 15 hours of audio and video recordings. They were provided logistic and organization instructions but received no help in group dynamics, group organization, or task completion.

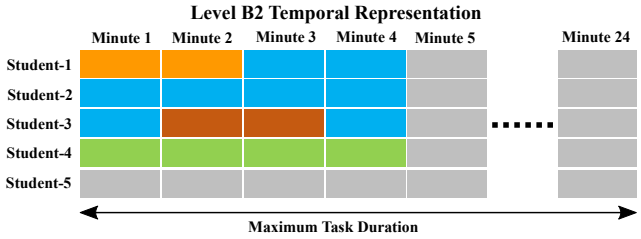

Figure 1: Level B2 temporal representation for a group having only 4 students and finishing the assigned task in 4 minutes. Colored cells illustrate the different Level B2 codes as described in Table 1, and the gray cells represent empty or unassigned codes.

Next, the data recordings were manually annotated by education researchers at SRI International. For the rest of the paper we will refer to them as coders/annotators. In our hierarchical conceptual model [2, 3], we refer to the collaboration quality annotations as Level A and individual student role annotations as Level B2. The coding rubric for these two levels is described in Table 1. Both levels were coded by three annotators. They had access to both audio and video recordings and used ELAN (an open-source annotation software) to annotate. A total of 117 tasks were coded by each annotator, with the duration of each task ranging from 5 to 24 minutes. Moderate-agreement was observed across the coders as seen from the inter-rater reliability measurements in Table 2.

Level A codes represent the target label categories for our classification problem. To determine the ground-truth Level A code, the majority vote (code) across the three annotators was used as the ground-truth. For cases where a majority was not possible, we used the Level A code ordering depicted in Table 1 to determine the median as ground-truth of the three codes. For example, if the three coders assigned *Satisfactory, Progressing, Needs Improvement* for the same task then *Progressing* would be used as the ground-truth label. Note, we did not observe a majority Level A code for only 2 tasks. To train the machine learning models we only had 351 data samples (117 tasks $\times$ 3 coders).

2.3 Temporal Representation

In our dataset, the longest task was little less than 24 minutes, due to which the length for all tasks was also set to 24 minutes. Level B2 was coded using fixed-length 1 minute segments, as illustrated in Figure 1. Due to its fixed-length nature, we assigned an integer value to each B2 code, i.e., the seven B2 codes were assigned values from 1 to 7. The value 0 was used to represent segments that were not assigned a code. For example, in Figure 1 we see a group of 4 students completing a task in just 4 minutes, represented by the colored cells. The remaining 20 minutes and the 5^{th} student is assigned a value zero, represented by the gray cells. Thus for each task, Level B2 temporal features will have a shape 24×5, with 24 representing number of minutes and 5

representing number of students in the group.

Baseline Histogram Representation: We compare the performance of the temporal representations against simple histogram representations [22]. The histogram representations were created by pooling over all the codes observed over the duration of the task and across all the students. Note, only one histogram was generated per task, per group. Once the histogram is generated we normalize it by dividing by the total number of codes in the histogram. Normalizing the histogram removes the temporal aspect of the task. For example, if group-1 took 10 minutes to solve a task and group-2 took 30 minutes to solve the same task, but both groups were assigned the same Level A code despite group-1 finishing the task sooner. The raw histogram representations of both these groups would look different due to the difference in number of segments coded. However, normalized histograms would make them more comparable. Despite the normalized histogram representation being simple and effective, it fails to offer any insight or explainability.

3. EXPERIMENTS

Network Architecture: For the temporal-CNN deep learning model we used the temporal ResNet architecture described in [28]. The ResNet architecture uses skip connections between each residual block to help avoid the vanishing gradient problem. It has shown state-of-the-art performance in several computer vision applications [10]. Following [28], our ResNet model consists of three residual blocks stacked over one another, followed by a global-average-pooling layer and a softmax layer. The number of filters for each residual block was set to 64, 128, 128 respectively. The number of learnable parameters for the B2 temporal representations is 506949. We compare the performance of the ResNet model to the MLP models described in our previous work. Interested readers should refer to [22] for more information about the baseline MLP model that was used with the histogram representation.

Training and Evaluation Protocol: All models were developed using Keras with TensorFlow backend [5]. We used the Adam optimizer [13] and trained all models for 500 epochs. The batch-size was set to one-tenth of the number of training samples during any given training-test split. We optimized over the Patience and Minimum-Learning-Rate hyperparameters, that were set during the training process. We focused on these as they significantly influenced the model's classification performance. The learning-rate was reduced by a factor of 0.5 if the loss did not change after a certain number of epochs, indicated by the Patience hyperparameter. We saved the best model that gave us the lowest test-loss for each training-test split. We used a round-robin leave-one-group-out cross validation protocol. This means that for our dataset consisting of g student groups, for each training-test split we used data from $g-1$ groups for training and the left-out group was used as the test set. This was repeated for all g groups and the average result was reported. For our experiments $g = 14$ though we have temporal representations from 15 student groups. This is because all samples corresponding to the *Effective* class were found only in one group. Due to this reason and because of our cross-validation protocol we do not see any test samples for the *Effective* class.

Table 3: Weighted precision, weighted recall and weighted F1-score Mean±Std for the best MLP and ResNet models under different settings.

Feature	Classifier	Weighted Precision	Weighted Recall	Weighted F1-Score
B2 Histogram	SVM	84.45±13.43	73.19±16.65	76.92±15.39
	MLP - Cross-Entropy Loss	83.72±16.50	86.42±10.44	84.40±13.85
	MLP - Cross-Entropy Loss + Class-Balancing	83.93±17.89	85.29±14.37	84.16±16.23
	MLP - Ordinal-Cross-Entropy Loss	86.96±14.56	88.78±10.36	**87.03±13.16**
	MLP - Ordinal-Cross-Entropy Loss + Class-Balancing	86.73±14.43	88.20±9.66	86.60±12.54
B2 Temporal	ResNet - Cross-Entropy Loss	84.75±13.21	83.10±11.92	82.72±12.74
	ResNet - Cross-Entropy Loss + Class-Balancing	84.03±15.13	83.28±11.42	82.97±12.84
	ResNet - Ordinal-Cross-Entropy Loss	85.24±15.68	87.23±10.52	85.56±13.38
	ResNet - Ordinal-Cross-Entropy Loss + Class-Balancing	84.34±15.75	87.88±11.22	**85.68±13.58**

3.1 Temporal vs Histogram Representations

Here, we compare the performance of the ResNet and MLP models. Using the weighted F1-score performance, Table 3 summarizes the best performing ResNet and MLP models for the different feature-classifier variations. The table also provides the weighted precision and recall metrics. Bold values in the table represent the best classifier across the different feature-classifier settings. The ordinal-cross-entropy loss with or without class-balancing shows the highest weighted F1-score performance for both feature types. Here, class-balancing refers to weighting each data sample by a weight that is inversely proportional to the number of data samples corresponding to that sample's ground-truth label.

At first glance, the ResNet models perform slightly less than the MLP models. This could easily lead us to believe that simple histogram representations are enough to achieve a higher classification performance than the corresponding temporal representations. However, despite the performance differences, the temporal features and ResNet models help better explain and pin-point regions in the input feature space that contribute the most towards the model's decision. This is important if one wants to understand which student roles are most influential in the model's prediction. We will go over this aspect in more detail in the next section.

3.2 Grad-CAM Visualization

Grad-CAM uses class-specific gradient information, flowing into the final convolutional layer to produce a coarse localization map that highlights the important regions in the input feature space [19]. It is primarily used as a post hoc analysis tool and is not used in any way to train the model. Figure 2 illustrates how Grad-CAM can be used for our classification problem. We show two different samples from the Satisfactory, Progressing and Needs Improvement classes respectively. Each sample shows a group consisting of 4 students that completed the task in 5 to 8 minutes. Technically one can obtain C Grad-CAM maps for a C-class classification problem. Here, the samples shown correspond to the class predicted by the ResNet model, which is also the ground-truth class. It's clear how the Grad-CAM highlights regions in the input feature space that contributed towards the correct prediction. For instance, in the Needs Improvement examples, the Grad-CAM map shows the highest weight on the fourth minute. At that time for the first example, the codes for three of the students become Off-task/Disinterested. Similarly, for the second example we notice three of the students become Lone Solvers and the

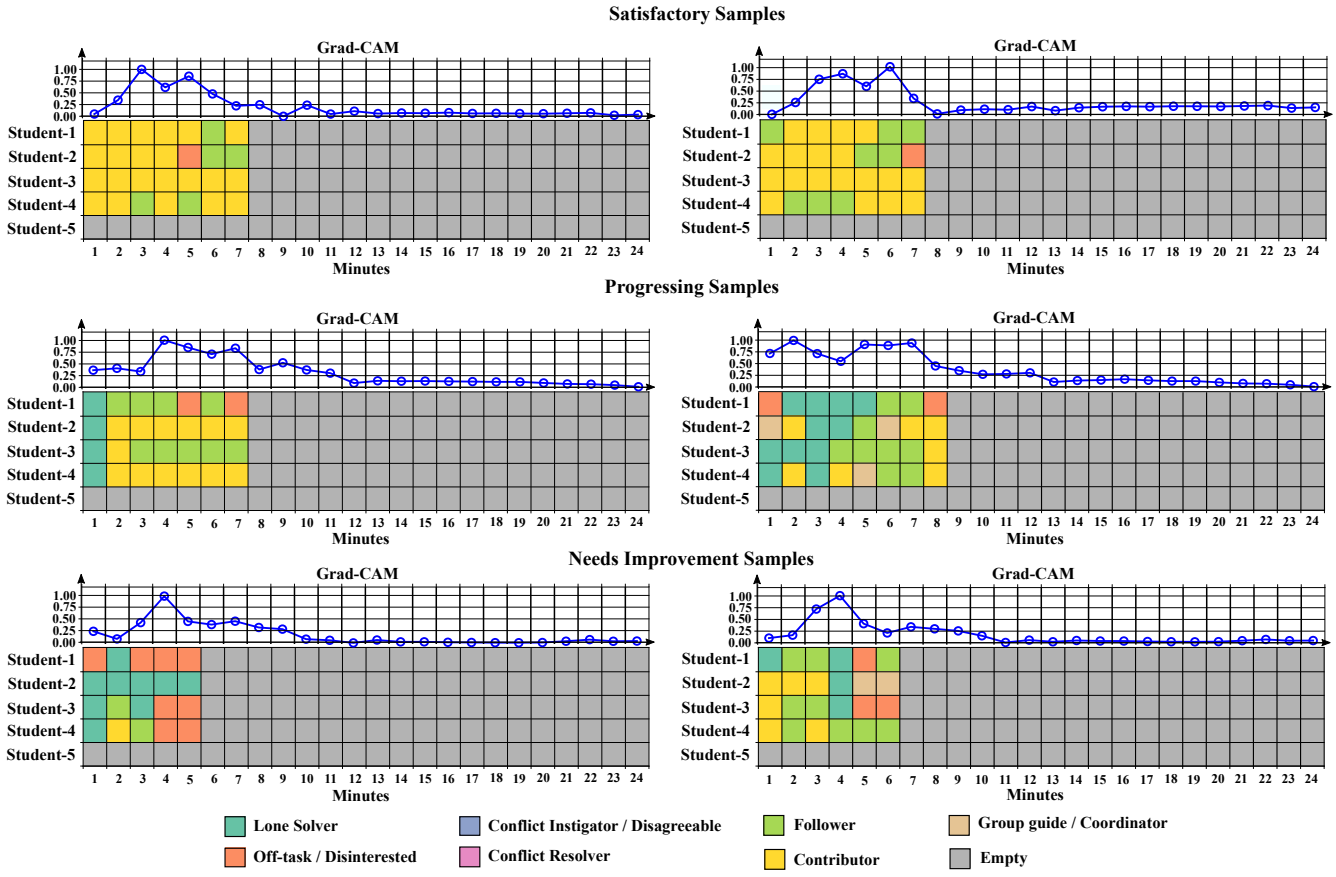

Figure 2: Grad-CAM visualization for two different temporal samples from different Level-A classes.

fourth student becomes a Follower. This is in stark contrast to the minute before when two of the students were Followers and the other two were Contributors. We also notice less importance being given to the Empty codes. These changes in roles and the Grad-CAM weights across the task make sense and help promote explainability in our deep learning models.

4. CONCLUSION

In this paper we proposed using simple temporal representations of individual student roles together with temporal ResNet deep-learning architectures for student group collaboration assessment. Our objective was to develop more explainable systems that allow one to understand which instances in the input feature space led to the deep-learning model's decision. We suggested use of Grad-CAM visualization along the temporal dimension to assist in locating important time instances in the task performed. We compared the performance of the proposed temporal representations against simpler histogram representations from our previous work [22]. While histogram representations can help achieve high classification performance, they do not offer the same key insights that one can get using the temporal representations.

Limitations and Future Work: The visualization tools and findings discussed in this paper can help guide and shape future work in this area. Having said that our approach can be further extended and improved in several ways. For example, we only discuss Grad-CAM maps along the temporal dimensions. This only allows us to identify important temporal instances of the task but does not focus on the important student interactions. The current setup does not tell us which subset of students are interacting and how that could affect the overall group dynamic and collaboration quality. To address this we intend on exploring other custom deep-learning architectures and feature representation spaces. We also plan on using other tools like LIME [18] and SHAP [16]. These packages compute the importance of the different input features and help towards better model explainability and interpretability. Also we only focused on mapping deep learning models from individual student roles to overall group collaboration. In the future we intend on exploring other branches in the conceptual model, described in [2, 3]. We also plan on developing recommendation systems that can assist and guide students to improve themselves by suggesting what they need to take on. The same system could also be tweaked specifically for teachers to give them insight on how different student interactions could be improved to facilitate better group collaboration.

ABSTRACT

In this paper, we introduce the Commonlit Ease of Readability (CLEAR) corpus. The corpus provides researchers within the educational data mining community with a resource from which to develop and test readability metrics and to model text readability. The CLEAR corpus improves on previous readability corpora include size (N = ~5,000 reading excerpts), the breadth of the excerpts available, which cover over 250 years of writing in two different genres, and the readability criterion used (teachers' ratings of text difficulty for their students). This paper discusses the development of the corpus and presents reliability metrics as well as initial analyses of readability.

Keywords

Text readability, corpus linguistics, pairwise comparisons

1. INTRODUCTION

Reading is an essential skill for academic success. One important way to support and scaffold literacy challenges faced by students is to match text difficulty to their reading abilities. Providing students with texts that are accessible and well matched to their abilities helps to ensure that students better understand the text and, over time, can help readers improve their reading skills. Readability formulas, which provide an overview of text difficulty, have shown promise in more accurately benchmarking students with their text difficulty level, allowing students to read texts at target readability levels.

Most educational texts are matched to readers using traditional readability formulas like Flesch-Kincaid Grade Level (FKGL) [19] or commercially available formulas such as Lexile [30] or the Advantage-TASA Open Standard (ATOS) [29]. However, both types of readability formulas are problematic. Traditional readability formulas lack construct and theoretical validity because they are based on weak proxies of word decoding (i.e., characters or syllables per word) and syntactic complexity (i.e., number or words per sentence) and ignore many text features that are important components of reading models including text cohesion and semantics. Additionally, many traditional readability formulas were normed using readers from specific age groups on small corpora of texts taken from specific domains. Commercially available readability formulas are not publicly available, may not have rigorous reliability tests, and may be cost-prohibitive for many schools and districts let alone teachers.

In this paper, we introduce the open-source the CommonLit Ease of Readability (CLEAR) corpus. The corpus is a collaboration between CommonLit, a non-profit education technology organization focused on improving reading, writing, communication, and problem-solving skills, and Georgia State University (GSU) with the end goal of promoting the development of more advanced and open-source readability formulas that government, state, and local agencies can use in testing, materials selection, material creation, and other applications commonly reserved for readability formulas. The formulas that will be derived from the CLEAR corpus will be open-source and ostensibly based on more advanced natural language processing (NLP) features that better reflect the reading process. The accessibility of these formulas and their reliability should lead to immediate uptake by students, teachers, parents, researchers, and others, increasing opportunities for meaningful and deliberate reading experiences. We outline the importance of text readability along with concerns about previous readability formulas below. As well, we present the methods used to develop the CLEAR corpus. We then examine how well traditional and newer readability formulas correlate with the reading criteria reported in the CLEAR corpus and discuss next steps.

2. TEXT READABILITY

Text readability can be defined as the ease with which a text can be read (i.e., processed) and understood in terms of the linguistic features found in that text [9][27]. However, in practice, many readability formulas are more focused on measuring text understanding (e.g., [18]) than text processing.

Text comprehension is generally associated with word sophistication, syntactic complexity, and discourse structures [17][31], three features whose textual elements relate to text complexity. For example, many studies have revealed that word sophistication features such as sound and spelling relationships between words [16][25], word familiarity and frequency [15], and word imageability and concreteness [28] can result in faster word processing and more accurate word decoding. The meaning of

words, or semanticity, also plays an important role in text readability, in that readers must be able to recognize words and know their meaning [26]. Therefore, word semanticity and larger text segments can facilitate the linking of common themes and easier processing based on background knowledge and text familiarity [1][23].

Effective readers should also be able to parse syntactic structures within a text to help organize main ideas and assign thematic roles where necessary [13][26]. Two features that allow for quicker syntactic parsing are words or morphemes per t-unit [8] and sentence length [21]. Parsing information in the text helps readers develop larger discourse structures that result in a discourse thread [14]. These structures, which relate to text cohesion, can be partially constructed using linguistic features that link words and concepts within and across syntactic structures [12]. Sensitivity to these cohesion structures allows readers to build relationships between words, sentences, and paragraphs, aiding in the construction of knowledge representations [4][20][23]. Moreover, such sensitivity can help readers understand larger discourse segments in texts [11][26].

Traditional readability formulas tend use only proxy estimates for measuring lexical and syntactic features. Moreover, they disregard the semantic features and discourse structures of texts. For instance, these formulas ignore text features including text cohesion [4][20][23][24] and style, vocabulary, and grammar, which play important roles in text readability [1]. Additionally, the reading criteria used to develop traditional formulas are often based on multiple-choice questions and cloze tests, two methods that may not measure text comprehension accurately [22]. Finally, traditional readability formulas are suspect because they have been normed using readers from specific age groups and using small corpora of texts from specific domains.

Newer formulas, both commercial and academic, generally outperform traditional readability formulas. These formulas rely on more advanced NLP features, although this may not be the case with commercial formulas for which text features within the formulas are proprietary and, thus, not publicly available. Newer formulas come with their own issues though. For instance, commercially available formulas, such as the Lexile framework [30] and the Advantage-TASA Open Standard for Readability (ATOS) formula [29], often lack suitable validation studies. In addition, accessing commercially available formulas may come at a financial cost that is unaffordable for some schools and education technology organizations. Academic formulas such as the Crowdsourced Algorithm of Reading Comprehension (CAREC) [7] have been validated through rigorous empirical studies, are transparent in their underlying features, and are free to the public. However, the datasets on which they have been developed, while much larger than traditional readability formulas, can still be considered as relatively small and specific. The populations the formulas are trained on (i.e., adults) may also not generalize well to other target populations like young students.

3. CURRENT STUDY

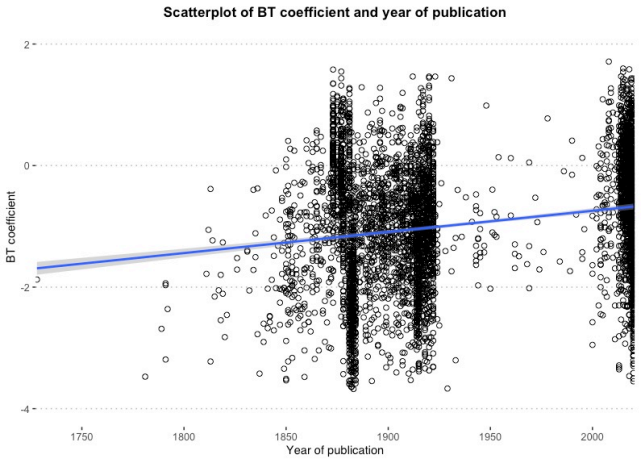
We hope to spur innovation to address many of the concerns noted above in reference to both traditional and newer readability formulas by publicly releasing the CommonLit Ease of Readability (CLEAR) corpus as well as hosting an open-source competition to develop readability formulas based on the CLEAR corpus. We hope that these formulas outperform existing readability formulas and can be used to better match 3rd-12th grade students to texts, thus improving learning outcomes in primary and secondary classrooms.

4. THE CLEAR CORPUS

4.1 Corpus Collection

We collected text excerpts from the CommonLit organization's database, Project Gutenberg, Wikipedia, and dozens of other open digital libraries. Excerpts were selected from the beginning, middle, and end of texts and only one sample was selected per text. Text excerpts were selected to be between 140-200 words, with all excerpts beginning and ending at an idea unit (i.e., we did not cut excerpts in the middle of sentences or ideas). The text excerpts were written between 1791 and 2020, with the majority of excerpts selected between 1875 and 1922 (when copyrights expired) and between 2000 and 2020 (when non-copyright texts were available on the internet). Visualizations of these trends are available in Figure 1.

Figure 1



Excerpts were selected from two genres: informational and literature texts. We started with an initial sample of ~7,600 texts. Each excerpt was read by at least two raters and judged on acceptability. The two major criteria for acceptability were the likelihood of being used in a 3rd-12th grade classroom and whether or not the topic was appropriate. We used Motion Picture Association of America (MPAA) ratings (e.g., G, PG, PG-13) to flag texts by appropriateness. Texts that were flagged as potentially inappropriate were then read by an expert rater and either included or excluded from the corpus. We also conducted automated searches for traumatic terms (e.g., terms related to racism, genocide, or sexual assault). Any excerpt flagged for traumatic terms was also reviewed by an expert rater. Lastly, we limited author representation such that each author had no more than 12 excerpts within the corpus. After removing excerpts based on these criteria, we were left with 4793 excerpts. These excerpts were copy-edited to ensure texts did not contain grammatical, syntactic, and spelling errors. Punctuation was also standardized in the texts, as were line-breaks. Lastly, selected archaic spellings (e.g., to-day, Servia) were replaced with modern spellings (e.g., today, Serbia) and identified British English spellings were converted to American spellings.

4.2 Human Ratings of Readability

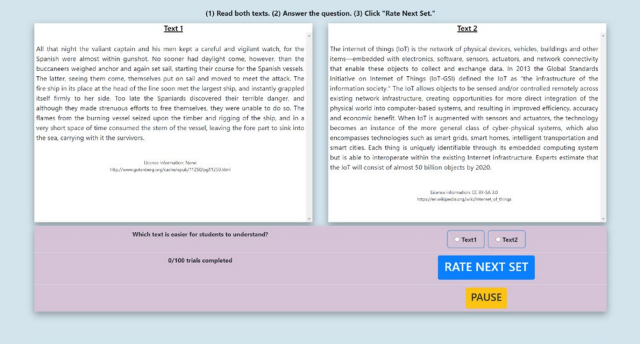
We recruited ~1,800 teachers from the CommonLit teacher pool through an e-mail marketing campaign. Teachers were asked to participate in an online collection experiment. They were

expected to read 100 pairs of excerpts and make a judgment for each pair as to which excerpt was easier to understand. Teachers were paid $50 in an Amazon gift card for their participation.

4.3 Data Collection Site

We developed an online data collection website. The basic format of the site was to show two excerpts side by side and ask participants to judge which of the two texts would be easier for a student to understand using a checkbox format. There were two additional buttons on the website. The first moved the participant to the next comparison and the second allowed participants to pause the experiment. The website also included a progress tally to show participants how many comparisons they had made (see Figure 2 for screenshot of pairwise comparison task).

Figure 2



The website first provided participants with informed consent and an overview of the expectations. The website then collected simple demographic information and survey information about reading/writing and television habits. Participants were then given a practice excerpt comparison to familiarize them with the design. After the practice comparison, participants moved forward with the data collection. Excerpts were paired randomly, and excerpts were shown on either the right or left-side panel randomly. The licensing information and the uniform resource locator (URL) for each text were displayed on the bottom side of each panel. Participants were redirected to a break screen after completing every 20 comparisons. The break screen showed how much time (in total and per comparison) the participant had spent on the task. A button allowing the participant to continue to the next comparison appeared after spending one minute on the break screen, meaning that the participants were required to take at least a one-minute break per 20 comparisons. After completing 100 comparisons, the participants were given a completion code that they could redeem for the gift card. The website was written in Python, JavaScript, CSS, and HTML. The website was housed on a cloud server.

4.4 Participant Reliability

Of the ~1,800 participants that initially logged into the experiment, 1,198 completed the entire experiment. However, not all participant data was kept. We removed participants who did not complete the entire experiment. We also removed participants to increase the reliability of the pairwise scores based on deviant patterns and time spent on judgments. In terms of deviant patterns, we removed all participants who selected excerpts in either the right or left panel more than 70% of the time. We also removed participants who had binary patterns of selecting left/right or right/left panels more than 20 times in a row. In terms of time spent on judgments, we removed participants who spent less than 10 seconds on average per comparison and/or spent a median time under 5 seconds. After removing participants based on patterns and time, we were left with data from 1,116 participants. Those participants made 111,347 overall comparison judgments (M = 99.773 judgments per participant). On average, each excerpt was read 46.47 times and participants spent an average of 101.36 seconds per judgment. However, we did not remove participants for taking too long on judgments, especially since pauses were allowed. Thus, our data for time was right skewed.

4.5 Pairwise Rankings for Readability

To calculate pairwise comparison scores for the human judgments of text ease, we used a Bradley-Terry model [3]. A Bradley-Terry model describes the probabilities of the possible outcomes when items are judged against one another in pairs (see Equation 1). The Bradley-Terry model ranks documents by difficulty based on each excerpt's probability to be easier than other excerpts. The model creates a maximum likelihood estimate which iteratively converges towards a unique maximum that defines the ranking of the excerpts (i.e., the easiest texts have the highest probability).

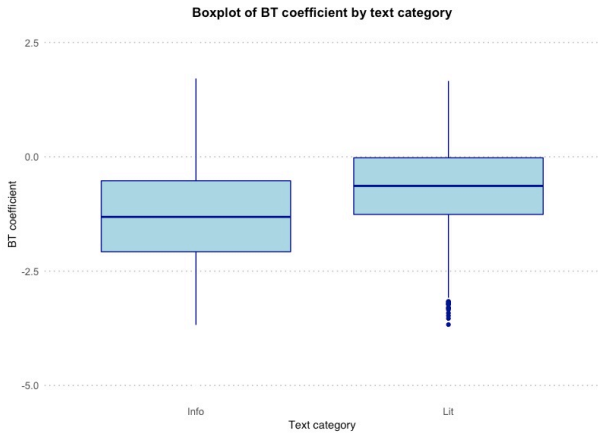
Equation 1: Bradley-Terry Model

$$P(\llbracket text \rrbracket\_i \text{ more difficult than } \llbracket text \rrbracket\_j) = \gamma\_i/(\gamma\_i+\gamma\_j)$$

After computation, the Bradley-Terry model provides a coefficient for each text along with a standard error. We examined both coefficients and standard errors for outliers. We found 52 texts that had a coefficient with a standard deviation greater than 2.5 and additional 17 excerpts with a standard error greater than 0.65. These were removed from the final dataset leaving us with a sample size of 4,724. We conducted two additional analyses of the final data set in terms of differences in Bradley-Terry coefficients between informational and literature texts and trends in the coefficients as a function of time of publication for the texts.

As expected, we found significant differences between informational and literature texts such that informational texts were rated significantly more difficult ($t(4723) = -20.95$, $p < .001$), with a moderate effect size ($d = -0.61$). See Figure 2 for a box plot depicting this difference in text categories. In addition, we used a Pearson's correlation test to test whether Bradley-Terry coefficients were correlated with the texts' year of publication, finding a weak correlation, $r(4722) = .20$, $p < .001$). Thus, more recent passages were often rated as simpler than older passages (see Figure 1).

Figure 3



4.6 Pairwise Scoring Validation Checks

To examine convergent validity for the pairwise scores, we examined correlations between the scores and classic and newer readability formulas. The formulas we included were Flesch Reading Ease, Flesch Kincaid Grade Level, the New Dale-Chall, and the Crowdsourced Algorithm of Reading Comprehension [7]. All formulas were calculated using the Automatic Readability Tool for English (ARTE) [6]. ARTE provides free and easy access to a wide range of readability formulas and is available at linguisticanalysistools.org. ARTE automatically calculates different readability formulas for batches of texts (i.e., thousands of texts can be run at a time) and produces readability scores for individual texts in an accessible spreadsheet output. ARTE was developed to help educators and researchers easily process texts and derive different readability metrics allowing them to compare that output and choose formulas that best fit their purpose. The tool is written in Python and is packaged in a user-friendly GUI that is available for use in Windows and Mac operating systems. Correlations for this analysis are reported in Table 1.

Table 1: Correlations between readability formulas and text ease

	FRE	FKGL	NDC	CAREC
Text ease	0.547	-0.517	-0.557	-0.582
FRE		-0.913	-0.829	-0.726
FKGL			0.676	0.579
NDC				0.739

*FRE = Flesch Reading Ease, FKGL = Flesch Kincaide Grade Level, NDC = New Dale Chale, CAREC = Crowdsourced Algorithm of Reading Comprehension

The results indicate strong overlap between the four selected readability formulas and the text ease scores reported by the Bradley-Terry model. The strongest correlations were reported for CAREC while the weakest correlations were reported for FKGL. While strong, the correlations indicate that the readability formulas only predict around 27%-34% of the variance in the reading ease scores. Thus, there are opportunities for improvement in future readability formulas.

5. DISCUSSION

In this paper, we introduced the CommonLit Ease of Readability (CLEAR) corpus. The corpus provides researchers within the educational data mining community with a resource from which to develop and test readability metrics and to model text readability. The CLEAR corpus has a number of improvements over previous readability corpora, which are discussed below.

First, the CLEAR corpus is much larger than any available corpora that provide readability criterion based on human judgments. While there are large corpora that provide leveled texts (e.g., The Newsela corpus), these corpora only provide indications of reading ability based on levels of simplification (i.e., beginning texts as compared to intermediate texts). The corpora do not provide readability criterion for individual texts. Individual reading criteria, like that reported in the CLEAR corpus, allows for the development of linear models of text readability. While there are other corpora that have reading criteria for individual texts, the corpora are much smaller (N = ~20 - 600 texts), and they do not contain the breadth of texts found in the CLEAR corpus. The size of the CLEAR corpus ensures wide sampling and variance such that readability formulas derived from the corpus should be strongly generalizable to new excerpts.

The breadth of excerpts found in the CLEAR corpus is an additional strength. The corpus was curated from the excerpts available on the CommonLit website, all of which have been specially leveled for a particular grade level. The CommonLit texts were supplemented by hand selected excerpts taken from Project Gutenberg, Wikipedia, and dozens of other open digital libraries. The text excerpts were published over a wide range of years (1791-2020) and are representative of two genres commonly found in the K-12 classroom: informational and literary genres. The texts were read by experts to ensure they matched excerpts used in the K-12 classroom and checked for appropriateness using MPAA ratings. All texts were hand edited, so that grammatical, syntactic, and spelling errors were limited, while punctuation was minimally standardized to honor the authors' expression and style.

A final strength is the reading criteria developed for the CLEAR Corpus. Previous studies have developed reading criteria based on cloze tests or multiple-choice tests, both of which may not measure text comprehension accurately [22]. Additionally, while many readability formulas are marketed for K-12 students, their readability criteria are based on a different population of readers. The best example of this is Flesch-Kincaid Grade Level, which was developed using reading tests administered to adult sailors. We bypass these concerns, to a degree, by collecting judgments from schoolteachers about how difficult the excerpts would be for their students to read. This provides greater face validity for our readability criteria, which should translate into greater predictive power for readability formulas developed on the CLEAR corpus.

Lastly, while the purpose of the CLEAR corpus is for the development of readability formulas, the corpus includes meta-data that will allow for interesting and important sub-analyses. These analyses would include investigations into readability differences based on year of publication, genre, author, and standard errors, among many others. The sub-analyses afforded by the CLEAR corpus will allow greater understandings of how variables beyond just the language features in the excerpts influence text readability.

6. FUTURE DIRECTIONS

The next step for the CLEAR corpus is an online data science competition to promote the development of new open-science readability formulas. The competition will be hosted within an online community of data scientists and machine learning engineers who will enter a competition to develop readability formulas using only the reading excerpts and the reported standard errors to predict the Bradley-Terry ease of reading co-efficient scores. Prize money will be offered to increase the likelihood of participation. Once winners from the competition are announced, the winning readability formulas will be included in ARTE so that access to the formulas is readily available to teachers, students, administrators, and researchers. ARTE will also be expanded to include an online interface and a functional API. The online interface will allow end-users to easily upload texts to analyze for readability to better match texts to readers. The API will allow other educational technologies to include text readability formulas in their systems to help select texts for online students.

7. ACKNOWLEDGMENTS

We want to thank Kumar Garg and Schmidt Futures for their advice and support for making this work possible. We also thank other researchers who helped develop the CLEAR corpus and to

the nearly two thousand teacher participants who provided judgments of text readability.

ABSTRACT

We present an algorithm using interpretable convolutional neural networks for mining sequential patterns from event log data. The key to our approach is utilizing structured regularization to achieve sparse parameter values that closely resemble the results of typical pattern mining algorithms, and allows the learned convolution filters to be interpreted easily. Our method can handle both sequences of individual, unique elements and concurrent multiple-element sequences, which represents most situations where sequences may occur in logs of student actions. We applied our structured regularization method to a self-supervised problem predicting future actions from past actions in two different educational datasets as example applications. Furthermore, we generated features from the learned patterns to evaluate the utility of patterns and trained a supervised model with these features to predict academic outcomes via transfer learning. Our algorithm improves the correlation of sequences with outcomes by an average of $r = .131$ on one dataset and $r = .101$ on the other dataset versus a traditional sequential pattern mining algorithm. Finally, we visualize the extracted patterns and demonstrate that they can be interpreted as a sequence of actions.

Keywords

Interpretability, pattern mining, convolutional neural networks, sequential data

1. INTRODUCTION

Convolutional neural networks (CNNs) have been successfully applied to various applications in educational data mining [2, 9, 15, 16, 22, 24]. However, CNNs have a major shortcoming in terms of transparency, because they typically form "end to end" models that make high-level inferences from low-level inputs through a series of opaque layers. Thus, resulting models are often hard to understand and interpret. As a consequence, both instructors and students do not know what kinds of student behaviors actually impact predictions, which is important for understanding and supporting students' learning behaviors and instructors' regulation of student learning. Our work addresses this interpretability issue with CNNs to provide useful features for student modeling applications that utilize CNNs.

One particular application that requires understanding the patterns learned by a model (or any method) is sequential pattern mining. The typical approaches for sequential pattern mining is to identify a set of elements that frequently co-occur; in sequence data, that corresponds to finding a set of events, items, locations, etc. that often happen sequentially in the data [1, 3, 5, 6, 7, 8, 13, 14, 23, 25]. However, those methods of pattern discovery suffer from problems like pattern explosion [21], which occurs when the number of frequent patterns is myriad and the importance (or usefulness) of patterns is uncertain. Consequently, the large number of patterns and prioritization of common patterns can be especially problematic in educational data where low-support patterns may be of interest (e.g., when examining uncommon patterns specific to students from underrepresented demographic groups [20]). In addition, existing methods do not consider the context of a pattern. We aim to train convolutional neural networks that have inherently interpretable features (i.e., discrete absence/presence of a specific student event, like watching a video or posting to a discussion forum) and enforce learning of patterns that predict context. We can thus interpret and utilize these patterns in downstream tasks in the same way that patterns mined via sequence mining methods are.

This paper aims to train a CNN with self-supervised learning to produce a model that can predict future actions based on sequences of events, thereby encouraging the model to learn *predictive* sequences (rather than frequent, unique, or other criteria). The features learned by self-supervised neural networks can be shared by various downstream tasks, as has been demonstrated in previous research. In this paper, we report results from a CNN trained to predict future student activities from past activities, and which thus captures event dependencies.

To show the effectiveness of the proposed method, we applied it two large datasets of student actions logged in learning environments, and utilized transfer learning to predict student outcomes with features derived from the discovered patterns. Specifically, after learning the patterns from student data, we generated feature representations from each

pattern and trained a supervised model to predict students' grade outcomes. We demonstrate that in several cases our results outperformed and were more stable than a typical sequential pattern mining method.

In summary, our contributions include two parts:

1. We trained interpretable CNN filters to explicitly learn patterns consisting of either mutually-exclusive (unique) or concurrent (co-occurring) elements (i.e., actions).

2. We evaluated the quality of patterns learned with our method in a transfer learning task involving prediction of students' outcomes in two datasets.

2. APPROACH

Our goal is to find frequent, predictive patterns with fixed length given sequences of actions done by students (or events, or items). Each step can contain either a single unique action or multiple concurrent actions (depending on the dataset), which can be regarded as sequential actions, events, activities, or other categorical values. In this section, we first explain the framework of the unique event pattern detector, which is the simplest case and perhaps the most widely-applicable. We then describe the solution for the multiple concurrent events pattern detector, as an illustration of how the unique-element approach can be generalized to other variations of the problem. We also describe a "warm-up" strategy, which is necessary to effectively train the pattern mining models. During the evaluation phase, we then derive features from the extracted patterns and apply them to a supervised student outcome prediction task as a measure of the quality of the patterns.

2.1 Unique Element Patterns Detector

We begin with the representation for each action and propose our pattern detection model for unique element sequence mining At the first stage, we use one-hot encoding to represent each action that was taken by students. After that, we use a one-dimensional CNN (i.e., convolving only over time), without bias weights, to extract patterns of action subsequences. We constrain the parameters of CNN filters to directly impose an interpretable, discrete structure on the weights. To predict future actions, we append a fully-connected layer and sigmoid function.

The crux of our approach to discovering interpretable patterns of specific actions is to force each row (corresponding to one step in a sequence) in the CNN filters to have only one parameter that is close to 1, while all others are close to 0. To achieve the desired weight structure, we applied regularization to CNN filter parameters as part of training.

In our method, the primary training objective is to minimize the binary cross-entropy loss for predicting future actions. To enforce discrete structure of the filters of CNN, we utilize regularization to force the sum of each row of the parameters of each CNN filter to 1, while most parameters are 0, thereby leaving only a single 1 corresponding to a single action. We split the approach into two steps. The first step is to ensure the sum of the parameters in each row is close to 1, by adding the loss:

$$L_{\text{r\_sum}} = \sum_{p=1}^{M} \sum_{n=1}^{k} \left(1 - \sum_{j=1}^{d} W_{pnj}^{3}\right)^2 \tag{1}$$

where W refers to weight of convolutional neural network, d is the number possible actions (i.e., the size of each one-hot encoded vector), k is the number of sequence steps in each CNN kernel (i.e., the length of pattern to learn), and M is the number of filters in the CNN (i.e., the number of patterns to learn).

The second step is to encourage parameters to go toward 0 via row-wise L1 loss, leaving only one parameter close to 1 to minimize the $L_{\text{r\_sum}}$ row sum loss.

$$L_{\text{r\_l1}} = \sum_{p=1}^{M} \sum_{n=1}^{k} \sum_{j=1}^{d} |W_{pnj}| \tag{2}$$

Finally, we optimize the following joint objective function during training:

$$L = L_{\text{prediction}} + \alpha L_{\text{r\_sum}} + \beta L_{\text{r\_l1}} \tag{3}$$

where L_r is the whole structured regularization loss, and α and β are coefficients for each regularization part, included to balance the contrasting minimization objectives of $L_{\text{r\_sum}}$ and $L_{\text{r\_l1}}$.

2.2 Multiple Concurrent Elements Pattern Detector

The limitation of the unique action detector is that it can only handle situations where each step in the sequence contains exactly one action. In some circumstances, each step contains many actions or events, such as when a student does several activities logged with the same timestamp. We extended our approach to handle this condition, following the model proposed in the previous section with different constraints. Specially, we force each CNN kernel weight to be either close to 0 or close to 1, ignoring the sum of all weights and thus allowing multiple actions per step. To achieve this goal, the regularization loss for each parameter is minimized when the parameter is either 0 or 1.

We operationalized this regularization goal via the following quadratic equation:

$$L_{\text{r\_m}} = \sum_{p=1}^{M} \sum_{n=1}^{k} \sum_{j=1}^{d} |W_{pnj}^{2} - W_{pnj}| \tag{4}$$

Overall, the objective function is:

$$L = L_{\text{prediction}} + \gamma L_{\text{r\_m}} \tag{5}$$

In $L_{\text{r\_m}}$, γ serves as a weight we tuned to ensure that the structured regularization loss $L_{\text{r\_m}}$ has the desired effect on the CNN weights without over-emphasizing regularization relative to the prediction loss.

The prediction loss for our multiple concurrent elements example is to minimize binary cross-entropy with logits loss, though other loss functions could be applied.

2.3 Warm-up Period

Table 1: Performance comparison (Pearson's r correlation coefficient between predicted and actual student grades) of our method versus CM-SPAM on two datasets. The EPM dataset has grades for five learning sessions (labeled 2–6), while OULAD has grades for seven courses (labeled A–G). Results without warm-up and structured regularization are provided as points of comparison, though the CNN filters without structured regularization are not interpretable.

	EPM					OULAD						
	Course 2	3	4	5	6	Course A	B	C	D	E	F	G
CM-SPAM [5]	-.050	.603	.139	.134	.333	.318	.341	.341	.440	.381	.381	.510
Without warm-up	**-.032**	.729	.425	.055	.430	.324	.414	.514	.433	.456	.394	.544
Our approach	-.092	**.792**	.432	**.227**	**.450**	.330	**.461**	**.532**	**.500**	.498	**.433**	**.563**
Traditional CNN	-.199	.672	**.518**	.209	.375	**.365**	.416	.547	.511	**.506**	.422	.550

Frequently, models learned a local optimum where regularization losses were immediately optimized. To avoid getting stuck at local optima of the objective, we introduced a "warm-up" period to stabilize training [17]. In our experiment, we trained the model without regularization loss for five epochs. Subsequently, we linearly increased the coefficient of the regularization loss over the course of ten epochs.

2.4 Features for Transfer Learning

After learning the set of predictive patterns, we evaluated the utility of learned patterns for a subsequent prediction task (i.e., transfer learning with the learned patterns). We froze the weights of the CNN, then applied the network to generate pattern features for each student's sequence of actions. Note that each sequence is typically much longer than the number of steps in each CNN kernel. Thus, we aggregated filter activations for each pattern by applying basic statistical calculations, including sum, standard deviation, max, min, skew, kurtosis, and different quantiles (10%, 30%, 50%, 70%, 90%).

We then concatenated all of these aggregated values of all extracted patterns to create feature vectors. As a means to judge the quality of the pattern features, we predicted students' learning outcomes with a random forest regression model [4].

3. EXPERIMENTS

In this section, we first introduce the details of two datasets and a baseline pattern discovery algorithm, against which we compare our proposed method (Table 1). We use visualization to examine the learned patterns, and compare transfer learning predictions of student outcomes via Pearson correlations. Finally, we discuss the convergence of our method.

3.1 Datasets

We work on two public datasets that contain learning behaviors of students represented by actions from different courses.

Educational Process Mining (EPM). The EPM dataset [19] contains sequential records of 100 students' activities during 6 laboratory sessions (5 of which have outcome labels) of the digital design course at the University of Genoa. Actions were logged in sequential order, such that each row represented a unique action taken by a student. We describe activities included in EPM dataset, including their frequency, in the Appendix.

Open University Learning Analytics Dataset (OULAD). The OULAD dataset [12] contains data about courses, students, actions of students, and their interactions with a virtual learning environment (VLE; specifically, Moodle) for seven courses, which started from either February or October. We merged multiple semesters of the same course because the patterns in the same courses should be relatively (if not exactly) consistent. The detail of interaction events included in the dataset shown in the Appendix (we merged some infrequent interactions into *other* category because the frequency of occurrence of these interactions was rare).

3.2 Baseline Comparison Method

Typical sequential pattern mining algorithms include those like CM-SPAM, GSP [18], PrefixSpan [8], and SPADE [25]. We use CM-SPAM as a baseline method here because it can easily find patterns of a specific length, which allows fair comparison to our proposed method.

CM-SPAM [5] is a sequential pattern mining algorithm based on Sequential PAttern Mining (SPAM; [3]). SPAM is a depth-first sequential frequent pattern search algorithm. CM-SPAM prunes the SPAM search space to improve computational complexity. We focused on mining patterns with the highest support and matched the length of patterns in our method, selecting 25 of the highest-support patterns to compare against the 25 patterns learned by our method.

3.3 Experimental Setup

We optimized CNN models with Adam [10] for 50 epochs. We tuned hyperparameters including learning rate, loss coefficients, and warm-up duration, based only on results in OULAD course A, to avoid over-fitting hyperparameters to the other six OULAD courses or the EPM dataset. Hyperparameters related to the structure of input and the model architecture we left fixed. Specifically, we convolved CNN filters of length 3 over subsequences of current events of length 5, with stride length 1, and predicted the next 1 event. Models had 25 convolution filters (patterns to learn). We concatenated convolution filter outputs and used a fully-connected layer with sigmoid activation for predicting the next action. We found that the model worked best with the learning rate set to .001, after testing .01, .0075, .005, .0025, and .001.

Components of the structured regularization loss have notably different magnitudes for the unique action case, since the L1 loss component ($L_{\text{r\_l1}}$) is several times larger than

the filter row sum component (L_{r_l1}). We thus applied a relatively large weight for L_{r_l1} and small weight for L_{r_l1} to balance regularization terms and achieve the desired weight structure. We tried different ratios of α/β, including 1, 10, 20, 30, 40, 50, 60, 70, 100, and 200. With $\alpha = 0.075$ and $\beta = 0.0075$, loss converged well. For the warm-up procedure, after testing 1 epochs, 5 epoch, and 10 epochs, we found the model converged best with $n_{total} = 5$ epochs.

For evaluating pattern utility via transfer learning with random forest regression, a higher correlation score (Pearson's r ranging from -1 to 1) represents patterns with higher utility for the downstream task.

3.4 Performance Analysis

Outcome prediction is a natural way to evaluate the utility of patterns [11]. We did so using the transfer learning approach described above, and split each course from each dataset into a train/test set at the student level with a ratio of 2:1 for evaluation.

3.4.1 Quantitative Results

The results of our method are shown in Table 1. Because students' learning actions contain meaningful sequential dependencies with each other, which patterns that happen frequently do not naturally capture. Consequently, CM-SPAM patterns were slightly less useful for inferring high level information (predicting student outcomes), as shown in Table 1. Additionally, instructors may be able to interpret the patterns extracted by our methods to intervene in future courses, given that the extracted patterns are few enough in number (25) to manually review and are related to outcomes. Generally, our approach outperformed traditional sequential pattern mining for almost all courses across the two datasets. Our approach improved the correlation of sequences with outcomes by an average of $r = .131$ on the EPM dataset, and was as good or better than CM-SPAM (r improved by .101) on the OULAD dataset. The result confirmed the usefulness of our predictive patterns derived via self-supervised learning.

3.4.2 Pattern Visualization and Analysis

We visualize the patterns extracted by our approach, demonstrate that they have the desired structure, and compare them with the traditional CNN filters.

To compare our method and typical CNN patterns, typical densely-distributed CNN weights lend little insight into the specific sequences of actions that activate filters (shown in Figure 1). These CNN patterns conflate selection of relevant input actions with weighting those patterns, which prevents their use as a sequence mining method. In addition, typical CNNs only extract patterns that correlate with student outcomes (in fully supervised applications). As a result, they do not necessarily learn dependencies among students actions; it remains to be seen whether our method applied in a fully-supervised model would produce notably different sequences of behaviors. Regardless, the patterns learned by our method are interpretable relative to typical CNN filter weights, which makes them straightforward to utilize for other downstream tasks even though they come from a self-supervised model. However, patterns with multiple concurrent actions are still less easily interpreted than patterns for unique actions given the possibility of many different concurrent actions. They are, however, still straightforward to transfer to downstream tasks.

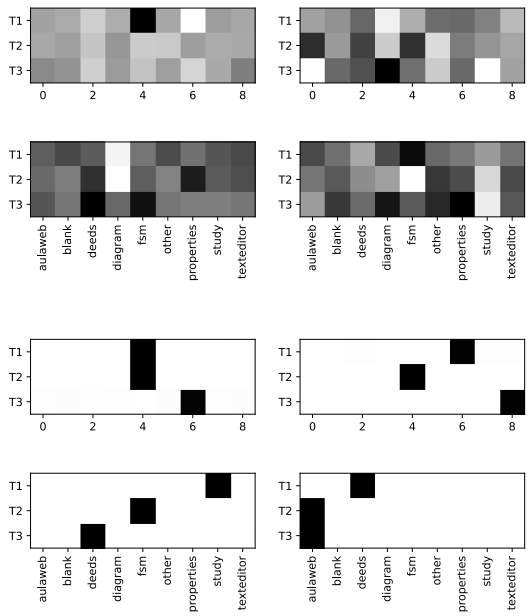

Figure 1: The bottom two rows are randomly-chosen example patterns extracted by our approach based on EPM course 2. The top two rows are traditional CNN filters.

4. CONCLUSION

In this paper, we presented a general self-supervised sequence mining algorithm that works for both sequences of individual actions and multiple concurrent actions. We mined sequential patterns by convolutional neural networks, and applied transfer learning to judge the quality of the extracted patterns for predicting student outcomes as an example downstream prediction task. Our results showed that the extracted patterns were indeed useful, as measured by the correlation between predictions and student outcomes.

We empirically demonstrated that the patterns extracted by our method have similar or higher utility for two prediction tasks than those extracted via a traditional frequent pattern mining algorithm, while the extracted patterns can still be easily interpreted. Furthermore, our approach deals with common pattern mining problems like pattern explosion by training a fixed number of convolutional filters, where filters are selected from the space of all possible filters via stochastic gradient descent.

In summary, our approach is a novel and interpretable way to extract predictive patterns of actions from sequential data.

ABSTRACT

Recent studies proved the existence of a relationship between the complexity of university curricula and graduation rates. As a result, extensive efforts have been done in an attempt to restructure curricula in order to improve graduation rates. In this paper, we propose a new model for evaluating and quantifying the impact of restructuring curricula on graduation rates using a Bayesian network framework. We validate our model by analyzing a common curricular pattern found in most of the engineering programs. We demonstrate its usefulness using actual data for students at the University of New Mexico. We also extend this model to include a helpful tool that can be used to predict student performance. The advantage of our work is characterized by its data-driven nature which makes it more reliable than other proposed models.

Keywords

Curricular analytics, Bayesian networks, education, curriculum complexity, student success, graduation rate

1. INTRODUCTION

Recently a significant amount of work has been done on curricular analytics to show its impact on student success [16, 15, 12, 13, 2, 14]. The work done mainly spots the light on the importance of curricula structure on student performance characterized primarily by graduation and retention rates. These studies argue that the complexity of prerequisite dependencies between the requirements of a curriculum can increase the risk of students stopping out and eventually dropping the school. A lot of work has been done recently identifying factors that help students retain their school and hence graduate at faster rates [6]. This includes new learning pedagogy styles, dorms, flipped classrooms, learning centers, etc. However, such factors solely might fail to significantly contribute to student success if other institutional factors are overlooked; essentially curricula structure [11]. As mentioned earlier, it is already proved that the structure of a curriculum has a direct impact in student success [2, 3]. In this regard, Klingbeil and Bourne considered a case study and analyzed the structure of a common curricular pattern found in most of the engineering programs (Figure 1) [5]. They noticed that, in the sophomore year, most of the engineering programs require Differential Equations as a prerequisite to a domain specific course (in electrical engineering programs, Circuits I is domain specific; in mechanical engineering, Mechanics (statics and dynamics) is domain specific; etc.). They also noticed that all the learning outcomes in Differential Equations, except for solving linear differential equations, are not necessarily required to pass the domain specific course. Thus they suggested to create a new course in the freshman year to teach how to solve linear differential equations along with the Precalculus materials. They called this new course Engineering 101. As a result of this observation, they pointed out that Differential Equations is not required anymore as a prerequisite for the domain central course; only Engineering 101 does. This resulted in a revised curricular pattern shown in Figure 2. Klingbeil and Bourne claim that this new curricular pattern will help students graduate in a timely fashion. This is driven by the fact that the students are not required anymore to follow the long chain of prerequisites before they are allowed to take a domain specific course-as it is the case in the original curricular pattern. This new pattern is now pursued by a number of universities [5]. And to validate the legitimacy of such changes to curricular patterns, a number of researchers came up with different mathematical models that prove the significance of these changes on student success outcomes. Slim et al. came up with a metric that quantifies the complexity of any curricular pattern [16]. Their metric showed that the revised engineering pattern shown in Figure 2 is less complex than that of the original one shown in Figure 1[2]. Thus, according to their metric, students are expected to finish their degrees at a faster pace. Furthermore, Hickeman showed that the revised engineering pattern can significantly improve graduation rates [3]. He proved that by implementing a Monte Carlo simulation through which virtual students are allowed to flow through a curricular pattern. For more details on different models see [2]. Although these models put a mathematical foundation to prove the advantage of restructuring curricula, they still have a major limitation. None of these models include actual student data in their implementations. In other words, these models only show the advantage of restructuring curricular patterns in its abstract state without using any data-driven approaches. This makes the models less reliable in proving the need to revise any curricular pattern. In this paper we propose a data-driven model that uses actual student data to achieve this. Particularly we use a Bayesian Network (BN) model to statistically prove the validity of any effort to restructure

a curricular pattern. This is mainly characterized by adding and removing courses/prerequisites within a curricular pattern which can be neatly captured using a BN. The main motivation behind our proposed model is the ability to use the notion of hidden/latent variables in building a BN. These hidden nodes represent new added courses in the revised curricular pattern. Thus they can be used to check the validity of the changes made to the original curricular pattern and accordingly decide whether to apply these changes or not. It is important to note that our model can be generalized to find the optimal structure of a revised curricular pattern using different methods of structural learning for a BN [1]. However we will not cover this part in our paper. We will leave it for a future work. The remainder of this paper is structured as follows. In Section II we present the details of our proposed framework and provide a case study. In Section III we present a number of applications for our proposed model and show some simulation results. Finally, Section IV presents some concluding remarks.

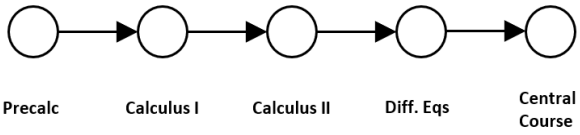

Figure 1: The original curricular pattern found in most engineering programs. The nodes represent the courses and the directed edges represent the prerequisite dependencies.

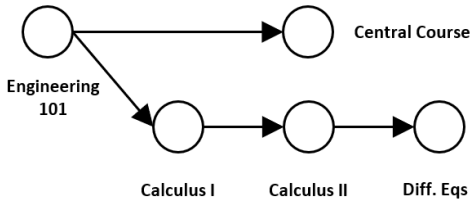

Figure 2: The revised curricular pattern.

2. BAYESIAN NETWORKS AND HIDDEN VARIABLES

A BN is a directed acyclic graph (DAG) representing correlations between a number of random variables [4]. The graph-like structure reflects a confined representation of the joint probability distribution underlying these variables. The presence of an edge between two nodes indicates the existence of a relationship between two variables and the direction of the edge indicates the direction of the causal relationship. That is a directed edge from node A to node B indicates that A causes B. In BNs, these types of relationships are quantified by conditional probability tables (CPTs). The main feature of a BN is its compact representation of the conditional dependencies of the random variables. However, in some applications the BN gets complicated and thus in this case adding hidden nodes would be essential for two main reasons [8]:

1. **Knowledge discovery**: reveals interesting relationships among the variables of the data
2. **Lower complexity**: attains lower structure complexity of the network

For example, consider the case where we observe a bunch of variables representing different patient's symptoms. The joint probability distribution for these symptoms might be highly connected. In this case, the BN representation of these symptoms would be highly

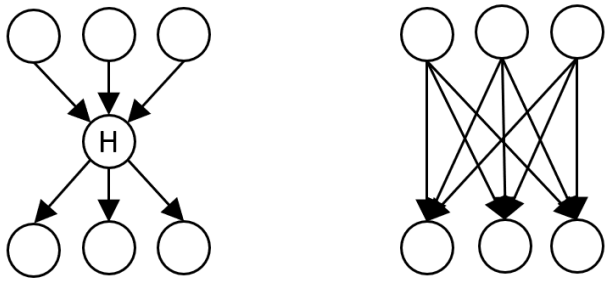

Figure 3: Two DAGs (one with a hidden node and the other without) representing the relationship between symptoms, causes and mediating factors. Symptoms, such as chest pain, are represented by the leaves. Causes, such as smoking and diet, are represented by the roots. Mediating factors, such as heart disease, are represented by the hidden nodes. This figure shows how hidden nodes can reveal a better understanding of the relationship between variables by attaining a lower structure complexity of the network.

complicated. However if we introduce a "cause" node representing the underlying disease for these symptoms then we can get a noticeably simpler network. We call this cause node a hidden node. Figure 3 (inspired from [7]) illustrates this example in more details. In a similar scenario in an educational context, a curricular pattern can be modeled as a BN. A node maybe a course, and the states of the node would be the possible letter grades (i.e., $A, B+, B, C+$, etc.). A directed edge from course A to course B indicates that the performance in A influences that in B. In this context adding a hidden node to the BN is equivalent to adding a new course to a curricular pattern. This hidden node might represent the underlying prerequisite course that needs to be taken prior taking other courses. This notion constitutes the bulk of our proposed work and the subsequent sections elaborate more about this idea. Following this notion, restructuring the BN of any curricular pattern would include these steps:

- Removing an existing course(s) (i.e., removing a node)
- Adding a new course(s) (i.e., adding a hidden node)
- Removing an existing prerequisite(s) (i.e., removing a directed edge)
- Adding a new prerequisite(s) (i.e., adding a directed edge)

We denote the restructured BN by R, characterizing the revised curricular pattern. Once R is constructed, we fit the CPTs using actual student data, denoted by D, and then compute the likelihood of R, $p(D/R)$. Similarly, we denote by O the BN of the original curricular pattern. Once it is constructed, we compute its likelihood, $p(D/O)$. If $p(D/R)$ is greater than $p(D/O)$, then the revised version of the curricular pattern fits the student data better than that of the original one. In this case, the proposed revised curricular pattern can be a good candidate to replace the original one. To elaborate more about this, we present a case study in the following section.

2.1 Engineering Curricular Pattern: A Case Study

In this section, we consider, as a case study, the engineering curricular patterns shown in Figure 1 and Figure 2. Recall that the graph in Figure 1 represents the original pattern whereas that in Figure 2 represents the revised one. For these two graphs, we construct two BNs denoted by O and R respectively. These two BNs are shown in

Course Number	Course Name
MATH 150	Precalculus
MATH 162	Calculus I
MATH 163	Calculus II
MATH 264	Calculus III
MATH 316	Differential Equations
PHYC 160	General Physics I
PHYC 161	General Physics II
ECE 203	Circuits I
ENG 101	New Course Proposed

Table 1: Engineering courses taught at freshman and sophomore level at UNM.

Figure 4 and Figure 5. The variables used to construct O and R are shown in Table 1. These variables represent actual courses taught at the University of New Mexico (UNM). The states of each of these variables are the letter grades: A, B, C and D/F where D and F are assumed to represent one state. The CPTs for both O and R are computed using a dataset, denoted by D, for $1,000$ UNM student. Each row in this dataset contains the letter grades achieved in the courses shown in Table 1. Some grades for some students were not available. Thus, the dataset included missing values. In addition, ENG 101 in Figure 5 is considered a hidden variable because it is supposed to represent the new proposed course and thus we do not have the letter grade values. Therefore, to compensate for hidden and missing values in our dataset, we used the expectation-maximization (EM) method to compute the CPTs for O and R [9]. Using EM, we computed the ratio of the likelihood, $\frac{p(D/R)}{p(D/O)}$, to be 2.89. This means that R fits the student data better than O. This result suggests that the proposed revised curricular pattern is a good candidate to replace the original one. Not only does it have a less complex structure but also the revised curricular pattern has the potential to improve student performance when compared to the original pattern. We concluded this using actual student data which is an advantage over other proposed models in literature [2]. In the following sections we present more applications of BNs in the context of course network.

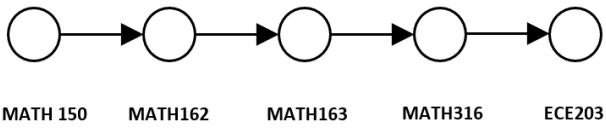

Figure 4: The original curricular pattern found in the electrical engineering curriculum.

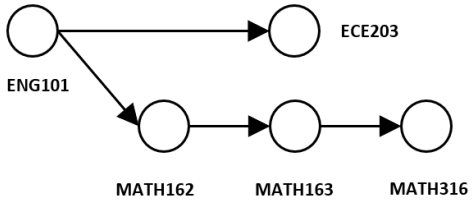

Figure 5: The revised version of the curricular pattern in the electrical engineering curriculum.

3. INFLUENCE OF STUDENT CHARACTERISTICS ON ACADEMIC PERFORMANCE

As mentioned earlier, many institutions are dedicating lot of efforts on student success. Colleges and universities are applying ever more sophisticated analytical tools to track their student progress in an attempt to improve their performance characterized mainly by graduation and retention rates. Intuitively, early indicators of student performance in this context is crucial to provide suitable interventions when needed. Thus predicting the performance of students in future courses is essential to achieve it. In this regard, historical information about previous academic achievement of a student could be used to project future performance. For example, a student who receives a 'B' in Calculus I is expected to receive a better grade in Calculus II compared to those who receive a 'D'. A BN in the context of course network can capture the correlation in performance between such courses. Further, it can be used to predict the letter grades of a student in subsequent classes based on the grades of previous classes. The accuracy of prediction can further be improved by adding other factors related to student characteristics. Factors such as age, gender, high school GPA, socioeconomic status, etc. proved to influence student performance [11]. For this reason, it would be rational to add such factors as additional variables to the BN of a course network. The advantage of using a BN model to capture all these variables together is two-folded: it can be used as a knowledge discovery model that can neatly display the correlation between the variables and also it can be used as an inference tool to predict student performance. In this section, we construct a BN for eight engineering courses along with five other variables representing student characteristics. The eight courses are: MATH 150, MATH 162, MATH 163, MATH 264, MATH 316, PHYC 160, PHYC 161 and ECE 203 (Table 1). These courses are considered to be the most crucial classes at the freshman level. As for student characteristics, we considered Gender, ACT score, and high school GPA. As mentioned earlier the student characteristics are proved to influence student performance. Thus it would be interesting to discover and visualize how all these variables are related to each other. In the following section we show the constructed BN along with some applications. However, it is important to mention here that a similar work has been done in [10]. The authors of this work used a domain expert to construct the BN for these variables. This means that the process of constructing the BN is not automated and doesn't guarantee a good fit to the student data. In this paper, however, we automated the process of learning the structure of the BN using a score-based learning algorithm [1]. Particularly, we used the hill climbing (hc) greedy search that explores the space of the DAGs by single-arc addition, removal and reversals.

3.1 A BN for Engineering Courses

To construct and validate our framework, we collected a dataset of 3,000 undergraduate student in the college of engineering at UNM. The dataset represented different demographical and academical variables of the students. The states for each of these variables are show in Table 2. It is important to note that MATH 162 is the prerequisite for MATH 163, MATH 163 is the prerequisite for MATH 316 and MATH 264, and MATH 316 is the prerequisite for ECE 203. The constructed BN is presented in the graph shown in Figure 6. It is tempting to interpret this graph in terms of causality. In particular, it seems that ACT score, high school GPA and gender, in contrast to ethnicity, causally influence the performance of students in these engineering courses. Also, this graph shows that the performance in PHYC 160 influences that in MATH 264 and ECE 203. This is an interesting observation because, according to the department policy, PHYC 160 is not a required prerequisite for neither of these courses. Though it has an impact on both these courses. Another interesting observation is the absence of any correlation in performance between MATH 316 and ECE 203 even though MATH 316 is a prerequisite to ECE 203. This observation confirms the fact that

Variable	States
Gender	Female, Male
Ethnicity	7 different ethnicities
ACT score	Integer between 10 and 36
High school GPA	Real value between 1 and 4
MATH 150,162,163,264,316	A,B,C, D/F
PHYC 160,161	A,B,C, D/F
ECE 203	A,B,C, D/F

Table 2: The courses and the student characteristics used to build the BN.

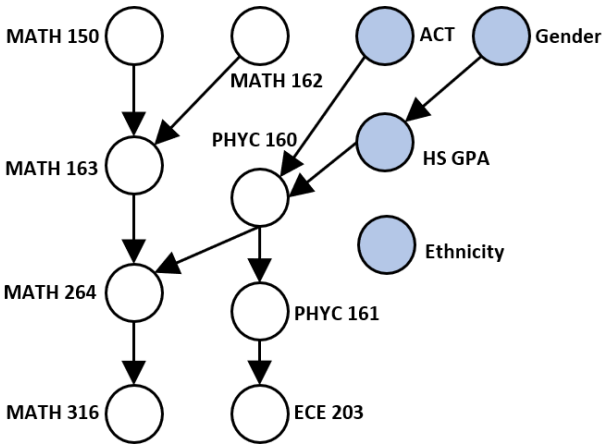

Figure 6: The constructed BN using UNM student data.

only a small portion of the learning outcomes in MATH 316, namely the ability to solve linear differential equations, are actually used in ECE 203 and the absence of a link between these two courses proves it. This is another evidence that supports the claim that it is needed to restructure the original curricular pattern shown in Figure 1.

4. CONCLUSION

In this paper we presented a framework that models a curriculum as a Bayesian Network (BN). We showed that this model, in the context of a course network, can be used to quantify any effort to restructure curricular patterns. In particular, we used the notion of hidden variables to achieve this. We validated our proposed model using a common curricular pattern found in most of the engineering programs. For that, we used actual data for students at the University of New Mexico. The results showed that the likelihood of the revised version of the engineering curricular pattern is higher than that of the original one. This suggests that the revised version can help students perform better in their courses as well as graduate at a faster pace. The advantage of our model over other proposed models in literature is its data-driven nature which makes it more reliable. Furthermore, we extended our model to use it as a knowledge discovery and inference tool. Particularly we added variables related to student characteristics (e.g. gender, ACT score, high school GPA, etc.) and showed how they can influence student performance. We also showed how to exploit the constructed BN to predict the grades of a student in following semesters based on grades of previous semesters.

ABSTRACT

Feedback is a crucial element of a student's learning process. It enables students to identify weaknesses and improve self-regulation. However, studies show this to be an area of great dissatisfaction in higher education. With ever-growing course participation numbers, delivering effective feedback is becoming an increasingly challenging task. Hence, this paper explores the use of automated content analysis to examine feedback provided by instructors for good feedback practices measured on *self*, *task*, *process*, and *self-regulation* levels. For this purpose, four binary XGBoost classifiers were trained and evaluated, one for each level of feedback. The results indicate effective classification performance on self, task, and process levels with accuracy values of 0.87, 0.82, and 0.69, respectively. Additionally, inter-language transferability of feedback features is measured using cross-language classification performance and feature importance analysis. Findings indicate a low generalizability of features between English and Portuguese feedback spaces.

1. INTRODUCTION

Despite widespread recognition of feedback's importance to learning [23, 29, 10], much of the current literature indicates a pervasiveness of low quality feedback in higher education [13]. Feedback quality is consistently rated one of the greatest causes of dissatisfaction for higher education students [9]. LA researchers are actively exploring automated feedback solutions that can enable instructors to efficiently identify and employ good feedback practices, and improve the speed of feedback delivery to students [15]. In that vein, several studies [17, 19, 28, 30] have examined the use of data mining methods to generate automated textual feedback. These analyses are often limited to domain specific areas such as computer programming or writing, or lack of grounding in educational theory. Much less work has gone into the exploration of automated domain-agnostic analysis to identify good feedback practices [4, 24]. Progress in such areas can enhance the instructor's ability to provide effective feedback comments and analyze features associated with good feedback practices for generalizable feedback generators. Therefore, this study aims to answer the following Research Questions (RQs):

1. To what extent can the automated analysis of feedback messages be used to identify good feedback practices?
   (a) How accurate are the predictions that are made about these feedback practices?
   (b) What are specific features of text that can be used to predict the use of good feedback practices?
2. How transferable are the identified feedback features to text written in different languages?

2. METHOD

2.1 Data

The dataset used in the current study consisted of feedback comments provided by instructors in Learning Analytics, Software Engineering, and Environmental Studies courses. A total of 2,092 observations were taken; 1,000 Portuguese records and 1,092 English records.

2.2 Coding Scheme

This study utilized Hattie and Timperley's [14] four levels of feedback due to its suitability for textual analysis due to its focus learning tasks, learning process, and self-regulation Cavalcanti et al. [4]. Hence, feedback examples were coded using Hattie and Timperley's [14] proposed four levels of feedback (see Table 1).

Feedback examples were coded by experts using instructions of Hattie and Timperley's [14] study. Each feedback record was examined by two expert coders separately. After this step, the differences between each pair of experts were compared. For the Portuguese feedback examples, the inter-rater agreement reached 72.2% with a Cohen's kappa (inter-rater ability considering chance [7]) of 0.44. The English feedback comments had inter-rater agreement of 63.8% and Cohen's kappa of 0.38. These measures met expectations for content analysis experimentation [20].

Ikenna Osakwe, Alexander Whitelock-Wainwright, Guanliang Chen, Rafael Ferreira Mello, Anderson Pinheiro Cavalcanti and Dragan Gašević "Towards automated content analysis of feedback: A multi-language study". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 771-776. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Table 1: Four levels of feedback identified by Hattie and Timperley [14]. Each level specifies different elements that the feedback is targeting and can be regarded as hierarchical, ranging from general comments made about the student themselves up to directives on how to improve self-regulation.

Level	Description	Example
Feedback about the self (FS)	Personal evaluations about the learner	"You are a bright student"
Feedback about the task (FT)	How well tasks are understood or performed	"You need to include more about the Treaty of Versailles."
Feedback about the process (FP)	Processes needed to understand or perform tasks	"You need to edit this piece of writing by attending to the descriptors you have used so the reader is able to understand the nuances of your meaning."
Feedback about self-regulation (FR)	How to improve self-regulation	"You already know the key features of the opening of an argument. Check to see whether you have incorporated them in your first paragraph."

Table 2: Number of instances for each class in the training and test datasets for each level of feedback.

		Class 0	Class 1	Total
FS	**Train**	1149 (82.19%)	249 (17.81%)	1398 (70%)
	Test	567 (82.17%)	123 (17.83%)	690 (30%)
FT	**Train**	602 (43.06%)	796 (56.94%)	1398 (70%)
	Test	297 (43.04%)	393 (56.96%)	690 (30%)
FR	**Train**	1290 (92.27%)	108 (7.73%)	1398 (70%)
	Test	637 (92.32%)	53 (7.68%)	690 (30%)
FP	**Train**	808 (57.80%)	590 (42.20%)	1398 (70%)
	Test	399 (57.83%)	291 (42.17%)	690 (30%)

The annotation process led to a dataset with four sets of binary classes: class 0 if a feedback message did not belong to a particular level; class 1 if the feedback message belonged to the feedback level.

2.3 Feature Engineering

Feature extraction was informed by relevant studies [4, 24, 16]. The studies promote the use of linguistic features such as those developed in LIWC (Linguistic Inquiry and Word Count) [27] and Coh-Metrix [11] over traditional textual features such as lexical N-grams or Part-Of-Speech. According to Kovanović et al. [16], these features encourage overfitting by inflating the feature space. Additionally, these traditional features are data dependent and thus make it difficult to define the feature space beforehand [16]. Hence, we used feature sets that incorporated 86 LIWC [27] features, 78 Coh-Metrix [11] features, and two additional features, which are relevant to this content area — number of named entities and language of delivered feedback.

2.4 Analysis

2.4.1 Data Analysis and Pre-processing

For the general classifier, feedback examples from both the English and Portuguese datasets were combined and split into 70% training and 30% test sets (Table 2). The training data suffered from class imbalances; particularly at the FS and FR levels.

2.4.2 Handling Class Imbalance

Studies have shown class imbalances can have a negative impact on model prediction performance [26]. To alleviate the class imbalance problem, sampling algorithms are often employed to adjust the ratio of represented classes. SMOTE is a popular oversampling method that analyzes the data records in a two-dimensional vector space of given classes and generates data points as a linear combination of existing data points [5].

2.5 Model Selection and Evaluation — RQ1a

Decision tree ensembles are widely regarded classification algorithms that are well suited to feedback analysis [4, 24]. This is due to their white-box properties, easy interpretability, high accuracy and ability to identify important features in a dataset [4, 24, 6, 8].

This study employed a decision tree implementation called XGBoost [6]. XGBoost has been shown to outperform Random Forest on numerous classification tasks [22, 31]. The algorithm utilizes gradient boosting, which involves sequentially combining models (in this case, decision trees) that predict the residuals or errors of previous models at each iteration to improve overall accuracy [6]. XGBoost is ideal due to their superior accuracy and their implicit analysis of feature importance [6]. Four binary XGBoost classifiers were trained; one for each level of feedback.

2.5.1 Feature Analysis —- RQ1b

The outputs of decision tree models can be analyzed with tools such as SHAP (SHapley Additive exPlanations) [18].Given an input of a machine learning model and data records, SHAP leverages the concept of Shapley values by measuring the average marginal contribution of a feature over all possible permutations. SHAP can diagnose the most impactful features using their SHAP value, which is the mean absolute contribution of each feature [18]. A higher SHAP value for a feature implies a greater importance compared to another feature.

2.5.2 Feature Transferability — RQ2

To measure the transferability of features across languages, the dataset was split by language, creating Portuguese and English feedback datasets. Each of these datasets was split into training and test splits (70% training and 30% test set), and binary classifiers were trained and tuned, resulting in English feedback trained classifiers, and Portuguese feedback trained classifiers for each level of feedback, with the exception of the FR level. For the Portuguese feedback examples, the FR level had just eight positive instances out

Table 3: Performance of the classifiers trained to address research question RQ1 on the combined dataset involving both the English and Portuguese datasets. Legend: ACC – Accuracy; K – Cohen's kappa; F1 - F1 Score.

	FS			FT			FR			FP		
Class Balancing	ACC	K	F1	ACC	K	F1	ACC	K	F1	ACC	K	F1
None	**0.88**	**0.52**	**0.58**	**0.82**	0.64	**0.83**	**0.92**	0.00	0.00	0.68	0.33	0.57
SMOTE	0.87	0.51	**0.58**	**0.82**	**0.65**	**0.83**	0.91	0.04	0.07	**0.69**	**0.35**	**0.59**

of 1,000 records, which was not enough to train a machine learning algorithm [12]; hence, this level of feedback was excluded from all transferability analysis.

Once the English and Portuguese trained classifiers were developed, feature transferability was measured by i) *the inter-language prediction performance*: the prediction performance (measured by accuracy, F1 score and Cohen's κ) of the English trained classifier on the English test set was compared to the predictor performance on the Portuguese test set for the FS, FT, and FP levels of feedback. The same process was repeated for the Portuguese trained classifier; ii) *A comparison of significant features*: The most important features for the English and Portuguese trained classifiers are compared at the FS, FT and FP levels of feedback.

3. RESULTS AND DISCUSSION

The goal of this study was to examine how accurately one can model the feature space of good feedback practices, and how this feature space varies across languages. In that vein, four research questions were answered using novel statistical learning methodologies, with a view of promoting good feedback practices at scale.

3.1 Model Performance —- RQ1a

Research question RQ1 focused on investigating the extent to which the automated analysis of feedback messages can be used to identify good feedback practices. Four binary classifiers were developed using a variety of features (see 2.3) The best performing models were effective in identifying FS, FT and FP. While not a direct comparison due to the addition of the English feedback examples, the models achieved better results over those reported by Cavalcanti et al. [4]. The classifiers were able to improve accuracy by 0.07 and 0.05 for FT and FP, respectively and increase kappa values by 0.11, 0.35, and 0.06 for FS, FT, and, FP, respectively.

Similar to previous works [4], the FR classifier was not as effective in identifying instances. The model obtained a poor kappa of 0.06, which was likely caused by the model's poor ability of detecting positive cases of FR. Poor performance on this level was due to the significantly lower cases of positive instances as compared to the other levels of feedback.

3.2 Feature Analysis —- RQ1b

The focus of research question RQ1b was analyzing the most important textual features associated with the four levels of feedback. Hattie and Timperley [14] state that FS involves evaluations of the person, which are often a form of praise. The current findings add weight to this claim, as those features found to be most important in predicting the FS level were affective processes (particularly, positive emotions) and social processes, which align with the concept of praise. FS is often thought to be the least effective level of feedback [3, 14] and relatedly, the FS classifier had a negative association with discrepancy words; this might indicate FS comments have little actionable information or insight.

FT is sometimes referred to as corrective feedback and provides information on details related to task accomplishment such as correctness or behavior. Accordingly, this study found the predictors most associated with FT were those that related to the amount of information provided. Specifically, higher values of word counts, frequency of content words and minimum frequency of content —- all of which can be linked to greater information —- were positively correlated with observance of FT. Hattie and Timperley [14] suggest instructors not to rely solely on FT, but rather to view it as a process that moves the student to FP and FR. This theory is backed by the finding of strong negative association of causation words and FT; hence, FT comments were less likely to illustrate the causes of the student's failings, which is essential for the learner's self-regulation [14, 3, 21].

Compared to FT, FP is believed to promote a deeper understanding of learning as it enables the identification of relationships between resources and output, and the development of stronger cognitive processes. To achieve this, Balzer et al. [1] state FP should concern information about actual relations in the learning environment, relations which have been recognized by the learner, and relations between the learning environment and the learner's perceptions. Therefore, the value of FP comes from providing useful information on relationships. The findings of this study corroborate the theoretical views of FP. Amongst the most important features for FP were frequency of content words, adverbs, negative connectives and discrepancy words. These imply that FP comments were tied to providing new and corrective information. Other significant features can be tied back to relationships; including frequency of semicolons (semicolons are often used to link together ideas) and features associated with space and relativity.

According to Butler [3], one of the goals of FR should be to improve the student's ability to monitor current progress and use that information to form effective learning strategies. Accordingly, some of the most important predictors of FR were greater present and future focused processes.

3.3 Feature Transferability -— RQ2

To address research question RQ2, we studied inter-language classifier performance, and compared the most significant features for classifiers trained on different language feedback. Barbosa et al. [2] used similar linguistic features to those used in this project, such as LIWC and Coh-Metrix, to study cross-language classification of cognitive presence in online discussions, and found features to be independent of language; hence, we expected to find a moderate level of generalizability of feedback features across languages. However, our findings indicate a low transferability of feedback features. As seen on Table 5, the average accuracy differential on inter-language performance amounted to -0.06, -0.59, and -0.26; while the average kappa differential was approximately -0.50, -0.27, and -0.33 for FS, FT, and FP, respectively. Likewise, the Portuguese and English trained classifiers showed minimal overlap in their most important

Table 4: Top 10 important features are measured using SHAP and displayed from most to least important for FS, FT, FR and FP classifiers.

FS			FT		
Variable	**Description**	**SHAP**	**Variable**	**Description**	**SHAP**

features across all levels of feedback.

One possible explanation for this finding might be the difference in courses represented in the English and Portuguese datasets. English feedback examples were primarily from STEM related courses, including Environmental Studies and Software Engineering, while Portuguese feedback examples had more of a mix, hailing from Biology and Literature courses. Hence, the different nature of represented courses might have influenced the transferability analysis.

Another explanation for the low transferability of features might be the cultural differences in communication. For instance, at the FS level of feedback, we observed greater association of friendship and social processes for the English feedback; i.e. English instructors might have displayed a greater level of familiarity with students. As an instructor can be viewed as an authority figure, this difference might be related to whether a culture is "horizontal", and therefore emphasizes equality, or "vertical", and emphasizes hierarchy [25]. The implications of this finding would indicate instructors will need to consider the cultural backgrounds of the learner while delivering feedback for improved efficacy.

4. CONCLUSION AND FUTURE RESEARCH

This study proposed four main contributions. First, this study explored how accurately a trained model can identify the presence of different feedback practices. The constructed classifiers, using primarily linguistic and psychological features, were effective in identifying the presence of FT, FP and FS levels of feedback and showed better performance than similar works in this content area; however, the FR classifier was marred by a lack of adequate data. The implications of these results provide a proof of concept for a tool that can automatically analyze and potentially diagnose the contents of an instructor's feedback. This promotes the understanding and utilization of good feedback practices to improve their efficacy on learner adoption.

Another goal of this paper was to identify the prominent textual features of good feedback practices. Identified features were able to corroborate the findings of educational research on feedback theory. The presented findings can be further used to inspire the design of future automated feedback generators, e.g., intentionally including the prominent terms specific to different feedback practices when generating feedback.

Finally, this study conducted an analysis of the transferability of feedback features across languages. Feedback tools should be generalizable enough to cater to a variety of languages. By analyzing the transferability of feedback features across languages, this study aimed to enhance the global adaptability of current and future feedback tools. The findings indicate feedback features have low transferability between feedback examples delivered in English and Portuguese. However, a more expansive study is suggested, with a greater size and variety of feedback from different languages.

Academic Integrity during the COVID-19 Pandemic: a Social Media Mining Study

Mohammad S. Parsa

ABSTRACT

Academic integrity has been a frequently reported challenge in online education. Given the widespread transition to online program delivery during the COVID-19 pandemic, we ask the following question: *How do college students feel about online cheating?* Our analysis is based on academic discussions on the Reddit social curation platform in Fall 2020 and, for comparison, Fall 2019. We found more discussions related to cheating in 2020 than in 2019, and the topics have expanded from plagiarism in programming assignments to online assessments in general. Topic modelling of the Fall 2020 discussions revealed three concerns raised by students: that cheating inflates grades and forces instructors to increase the difficulty of assessments; that witnessing cheating go unpunished is demotivating; and that academic integrity policies are not always communicated clearly.

Keywords

academic integrity, online education, social media, text mining

1. INTRODUCTION

Recent studies have reported that online academic misconduct has increased during the COVID-19 pandemic [12, 6, 2, 4, 3, 18]. We therefore ask the following question in this paper: *How do college students feel about online cheating?* To answer this question, we turn the Reddit social curation platform (reddit.com). Reddit hosts over 100,000 user-created discussion communities refereed to as *subreddits*. Within a subreddit, users create posts that other users comment on. Subreddit names begin with "r/" and correspond to the subreddit topic, e.g., r/politics or r/relationship_advice.

Descriptive subreddit names make it easy to locate discussions about specific topics or discussions initiated by various kinds of users. Of interest to our study are over 80 subreddits corresponding to Canadian and U.S. universities, which we call *academic subreddits*. We collected all posts and comments on academic subreddits created during the Fall 2019 and Fall 2020 semesters (September through December inclusive) that match at least one keyword related to cheating, such as 'cheat' or 'misconduct'.

Mohammad Parsa and Lukasz Golab "Academic Integrity during the COVID-19 Pandemic: a Social Media Mining Study". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 777-781. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Our analysis consists of two steps. First, collecting data from the same time period in 2019 and 2020 allows us to compare cheating-oriented discussions from before the pandemic, when classes were held in person, and during the pandemic, with most courses delivered online. To do so, we train a logistic regression classifier to distinguish between Fall 2019 and Fall 2020 content based on the words used. Next, we analyze Fall 2020 discussions in detail. We apply the Non-negative Matrix Factorization algorithm [20], which clusters posts and comments based on the words used and allows us to identify common discussion topics.

Related Work: Social media have become a go-to source of public opinion on a variety of topics. In particular, academic subreddits have been analyzed in recent work on students' mental health [1, 16], but academic integrity was not discussed. The closest works to ours are those in [4] and [5], which interviewed a small set of undergraduate students and educators. The participants identified some positive aspects of online education, but expressed concerns about cheating and the level of difficulty of online assessments. Our social media analysis explores these and other concerns in detail.

2. DATA AND METHODS

Previous work on students' mental health [1, 16] identified 83 *academic* subreddits corresponding to major U.S. and Canadian universities. We analyze the same subreddits in this paper, listed in the first column of Table 1 (U.S.) and Table 2 (Canadian). We collected all posts and comments on these subreddits from the Fall 2019 semester, when classes and examinations were held in person, and the Fall 2020 semester, when most campuses moved to online delivery (September-December inclusive). We downloaded the data using a publicly-accessible Reddit interface at pushshift.io.

Next, we retain only those posts and comments that contain at least one of the following keywords: 'cheat', 'plagiari', and 'misconduct'. We perform *substring* matching, meaning that 'plagari' also matches 'plagiarize' and 'plagiarism'. Tables 1 and 2 report the number of posts ("P") and comments ("C") on each U.S. and Canadian academic subreddit, respectively, in Fall 2019 and Fall 2020. The "Before" numbers correspond to all posts and comments. The "After" numbers correspond to posts and comments that matched at least one cheating-related keyword; note that there are three times as many such posts and comments in 2020 than in 2019 (7,809 vs. 2,524) even though the total number of posts and comments on academic subreddits has not changed much from 2019 to 2020 (see the total "Before" numbers in the last row of Tables 1 and 2).

We then perform standard text pre-processing. Following previous work on Reddit topic modelling [10, 16], we remove posts and

Table 1: Number of posts and comments on U.S. academic subreddits in 2019 and 2020 before and after filtering to find cheating-related discussions (C: Comments, P: Posts).

comments with fewer than 40 or more than 4000 characters: short ones are unlikely to be meaningful (and may correspond to URLs), while long ones may mention more than one topic. We also remove stopwords and lemmatize the remaining words using the Python NLTK parser.

To distinguish between cheating-related discussions before and during the pandemic, we train a logistic regression classifier to predict whether a post or comment was written in Fall 2020 or Fall 2019. We use term frequency–inverse document frequency (TF-IDF) word scores as features in the model. We chose logistic regression due to its interpretable nature: words with positive coefficients represent Fall 2020 content and words with negative coefficients represent Fall 2019. Our model obtained a 10-fold cross-validation accuracy score of 73%, a precision of 76%, a recall of 96% and an F1-score of 86%.

(We also tested logistic regression models with additional features, including word bigrams, the sentiment of the post or comment (computed using the Valence Aware Dictionary and Sentiment Reasoner (VADER) [8]) and linguistic features computed using Linguistic Inquiry and Word Count (LIWC) [17]. After adding these features, accuracy improved by two percent to 75%. However, none of these additional features were assigned large coefficients and therefore are not considered further in the remainder of the paper.)

Finally, we apply the Non-negative Matrix Factorization (NMF) topic modelling algorithm [20], which was used in prior work on Reddit mining [14, 7, 11], on the Fall 2020 posts and comments that match at least one cheating-related keyword. We again represent each post and comment using the TF-IDF scores of the words occurring in it. NMF clusters documents into topics and assigns a list of representative terms called *topic descriptors* to each topic. NMF also calculates the "representativeness" score of each topic descriptor, and we report the top-10 highest-scoring descriptors for each topic. Moreover, we report top-10 frequent word n-grams (for n up to three, i.e., sequences of up to three consecutive words) for each topic.

Additionally, NMF assigns a *closeness score* for each document-topic pair, indicating how close the document is to a topic. To obtain more information about the topics produced by NMF, for each topic, we manually inspect 5% of the posts and comments with the highest closeness scores.

NMF requires the number of topics as input. Following previous work [15], we run NMF to produce between 5 and 50 topics and compute the *coherence* score for each. Coherence measures the extent to which the top representative terms representing each topic are semantically related (higher is better). We obtained the highest scores for 5 and 20 topics. A preliminary analysis of the NMF output at five topics revealed that most topics consisted of several discussion themes. This observation suggested that a larger number of topics may be more appropriate, and thus we selected 20 topics.

3. RESULTS

We begin with the results of our logistic regression analysis, shown in Table 4 in the Appendix. The most positive coefficients, predicting Fall 2020 posts and comments, include 'chegg' (an online platform for answering college and high school questions), as well as words related to online proctoring such as 'proctor', 'proctorio', 'zoom', 'camera', 'webcam' and 'privacy'. The most negative coefficients, predicting Fall 2019 posts and comments, suggest in-person examinations ('cheat sheet', 'bring', 'sit') and programming assignments and projects ('code', 'program', 'project').

Next, we move to topic modelling. Table 3 shows the NMF topic descriptors, the frequent n-grams, and the percentage of posts and comments assigned to each topic. We group the topics into the following three categories based on the information in Table 3 and manual inspection of a sample of posts and comments.

First, about 40% of the posts and comments include concerns about cheating leading to grade inflation, which in turn leads to assessments becoming more difficult. Students have observed grade inflation (Topic 13) and expressed concerns that Fall 2020 examinations will be more difficult to reduce the class average (Topics 1 and 20). Moreover, students commented on various methods used by

Table 3: Fall 2020 topic modelling results

#	Topic descriptors	Frequent N-grams	%
1	work, really, time, way, learn, try, hard, help, school, good	*'feel like', 'work hard', 'first year', 'high school', 'office hour', 'mental health', 'learn material', 'get catch', 'make sure', 'in person'*	10.4
2	say, academic, email, integrity, case, code, worry, report, flag, mean	*'academic integrity', 'academic dishonesty', 'integrity violation', 'academic integrity violation', 'get flag', 'student conduct', 'academic offense', 'would say', 'get catch', 'even though'*	10.3
3	think, probably, pretty, fine, worry, fair, sure, reason, away, good	*'think would', 'think people', 'think get', 'like think', 'get away', 'make sure', 'really think', 'feel like', 'think go', 'think make'*	6.4
4	student, university, honest, case, punish, international, chinese, issue, school, conduct	*'international student', 'student get', 'many student', 'chinese student', 'honest student', 'academic integrity', 'student would', 'mental health', 'academic dishonesty', 'first year'*	5.7
5	know, want, let, wrong, happen, person, tell, need, mean, consequence	*'let know', 'want know', 'know people', 'get catch', 'know would', 'lot people', 'feel like', 'know know', 'know go', 'student know'*	5.5
6	prof, email, mark, ta, ask, tell, send, chance, midterm, try	*'prof make', 'first year', 'email prof', 'open book', 'feel like', 'prof say', 'prof ta', 'prof would', 'make sure', 'ask prof'*	5.4
7	question, answer, time, ask, quiz, look, minute, similar, wrong, google	*'answer question', 'go back', 'multiple choice', 'short answer', 'exam question', 'one question', 'look answer', 'question answer', 'question exam', 'choice question'*	5.1
8	test, open, book, note, close, online, tab, internet, easy, search	*'open book', 'open note', 'make test', 'take test', 'test open', 'close book', 'book exam', 'open book exam', 'exam open', 'book test'*	4.9
9	people, lot, stop, say, agree, mean, proctor, probably, maybe, care	*'people get', 'lot people', 'many people', 'people would', 'get catch', 'people like', 'mental health', 'people go', 'know people', 'feel like'*	4.8
10	like, feel, sound, look, yeah, lol, bad, thing, lot, shit	*'feel like', 'seem like', 'look like', 'sound like', 'something like', 'even though', 'would like', 'make feel', 'online school', 'like people'*	4.8
11	exam, proctor, final, online, open, book, sheet, time, hour, note	*'take exam', 'final exam', 'open book', 'online exam', 'make exam', 'proctor exam', 'write exam', 'take home', 'home exam', 'person exam'*	4.7
12	use, software, proctor, proctorio, computer, browser, note, flag, lockdown, webcam	*'lockdown browser', 'secondary device', 'make sure', 'proctor software', 'take exam', 'get flag', 'student use', 'use respondus', 'virtual machine', 'use note'*	4.5
13	course, year, average, math, midterm, final, assignment, fail, term, quiz	*'first year', 'take course', 'last year', 'math course', 'feel like', 'midterm final', 'year course', 'course average', 'final exam', 'class average'*	4.5
14	class, curve, online, semester, average, fail, homework, lot, easy, problem	*'take class', 'class average', 'online class', 'class get', 'one class', 'feel like', 'math class', 'class take', 'in person', 'make sure'*	4.4
15	grade, curve, average, semester, high, final, letter, higher, better, good	*'good grade', 'letter grade', 'final grade', 'get good', 'get good grade', 'grade get', 'get grade', 'grade inflation', 'grade curve', 'better grade'*	4.2
16	professor, happen, try, evidence, accuse, report, tell, prove, probably, email	*'professor make', 'take exam', 'make exam', 'professor would', 'professor might', 'make sure', 'student professor', 'professor try', 'in person', 'tell professor'*	4
17	catch, happen, wonder, lol, hear, dumb, expel, time, lmao, guy	*'get catch', 'people get', 'people get catch', 'first time', 'catch people', 'catch get', 'use chegg', 'get away', 'without get', 'without get catch'*	3.7
18	chegg, post, account, use, ip, information, address, answer, view, solution	*'use chegg', 'ip address', 'chegg account', 'get catch', 'post chegg', 'question chegg', 'post question', 'chegg exam', 'chegg answer', 'answer chegg*	2.8
19	group, chat, leave, join, share, report, quiz, snitch, post, want	*'group chat', 'share answer', 'get trouble', 'group member', 'join group', 'class group', 'leave group', 'academic integrity', 'group project', 'study group'*	2.5
20	make, harder, sure, sense, hard, easier, difficult, mistake, thing, pretty	*'make sure', 'make harder', 'make exam', 'make sense', 'harder make', 'want make', 'make mistake', 'make difficult', 'make feel', 'want make sure*	1.4

instructors to combat cheating and reduce grades, such as grading on a curve (Topics 14 and 15) and using anti-cheating and online proctoring software (Topics 9 and 11).

Next, students reported feeling demotivated when they know that cheating happens in examinations (Topics 4 and 5) and often goes unpunished (Topics 3, 10 and 17). Students discussed examples of cheating that instructors failed to identify, such as seeking answers on Google and question-answering websites such as Chegg (Topics 7, 8 and 18), and discussing solutions in online chat groups (Topic 19).

Finally, students reported concerns about new methods used to prevent cheating in online examinations. They worried that some legitimate actions may be misconstrued as cheating: looking away from the computer screen, accidentally pressing a button, or disconnecting from a video meeting due to internet connectivity issues (Topics 6 and 12). Furthermore, some students reported being accused of cheating during online examinations, but did not realize they did anything wrong (Topics 2 and 16).

4. CONCLUSIONS

Logistic regression analysis suggests that cheating-related discussions on academic subreddits have expanded from plagiarism in computer programming (representative of Fall 2019) to online assessments in general. The word 'chegg' was associated with Fall 2020 content, suggesting an increase in the use of Chegg and related websites, which is consistent with prior work [6, 3]. Furthermore, words indicating online proctoring were predictive of Fall 2020 content, e.g., 'camera', 'webcam' and 'record'. Inspection of the posts and comments containing these terms revealed students' concerns about their privacy during online examinations. Similar concerns were raised in recent work [4, 9].

Topic modelling analysis identified three discussion themes in Fall 2020. First, students believe that cheating causes grade inflation, which motivates instructors to make assessments harder and introduce strict anti-cheating protocols such as not being able to scroll back to a previous question on an online examination. Some of these concerns have been highlighted in previous work [18, 19, 2, 4, 13, 3], and our analysis reflects students' opinions on this topic. Second, unpunished cheating lowers students' morale and motivation. Students report feeling demotivated when classmates cheat and obtain high grades. Third, students report not knowing exactly what constitutes cheating and what is allowed, underscoring the im-

portance of clear academic integrity policies. These concerns were often reported in the context of online examinations, with students unsure of how their actions are being monitored.

Analyzing Ranking Strategies to Characterize Competition for Co-Operative Work Placements

ABSTRACT

Co-operative education is a form of work-integrated learning that includes academic study and paid work experience. This provides new learning opportunities for students and a talent pipeline for employers, but also requires participation in a competitive job market. We study competition through a unique dataset from a large North American co-operative program, in which students and employers rank each other after a round of interviews, then a matching algorithm assigns students to jobs based on the ranks, and finally students and employers evaluate each other at the end of the workterm. Our results reveal insights about competition and its impact on decision-making and satisfaction. An analysis of common ranking patterns suggests that small employers appear to be more strongly affected by competition and consider more options in their rankings, whereas large employers often do not provide any backup options and only identify their top choice. Additionally, competition appears to affect satisfaction since employers give higher workterm evaluations when matched with their top choice.

Keywords

co-operative education, work-integrated learning, ranking

1. INTRODUCTION

Co-operative (co-op) education is a form of work-integrated learning that includes both academic study terms and paid work experience, referred to as co-op work placements, workterms or internships. Prior work has examined the benefits of co-op, such as new learning opportunities for students and a talent pipeline for employers [13]. However, recent work has also reported that the competition related to interviewing for and securing co-op placements is a source of stress for students [10]. Motivated by these findings, in this paper we take a closer look at competition in co-operative education.

Our study is based on a unique dataset from a large North American undergraduate co-operative program. In this program, the co-op employment process proceeds as follows. Employers post job advertisements, students submit applications, and employers select students they wish to interview. After a round of interviews, students and employers rank each other. A *matching* algorithm then assigns students to jobs based on the ranks, with the goal of minimizing the sum of the student and employer ranks. For example, if the employer offering job A ranks student B one and vice versa, then the algorithm is guaranteed to assign job A to student B. In some cases, however, students and employers may be matched with their second or third choices, or not be matched at all. Finally students and employers evaluate each other at the end of the workterm.

One way to characterize competition in such a process is to identify job postings that receive the most applications. However, even entry-level or less desirable job postings may receive many applications, mainly from junior students. Instead, we turn to the ranking step of the process as a novel way to characterize competition. We investigate the following questions:

1. Do employers use different ranking strategies that reflect the level of competition they face? For example, an employer who is confident in their ability to attract top students may rank their preferred student one and not rank any other students as backup options. On the other hand, a less confident employer may rank multiple students.
2. Does competition appear to affect satisfaction? Are employers happier if they are matched with their top-ranked choices?

To answer these questions, we analyze ranking and workterm evaluation data from over 4,500 employers participating in the job matching process in three semesters, from September 2015 to August 2016. We answer the first question by mining frequent ranking patterns and identifying representative attributes of employers that use these patterns. To answer the second question, we compare the average employer evaluation scores when matched with their first choice versus a backup choice.

Related Work: Labour market competition has been studied from several angles, including improving talent recruitment by recommending resumes to job postings [11, 16], and reducing turnover by assessing personnel fit when making hiring decisions [2, 6, 3]. Further, it was found that job seekers' perceptions of hiring success, informed by their past job search success and prior knowledge of the company, motivate their decision to apply for a job and affect their decision to accept a job offer [1, 12]. In co-operative education, there has been work on student and employer satistfaction [8, 5, 4], as well as on clustering job opportunities, suggesting that junior students compete with each other for entry-level jobs and

Shivangi Chopra and Lukasz Golab "Analyzing Ranking Strategies to Characterize Competition for Co-Operative Work Placements". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 782-786. https://educationaldatamining.org/edm2021/

senior students compete with each other for more advanced positions [7, 14]. To the best of our knowledge, this is the first work to characterize competition based on employer rankings in a co-op process. Access to this unique data allows us to draw new insights into competition in co-operative education that can help manage students' and employers' expectations and improve their satisfaction.

2. DATA AND METHODS

2.1 Co-operative Process Overview

We begin with an overview of the co-op process at the institution studied in this paper. Initially, participating employers submit job descriptions, and any student (enrolled in a co-op program) may apply to any job. Next, employers interview selected candidates and rank them. A rank of zero, referred to as a "No Rank", means that the employer is not willing to hire the student. A rank of one, referred to as an "Offer", indicates that the employer wishes to hire the student. Ranks two to nine, referred to as "Ranks", represent the employer's backup or shortlist options, in order of preference. In other words, the employer would consider hiring these students if the top-ranked student declines the offer. In the remainder of this paper, we use the terms "shortlisted" and "received a Rank" interchangeably. Ranks do not need to be distinct, e.g., an employer may put five students on the backup list and give all of them a rank of two. After employers have submitted their rankings, students rank employers that made them offers or shortlisted them, between one and nine, indicating their order of preference.

The co-op matching system then removes student-employer rank pairs that add to zero (i.e., No Ranks) and applies a matching algorithm to assign students to jobs. The objective of the algorithm is to minimize the sum of the ranks of the resulting student-job assignment. Note that the lowest sum of ranks is two, and occurs when an employer offers a job to a student and the student gives a rank of one to this job. In this case, the student is guaranteed to be matched with this job[1]. In other cases, students or employers may be matched with their second, third, or lower choice, or may not be matched at all. Finally, at the end of a workterm, students and employers who were matched with each other evaluate each other.

2.2 Data

We analyzed one year of data, from September 2015 to August 2016, corresponding to 4,851 co-op job postings for students enrolled in co-op engineering programs:

- **Job Postings**, containing a job ID, job title, and employer name.
- **Employer Rankings**, containing a job ID and the distribution of ranks. Figure 1 shows an example with five employers, one per row. The first row indicates that employer (whose job ID is) E1 gave two ranks of zero (#R0) and no other ranks, i.e., E1 interviewed two students and was not willing to hire either of them. The second row indicates that E2 interviewed two students, rejected one (#R0), and put one on the shortlist with a rank of two (#R2), and so on.
- **Employer Evaluations**, containing a job ID, the rank the employer gave to the student who was hired, and the employer's evaluation of the student (on a 7-point scale: unsatisfactory, marginal, satisfactory, good, very good, excellent, outstanding).

[1]If a student were to give a rank of one to multiple Offers, the algorithm would randomly select one of these Offers.

	#R0	#R1	#R2	#R3	#R4	#R5	#R6	#R7	#R8	#R9
E1	2	0	0	0	0	0	0	0	0	0
E2	1	0	1	0	0	0	0	0	0	0
E3	4	2	0	0	0	0	0	0	0	0
E4	3	1	1	0	0	0	0	0	0	0
E5	1	1	1	1	1	1	0	0	0	0

Figure 1: Sample of employer ranking data

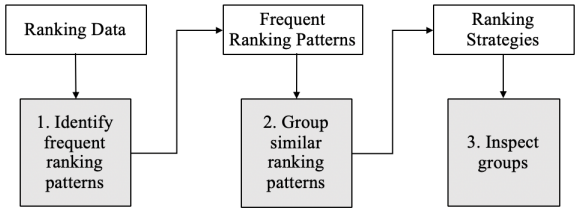

Figure 2: Summary of methods

2.3 Methods

Given that the matching algorithm is designed to minimize the sum of the ranks of the student-job assignments, employers may use different ranking strategies depending on the perceived level of competition. For example, employers may extend one or more offers but not shortlist any students if they are confident that their offer(s) will be accepted (i.e., that those students will reciprocate with a student rank of one). On the other hand, less confident employers may shortlist multiple students, and, to maximize their chances of hiring someone, they may give a rank of two to all shortlisted students instead of ranking them in order of preference.

The goal of this paper is to identify these kinds of ranking strategies and use them to describe the level of competition faced by different groups of employers. Our methodology, consisting of three steps, is summarized in Figure 2 and explained below.

1. **Identify frequent ranking patterns:** For employers, we identify commonly used *sets* of ranks. For example, an employer set of ranks of {0, 1} corresponds to employers who give only No Ranks (0) and Offers (1), and do not shortlist any students (ranks 2-9).
2. **Group similar ranking patterns:** Informed by the previous step and by the nature of the matching process, we group together similar sets of ranks. We refer to these as ranking strategies. For example, we may group employer rank sets of {0,1,2}, {0,1,2,3} and so on and label these as employers who make a shortlist (in addition to making some offers and rejecting some students). This step partitions employers according to their ranking strategies.
3. **Inspect groups:** We compare groups of employers with different ranking strategies based on their a) characteristics and, b) consequences on matching and evaluation. To identify differences among employers who use different ranking strategies, we inspect employer names and job titles. To understand the consequences of ranking strategies on matching

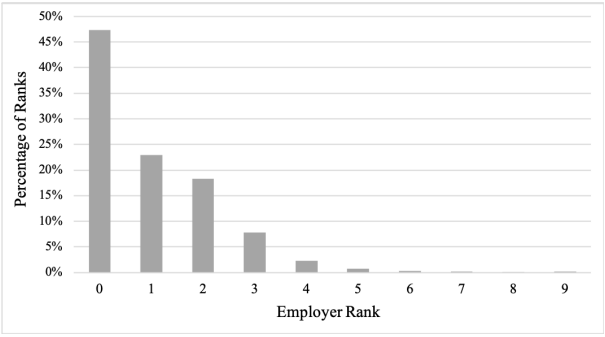

Figure 3: Distribution of employer ranks

Table 1: Most frequent sets of ranks given by employers

Set of Ranks	%
{0, 1, 2}	24
{0, 1}	19
{0, 1, 2, 3}	14
{1}	8
{0}	5
{1, 2, 3}	4
{1, 2}	4
{0, 1, 2, 3, 4}	4
{0, 2}	2
{1, 2, 3, 4}	2

and evaluation, for each group of employers who use a given ranking strategy, we calculate, a) the percentage who were not matched (represented as %NoMatch), b) the percentage who were matched with their first choice (represented as %MatchR1), and c) the percentage who were matched with their >1 choice (represented as %MatchR>1). Finally, we report the average evaluation scores that the employers gave to the students they matched with at the end of the workterm.

3. RESULTS

Section 3.1 analyzes the rankings given by 4,851 employers to identify frequent ranking patterns (Step 1 of Figure 2), group them into ranking strategies (Step 2 of Figure 2), and distinguish between employers with different ranking strategies (Step 3 of Figure 2). Section 3.2 analyzes the effects of ranking strategies on matching and satisfaction (Step 3 of Figure 2).

3.1 Employer Ranking Strategies

Figure 3 shows the distribution of ranks given by employers to students they have interviewed. Recall that rank 0 or "No Rank" indicates that the student was interviewed but not considered for the job, rank 1 represents an offer, and ranks 2-9 represent employers' shortlists in order of preference. As seen in Figure 3, nearly half the ranks are zero, a quarter are offers, and ranks lower than three are rare.

Next, Table 1 shows the most frequent *sets* of ranks given by employers. Many employers reject at least one student (rank 0), make at least one offer (rank 1), and shortlist at least one student, usually with ranks of 2 and/or 3. 19% of employers make offers without shortlisting anyone (second row: {0,1}).

Using Figure 3 and Table 1, we group employers with similar ranking patterns (Step 2 of Figure 2). Table 2 summarizes the groups. The first column, Label, describes each group. For example, the first group corresponds to employers that do not make any offers and do not shortlist (Rank) any students – that is, they only give zero ranks, meaning that they are not willing to hire any students they interviewed. The second and third columns indicate whether the employers in the given group gave any Offers and Ranks, respectively (we define *Top Ranks* to be ranks of two or three). The next column shows the percentage of employers assigned to each group (e.g., the first row indicates that 5% of employers did not give any Ranks or Offers). The next column reports the percentage of employers that were *not* matched with any students by the algorithm, labelled "%NoMatch"; clearly, employers who did not give any ranks or offers have no-match rate of 100%. The next column, "%MatchR1", shows the percentage of employers that were matched with their first choice and the average evaluation score the employers gave to these students (higher is better). Finally, the last column, "%MatchR>1", shows the percentage of employers that were matched with a student who was not their first choice and the average evaluation score the employers gave to those students. We will discuss the percentages further in Section 3.2.

Note that the sum of the percentages reported in the last three columns – "%NoMatch" plus "%MatchR1" plus "%MatchR>1" – is 100 for each row. In other words, there are three possible options for employers: does not match with any student, matches with their first choice, or matches with their not-first choice.

To characterize employers with different ranking strategies, we inspected their names and job titles (Step 3 of Figure 2). We found that employers who gave:

- "No Offer/s or Rank/s" (first row of Table 2) consisted of companies of all sizes and industries, mainly offering "analyst" and "assistant" positions.
- "Only Rank/s" (second row) were mainly business units of the institution, and mostly offered "analyst", "support", and "intern" positions.
- "Only Offer/s" (third row) consisted of large well-known technology and manufacturing companies, offering "software developer" and "design" positions.
- "Offer/s and Top Rank/s" (fourth row) consisted of (a) medium-sized companies offering positions in "software development" and "data science", (b) large companies with positions such as "application development", "UI designer", "quality assurance", and "process improvement", and (c) companies with specialized jobs in the fields of electrical engineering, hardware, medical engineering, banking, etc.
- "Offer/s and Other Rank/s" (fifth row) consisted of small to medium-sized companies with job titles including "quality assurance", "software testing", "support technician", and "systems administrator".

3.2 Consequences of Employer Ranking Strategies

This section analyzes how ranking strategies used by employers affect their chances of finding a match and whether employers with different ranking strategies evaluate their matches differently at the end of the workterm. To provide context, we start by reporting the

Table 2: Employer ranking strategies

Label	Offer/s	Rank/s	%	%NoMatch	%MatchR1 (Avg(Eval))	%MatchR>1 (Avg(Eval))
No Offer/s or Rank/s	No	No	5	100	-	-
Only Rank/s	No	Yes	9	81	-	19 (5.9)
Only Offer/s	Yes	No	27	48	52 (6.1)	-
Offer/s & Top Rank/s	Yes	Yes (all r$\leq$3)	48	31	46 (6.1)	24 (5.9)
Offer/s & Other Rank/s	Yes	Yes (some r>3)	11	20	48 (6.2)	32 (5.9)

matching percentage and evaluation scores averaged across all the employers who participate in the ranking process (i.e., those who give at least one non-zero rank).

Overall, 39% of employers who participate in the ranking process do not find a matching student. Out of the 61% who find a match, 75% match with their first choice (i.e., with a student to whom they gave an Offer), and 25% match with their >1 choice. On average, employers who match with their first choice evaluate their students slightly higher (6.1) than those who match with their >1 choice (5.9). This difference is statistically significant at a p-value of 0.05.

Next, we analyze the consequences of employer ranking strategies on matching and evaluation. Recall that Table 2 shows the percentage of employers with different ranking strategies who do not find a match, match with their first choice (i.e., with a student to whom they gave an Offer), and match with their >1 choice. For each ranking strategy, we also show the average evaluation scores given by employers to their students. Among employers who make offers, those who provide more backup options (Offers and Ranks) have a higher matching rate, with a greater proportion matching with their backup choice. Additionally, one-fifth of the employers who "Only Rank" (i.e., do not make any offers and only use ranks of two and above) find a match.

On average, regardless of the ranking strategy used, employers who match with their first choice evaluate their students similarly and so do employers who match with their >1 choice. In addition, irrespective of the ranking strategy used, employers who match with their first choice evaluate their students slightly higher than those who matched with their >1 choice. Therefore, while employer ranking strategy affects their chances of finding a match, employers with different ranking strategies do not evaluate their students differently.

4. DISCUSSION AND CONCLUSIONS

In this paper, we proposed a new way of characterizing competition in a co-operative job market by studying how employers rank students after a round of interviews. Based on a dataset from a large co-operative education program, we identified ranking strategies, studied the characteristics of employers who use different strategies, and analyzed the effects of ranking strategies on matching and workterm evaluation. Our main findings are as follows.

Ranking strategies characterize competition: Ranking strategies may be used to characterize the extent of competition in the co-op job market; employers appear to be aware of the competition they face and rank accordingly.

Large employers are less likely to provide backup options. Thus, it appears that these employers are confident in their ability to hire their top choices, and if their top choices decline the offers, these employers are willing to risk not hiring any students from this university. Small to medium companies, especially those offering entry-level positions, are more likely to provide backup options, perhaps as a consequence of perceived competition for their top choices. Therefore, an employer's popularity and quality of job they offer appear to be correlated with the ranking strategy they use. Similar observations were made in many competitive environments, including supply chains and legal contracting, where parties with more bargaining power leverage their reputation when negotiating with others [9, 15].

Rank of match affects satisfaction: Regardless of the ranking strategy, employers who match with their first choice evaluate their co-op students slightly higher on average than those who match with their backup choices. In other words, satisfaction only seems to depend on the rank of the match and not on the strategy used to obtain the match.

These results should be interpreted carefully since they are based on data from a single institution. However, the methodology we presented in this paper may be used by others to reflect the extent of competition in their institutions through ranking patterns. In addition, this study is limited to identifying frequent patterns in the data, but not cause-and-effect relationships. This provides a starting point for further study: interviewing students and employers about the competition they face in the co-op market is an interesting direction for future work. Nevertheless, we believe that our findings will be of interest to students, employers and the institution. We provide several examples of actionable insights below.

1. Our results can help students understand how co-op employers rank their options in various situations. This may inform students' strategies and decision-making during applications and ranking, in turn, increasing their chances of finding a suitable co-op job.
2. Our results can inform new employers about the extent of competition in the co-op market, which in turn can help them decide how to rank their options given the competition they are likely to face.
3. Our findings indicate that some employers are confident in their ability to hire their top choices, indicating that such jobs are highly sought after by students. The institution may consider recruiting more such employers. On the other hand, the institution may recommend smaller employers to less-experienced students to increase their chances of finding a match.
4. Our findings suggest that employers who match with a backup choice are less satisfied with their co-op students. This suggests a need for methods to help manage the expectations of employers and students in this situation.

ABSTRACT

High-stakes digital-first assessments are assessments that can be taken anytime and anywhere in the world and their scores impact test takers' lives. Computational psychometrics, a blend of theory-driven psychometrics and data-driven algorithms, provides the theoretical underpinnings for these data-rich assessments. The unprecedented flexibility, complexity, and high-stakes nature of these digital-first assessments poses enormous quality assurance challenges. In order to ensure these assessments meet both "the contest and the measurement" requirements of high-stakes tests [5], it is necessary to conduct continuous pattern monitoring and be able to promptly react when needed. In this paper, we illustrate the development of a quality assurance system, Analytics for Quality Assurance in Assessment (AQuAA), for a high-stakes and digital-first assessment. To build the system, educational data from continuous administrations of the assessments are mined, modeled and monitored via an interactive dashboard.

Keywords

high-stakes assessment, digital-first assessment, quality assurance

1. INTRODUCTION

Digital-first assessments are based on artificial intelligence (AI) tools that direct and optimize test-takers' experience. These digital tools include automatic systems for test development, scoring, and test delivery. In contrast to traditional large-scale assessments that are based on in-person administration to large groups of test takers in fixed locations, digital-first assessments are administered continuously to individual test takers, thus allowing for unprecedented flexibility. The advantages of the digital-first assessments have manifested themselves during the pandemic when traditional group assessments in brick-and-mortar test centers became impractical.

Manqian Liao, Yigal Attali and Alina A. von Davier "AQuAA: Analytics for Quality Assurance in Assessment". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 787-792. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

When digital-first assessments are used for high-stakes purposes (for example, for admissions or employment purposes), they, as any traditional high-stakes assessments, have a significant potential impact on test takers' lives. Thus, the digital-first high-stakes assessment also need to meet both "the contest and the measurement" requirements of high-stakes tests [5], where the "contest" here refers to the expectation that the test gives everyone a fair chance; the "measurement" refers to the requirement that the test is accurate and valid.

Quality assurance refers to a systematic process to maintain the high quality of the test and assessment scores and to prevent errors from all stages of the test, including test design, item design and development, test scoring, test analysis and score reporting [7]. Its complement, quality control, refers to a set of methods and statistics to evaluate the quality of the test. Many of the statistics and methods employed for quality assurance and quality control are similar, with quality control being part of the quality assurance overarching system. The International Test Commission Guidelines have articulated step-by-step procedures for quality control of general educational assessments but many of the steps are more applicable to traditional assessments, that is, "large-scale testing operations where multiple forms of tests are created for use on set dates."[7]

Since digital-first assessments differ from traditional assessments in many respects (e.g., administration frequency, item bank size), it is necessary to develop quality assurance procedures that are tailored for digital-first assessments. Developing such systems also requires research into the appropriate methodology to identify the most relevant statistics to be monitored for such new type of assessment, which is the focus of this paper.

In order to conduct quality assurance for digital-first high-stakes assessments, we developed a monitoring system named Analytics for Quality Assurance in Assessment (AQuAA), which is a blend of psychometrics and educational data mining packed into a dynamic and interactive dashboard-based system. AQuAA was designed to accommodate at least two unique characteristics of the digital-first assessments. On one hand, many key aspects of digital-first assessments, such as item generation and scoring, are automatically accomplished by machine. Therefore, compared to traditional assessments, the quality assurance of the digital-first assessments requires more extensive data mining techniques.

Computational psychometrics [18, 17] is leveraged to mine and model educational data in order to develop the statistics included in AQuAA. On the other hand, as a consequence of the continuous nature of administration, the quality assurance activities for digital-first assessments need to be conducted more frequently with a flexible timeline. In addition, tools that facilitate swift and efficient communication are indispensable so that prompt actions can be taken when issues are detected. In AQuAA, a variety of statistics are updated regularly and are integrated into an interactive dashboard for continuous pattern monitoring and timely communication purposes. AQuAA is also symbiotic with other activities (such as item development) given the fact that conclusions drawn from AQuAA could be used to direct the maintenance and improvement of the assessment.

This paper elaborates the development of AQuAA and aims to address three research questions: 1) What statistics should be used as indicators of test quality and score validity of digital-first assessments? 2) How to identify patterns and irregularities relevant to test quality of digital-first assessments? and 3) How to communicate the findings from the quality assurance process to stakeholders? This paper is focused on the the quality assurance of the test administration activities.

2. RELATED WORK

Quality assurance plays an important role in maintaining test score validity. [1] indicated that mistakes that jeopardize the assessment score validity could occur at all stages of assessment development and administration and that the mistakes could accumulate since many stages are contingent on previous stages. Therefore, quality control guidelines and step-by-step procedures [1, 2, 7] have been developed to help test developers identify possible mistakes as well as the causes of these mistakes, thereby helping them to identify solutions to fix the mistakes and prevent the mistakes from happening again.

Quality control procedures were mostly designed for traditional large-scale assessments that are administered in only a few test dates and have large test volumes in each administration [7, 1], with [2] being an exception. [2] recommended a quality control procedure for continuous mode tests (i.e., tests that are administered to small groups of test takers on many test dates) which share some similarities with digital-first assessments. Moreover, [2] have demonstrated an automated quality control system for continuous mode tests and the system consists of both an automatic part and a human review part. These two parts also apply to the quality assurance of digital-first assessments. In the automatic part, a number of steps that need to be conducted recurrently and can be implemented programmatically are packed into an automatic procedure with the use of digital tools. Steps in such an automatic procedure may include fetching the data from the database, conducting a variety of quality control analyses (see [9] for a review of quality control methods) and generating statistical reports. In the human review part, human experts are trained to review the statistical reports generated from the automatic procedure in order to identify potential irregularities or outliers, and determine whether or what actions need to be taken to handle these irregularities.

The foundation of an automated quality assurance procedure consists of a wide range of data mining and data visualization techniques. In the realm of quality assurance, the data mining and data visualization techniques serve two major purposes: First, to describe the trends and seasonal patterns of the assessment statistics; Second, to detect abrupt changes in the relevant assessment statistics. [9] have summarized a number of statistical methods and data visualization techniques for score quality assurance purposes. Various time series techniques can be chosen to describe trends or seasonal patterns, which include linear ANOVA models [4], regression with autoregressive moving-average [10], harmonic regressions [8] and dynamic linear models [19]. The Shewhart chart is a useful data visualization tool for continuous of the test score characteristics [9, 12, 14]. In terms of detecting abrupt changes in the assessment statistics, some model-based approaches have been applied to mine the data and identify abrupt changes in score time series, such as change-point models and hidden Markov model [9]. A data visualization techniques for detecting abrupt changes is cumulative sum (CUSUM) charts [13].

The products of the automated quality assurance procedure may include summary tables of the statistics, graphs and statistical testing results [2]. These statistical products could be organized into different formats, such as reports [2] and dashboards [11]. Since the products of the automated quality assurance procedure will serve as the starting point of the human review process [2], the choice of organizing format should be determined by the ease of communication to the targeted stakeholders.

3. MAJOR COMPONENTS OF AQUAA

This section illustrates how several key components of AQuAA address the research questions mentioned above. AQuAA has been launched as a minimum viable product (MVP) and additional features and statistics are being added to the system. This paper demonstrates the application of AQuAA the Duolingo English Test, a digital-first assessment. In order to help readers understand the context from which the AQuAA is developed, this section will start with a brief overview of the Duolingo English Test. However, the methodologies for designing AQuAA and the statistics considered for evaluation are intended to be adaptable to other digital-first assessments.

3.1 Overview of the Assessment

The Duolingo English Test is a high-stakes computerized adaptive test that is designed to be accessible anywhere and anytime [15]. Thus, it also falls under the category of continuous mode assessments [2]. The Duolingo English Test is an adaptive test, with a very large item bank that has been designed by subject matter experts (SMEs) and produced automatically by the machine. The items are reviewed by panels of SMEs to ensure quality and cultural fit. The items are scored automatically and the scoring methods are reviewed periodically by SMEs. Each individual test is proctored remotely using a complex and innovative asynchronous system that involves both AI-based tools and human proctors. Discrepancies or unusual situations are adjudicated by SMEs. Test results are reviewed through the quality assurance process in AQuAA. As part of this process, a wide range of process information related to test takers' behavior

Figure 1: AQuAA updating procedure

(e.g., time per item response, length of responses, etc.) is analyzed and monitored for quality assurance. The amount of data and the multiple sources and types of data are significantly more demanding of sophisticated analytics than is the case in more traditional assessments.

3.2 Overview of AQuAA

An overview of the procedure of developing and updating AQuAA is shown in Figure 1. Except for the first step (i.e., importing the data) that is relatively straightforward, the design of each step requires deliberation and, thus, is elaborated in the following sections. The steps in Figure 1 are scheduled to be automatically implemented on a daily basis (and in some cases more frequently). R [16] is the major programming tool used to develop AQuAA and automate the AQuAA updating process.

3.3 Checking and Cleaning Data

In general, the assessment data used for AQuAA can be separated into two types: Person-level data and item-response-level data. Person-level data contain variables that describe the overall person/session information, such as test takers' overall test score, sub-scores, test dates, and background characteristics. Item-response-level data contains variables that delineate information about each item the test taker responded to, such as item IDs, item difficulty levels, item responses and item scores, and other process information such as time duration test takers spent on each item.

After the data are imported, the integrity of the data is inspected to ensure that the data used for subsequent analyses are accurate and of high quality. For example, data are inspected for irregular values (e.g., negative values in time duration variables), and the causes of any such values are further investigated to identify any potential threats to the integrity of the data collection process.

3.4 Tracking Metrics and Statistics

The first research question is to determine what metrics and statistics are most relevant to monitor over time in order to evaluate the health of a continuous assessment. In order to support a statistical quality assurance system, AQuAA monitors results in the following five categories across time, adjusting for seasonality effects.

1. **Scores**. Test scores are directly used by test users (e.g., test takers, institutions), thus important indices at the level of test scores, including overall scores, sub-scores, and item type scores, are tracked in AQuAA. Score-related statistics include the location and spread of scores, inter-correlations between scores, bivariate or multivariate outliers, person fit, internal consistency reliability measures and standard error of measurement (SEM), and validity coefficients (e.g., correlation with self-reported external measures).

2. **Test taker profile**. The composition of the test taker population is tracked over time, as it could be used to explain the variability in test scores to some extent. Specifically, the (percentage) volume of test takers in the important population categories, such as country, native language, gender, age, intent in taking the test, and other background variables, are tracked. In addition, many of the score statistics are tracked across major test taker groups.

3. **Repeaters**. Repeaters are defined as those who take the test more than once within a 30-day[1] window. The prevalence, composition, and performance of the repeaters are tracked. The composition of the repeater population is defined with respect to the same test taker profile categories discussed above. The performance of the repeater population is tracked with many of the same test score statistics identified above, with additional statistics that are specific to repeaters: location and spread of both the first and second tests, as well as their difference, and test-retest reliability (and SEM).

4. **Item analysis**. As tests consist of items, ensuring that items are of high quality and that the item quality is stable over time are the prerequisites of maintaining the validity of the test scores. In AQuAA, item quality is quantified with four categories of item performance statistics: Item difficulty, item discrimination, item slowness (response time), and differential item functioning (DIF). Tracking these statistics would help test developers to develop expectations about the item bank with respect to item performance, flag items with extreme and/or inadequate performance, and detect drift in measures of performance across time.

5. **Item exposure**. The item exposure statistics concern how frequent each item (or each group of items) are used. An item being used either too frequently (over-exposure) or too infrequently (under-exposure) are undesirable for maintaining the item quality. An important statistic in this category is the item exposure rate, which is calculated as the the number of test administrations containing a certain item divided by the total number of test administrations. Tracking the item exposure rates can help flag under- or over-exposure of items.

3.5 Identifying Patterns and Irregularities

The second research question concerns the identification of patterns and irregularities in the data, which involves the development of the alarming mechanism of AQuAA. Developing the alarming mechanism in AQuAA is challenging partly due to the fact that the population of test takers is evolving and changing constantly, and, thus, many of the tracked metrics cannot be assumed to be stationary over time. Instead, the tracked metrics are often prone to systematic variation over and beyond predictable changes due to seasonality effects, thereby making it complicated to set an appropriate alarming criteria for the alarming mechanism.

[1]The day threshold of determining repeaters could be adjusted based on the test taking policy and the research purpose

The alarming mechanism in AQuAA is intended to detect persistent but smaller trends as well as alert large and abrupt changes that may be due to a problem in the assessment. To achieve these goals, we combined model-based psychometric analyses method with the time series and control charts techniques, both of which are useful for distinguishing systematic changes from chance variation in outcome processes.

The psychometric model-based methods allow us to track metrics after adjusting for certain factors (e.g., test takers' background characteristics), thus increasing the metrics' comparability over time. Specifically, in AQuAA, the item statistics and metrics are adjusted for test taker ability and background variables, and test taker statistics and metrics are adjusted for item characteristics.

3.6 Communicating Results

Our third research question involves how to communicate the information to the operational analysts as well as to the business unit. To visualize the trends and patterns of the statistics and facilitate the communication in the human review process, statistics are plotted using the ggplot2 R package [20]. Line plots are one of the most basic tools to visualize the time-series data. For example, Figure 2 demonstrates the stable trend of the mean of the overall test score during the Fall of 2020. Each dot in these figure represent a statistic calculated using a day worth of data; the lines are smoothed lines created by the locally weighted scatterplot smoothing (LOWESS) [3] method in order to represent the trends of the statistics.

Plots are also used to visualize the alerts raised by the AQuAA alarming mechanism introduced in Section 3.5. In AQuAA, the alerts are classified into three severity categories which are represented by different color codes. Specifically, yellow, orange and red represent low, medium and high levels of severity, respectively. For example, Figure 3 displays a monitoring plot for the daily median response time a few alerts in low severity. Once an alert is raised by AQuAA, messages are automatically sent to inform all the relevant stakeholders via email and the organization communication tool.

Various statistics and figures are integrated into an interactive dashboard using the flexdashboard [6] package. Figure A.1 demonstrates the layout of the dashboard. At the top of the dashboard (i.e., Section 1), there are five tabs corresponding to the five categories of statistics articulated in Section 3.4. Within each tab, the relevant statistics are arranged into storyboards: The statistics could be further classified into subcategories and allocated into different pages (i.e., Section 2); figures are displayed at the major section of the dashboard (i.e., Section 3); text description and some numerical results are displayed in the commentary section (i.e., Section 4).

4. THE APPLICATION OF AQUAA

As the quality assurance of digital-first assessments is a combination of automatic processes and human review processes, the AQuAA system is used as the starting point for the human review process, and the human review process, in turn, helps AQuAA to evolve into a more powerful tool to detect assessment validity issues. Figure B.1 demonstrates

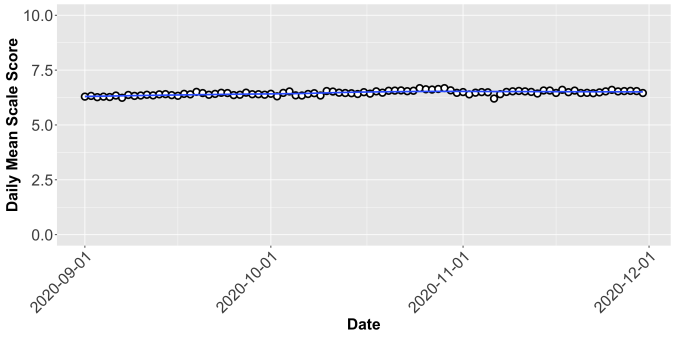

Figure 2: Trend of daily mean overall scores

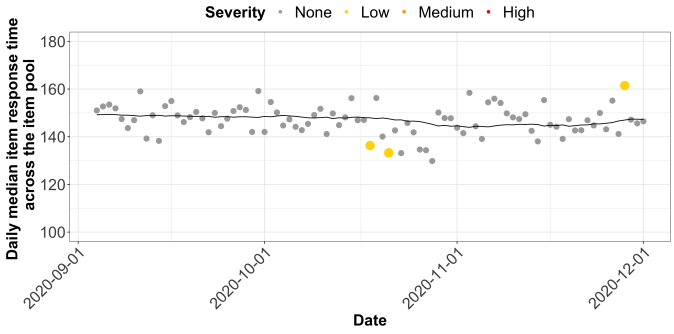

Figure 3: Trend of daily median response time with alerts.

an example human review process following every week's updates of AQuAA: SMEs meet to review the alerts raised by AQuAA alarming mechanism and review for any anomalies that are suggested by the AQuAA figures but have not been caught by the AQuAA alarming mechanism. The SMEs review each individual alert and determine whether it is an actual sign of a validity issue or it is a false alarm. If the alarm is believed to be caused by a validity issue, follow-up actions are taken to determine the severity and urgency, fix and document the issue. If the issue had not been caught by the AQuAA alarming mechanism, improvements would be made to the AQuAA functionality such that AQuAA would be more sensitive in detecting the issue.

5. DISCUSSION

This paper demonstrates the development of a quality assurance system that is tailored for digital-first assessments that are continuously administered. Several research questions motivated many of these approaches, as very few of the traditional methods apply to the digital-first assessments. The steps and considerations for building the quality assurance system have been elaborated, so that test developers could adapt the methodologies in this paper to their own assessments. It should be noted that the list of quality assurance statistics presented here is not exhaustive. Instead, due to the data-rich nature of the digital-first assessment, the list of monitoring statistics is expected to be lengthened and improved as the research in statistical techniques advances. The list of monitoring statistics should also be customized to the purposes and characteristics of the assessment. Hence, the infrastructure of AQuAA is designed to be so flexible as to incorporate and monitor additional statistics.

ABSTRACT

This study illustrated an exploratory study of LMS log data from undergraduate fully-online flipped classrooms. A total of 237 students' instructional video watching behaviors were extracted from LMS, and were analyzed with background variables to predict students' final performance. Regularization was proposed a suitable machine learning technique, as it produces interpretable prediction models. Specifically, Enet (elastic net) and Mnet were employed to handle possible multicollinearity in LMS log data, and the prediction models of Enet and Mnet identified 19 and 21 important predictors of final performance out of 157, respectively. In particular, both regularization models were able to screen lower-performing students as early as the first week of the course. Mere attempts to watch difficult videos after class increased the final scores.

Keywords

LMS log data, machine learning, regularization, flipped classroom, performance modeling

1. INTRODUCTION

The COVID-19 pandemic has changed the education system worldwide. Online learning is no longer an option, and an increasing number of online classes incorporate components of flipped classrooms (FC) in an effort to improve the quality of learning and instruction. Despite varying results regarding the effectiveness of flipped learning in higher education [1, 2, 3, 4], FC has grown rapidly as an innovative pedagogical approach in recent decades. In FCs, students' active involvement in pre-class activities is greatly emphasized as a necessary condition to enhance in-class learning and instruction [5]. However, there has been little empirical research on whether students completed the assigned pre-class activities and whether pre-class activities lead to desired outcomes.

This may relate to analytical limitations of the previous research in terms of data and methods. First of all, learning management system (LMS) log data are a crucial source of information in order to capture students' learning activities. However, not all the studies on FC collected data from LMS, particularly when pre-class assignments do not involve activities in LMS. For instance, the assignment of reading materials cannot be properly recorded outside of LMS. Researchers can ask students ex post facto in a self-report survey. However, self-report questionnaires rely on memories and reflections, and thus are prone to social desirability bias. On the other hand, LMS log data unobtrusively collect near-real-time information; students' activities in LMS are automatically stored in the log files without the students' cognizance [6, 7, 8, 9]. Particularly in the COVID-19 situation, fully-online FCs has emerged. In fully-online FCs both pre-class and in-class activities take place online using platforms such as LMS, and therefore collecting trace data has become much easier than in the original FCs.

Next, there is room for improvement in terms of analysis methods. Despite the aforementioned advantages that log data bring to data analyses, the intractability of log data has been a practical hindrance. Log data are unstructured, which can lead to high-dimensional data (i.e., more variables than observations), depending on data pre-processing and cleaning. Previous research on LMS log data to model students' achievement have analyzed students' behavioral data (e.g., instructional video watching behaviors) [6, 10, 11, 7, 12] as well as background (e.g., gender) [10, 13] and exam data [11, 13]. In particular, behavioral data were used as a tool to measure students' self-regulated learning [6, 10, 11, 7, 13, 12, 14, 15, 16], but aggregate variables such as total login frequencies or average login hours were analyzed with traditional methods [13, 15] or early ML (machine learning) techniques [14, 16]. As traditional methods are likely to result in nonconvergence problems with high-dimensional data, previous research may have used aggregate variables.

However, study time relevant to a specific instructional unit can be traced from log data, which will serve as a better indicator than the sum of study time, a crude measure of time investment in studying [15]. Such detailed information in turn will be conducive to understanding learning and instruction and giving specific, targeted, and timely feedback to students. This relates back to the issue of the previous LMS log data research: lack of empirical research on the relationship between pre-class assignments and students' performance at an instructional unit level. Particularly when behavioral variables at an instructional level are to be ana-

Jin Eun Yoo and Minjeong Rho "LMS Log Data Analysis from Fully-Online Flipped Classrooms: An Exploratory Case Study via Regularization". 2021. lyzed, ML is a necessary technique to analyze LMS log data from fully-online FCs.

Since completing pre-class assignments and preparing for interactive in-class activities is critical in FC, a high level of self-regulated learning (SRL) is necessary for students to succeed. SRL strategies related to students' academic success such as effective time management, metacognition, effort regulation, and critical thinking have been shown to have a significantly positive effect on students' academic success [17]. The question is which behaviors indicate SRL. Students carrying out SRL would naturally include more time on attending lectures and self-study which have a positive effect on academic achievement [18]. Previous studies have used variables such as login frequencies, LMS menu usage, material download, content pages viewed, and posted messages [6, 10, 11, 13, 14, 15, 16]. However, aggregate measures of these data display inconsistent effects on student achievement. For instance, login frequencies [13, 16] and LMS menu usage [13, 14, 15] were statistically significant or important indicators to students' academic achievement in online learning. In contrast, in MOOC (massive open online course) environments, forum variables such as numbers of messages posted, or comments received were found to be not directly related to students' learning [11].

Constant effort put into preparing for FCs may be difficult to capture with aggregate data. That is, instructional unit based log data would be a better predictor for academic success. A study predicting online student performance [19] demonstrates that the study habits of students with high levels of academic success can even be observed even in the first few weeks of a course. The implication is that instructional unit based analysis could yield richer information about the study patterns of students which eventually leads to timely intervention by the instructor.

Among ML, this study proposes regularization. Although 'prediction' is the operative word in ML, learning analytics is one of the fields which needs to be augmented with explanation. Regularization or penalized regression is known to produce explainable prediction models. Based on linear regression, the regression coefficients of regularization can be interpreted in the similar way as those in traditional, non-penalized regression. This is a great advantage in LMS data analysis, as prediction models need to be interpreted under certain educational settings, for instance to plan more effective intervention strategies for at-risk students. There has been little study employing regularization methods in LMS log data analysis. Specifically, this study chose Enet [20, 21] and Mnet [22] among regularization as they handle multicollinearity, a likely challenge in LMS data analysis. The two main research questions were as follows:

1. What are the students' instructional video watching behaviors like at an instructional unit level? Do students complete pre-class assignments in fully-online undergraduate flipped classrooms?

2. Among students' behavioral and background variables, which variables are important to predict students' academic achievement?

2. MACHINE LEARNING

For a Gaussian family, Enet and Mnet are expressed as equations 1 and 2, respectively. The second term on the right-hand side of equation 1 is the penalty function of Enet, consisting of two tuning parameters: λ and α. Enet is a combination of LASSO and ridge. The parameter λ regularizes shrinkage of the coefficients, and the parameter α controls the amount of ridge. When α is 1, equation 1 reverts to the LASSO equation, and when α is 0, it reverts to the ridge equation. Aforementioned, by adding the ridge component to the equation, Enet can handle multicollinearity.

$$\hat{\beta}^{\text{Enet}} = \operatorname{argmin}_{\beta} \left[\frac{1}{2n} \left\| y - \sum_{k=1}^{K} X_k \beta_k \right\|^2 + \lambda \sum_{k=1}^{K} \left(\alpha \left\| \beta_k \right\| + (1-\alpha) \left\| \beta_k \right\|^2 \right) \right]. \tag{1}$$

$$\hat{\beta}^{\text{Mnet}} = \operatorname{argmin}_{\beta} \left[\frac{1}{2n} \left\| y - \sum_{k=1}^{K} X_k \beta_k \right\|^2 + \sum_{k=1}^{K} J\left(\left\| \beta_k \right\| | \lambda_1, \gamma \right) + \lambda_2 \sum_{k=1}^{K} \left\| \beta_k \right\|^2 \right],$$
$$\text{where } J(\mathrm{x}|\lambda_1, \gamma) = \left\{ \begin{array}{ll} -\frac{1}{2\gamma} x^2 + \lambda_1 |x|, & |x| \le \gamma\lambda_1 \\ \frac{1}{2}\gamma\lambda_1^2, & |x| > \gamma\lambda_1 \end{array} \right\}. \tag{2}$$

Enet uses convex penalties, which increase linearly regardless of the coefficient size. By contrast, Mnet uses a concave penalty, which tapers off for coefficients in larger absolute values, yielding nearly consistent coefficient estimates[22]. Mnet has three tuning parameters (equation 2). The parameter λ_1 has the same regularization function as the λ penalty in Enet (equation 1). The γ parameter of Mnet controls the concavity of the convex penalty. When the concavity penalty goes to infinity, the MCP penalty reverts back to the LASSO penalty. Mnet also deals with multicollinear data; the penalty associated with λ_2 adds the ridge component to the equation.

To consider the bias resulting from data-splitting in model validation, this study executed subsampling techniques for variable selection [23, 24]. The following three steps were repeated 100 times with random data-splitting. First, the whole data were randomly divided with the ratio of 7:3 to get the training and test data, respectively. Second, for a value of the penalty parameter, the training data were split with the ratio of 4:1 to execute 5-fold CV. For a value of λ, the prediction error is calculated, which was referred to as the CV error of the λ [20]. Third, the second step was repeated for every λ in range, and the λ of the lowest CV error served as the penalty value of the regularization. That λ value was appplied to the test data in step 1, which yielded prediction measure.

The selection or non-selection of each variable from step 2 was counted in the 100 iterations, which served as the selection counts of the study. Particularly, this study presented

variables selected 1, 25, 50, 75 times or more, and all 100 times [25, 26]. All the programs were written in R 3.6.2. Specifically, the grpreg library [27] was used for regularization.

3. MATERIALS

In the Fall semester of 2020, 242 undergraduate students in pre-service teacher program enrolled in 8 fully-online undergraduate classes titled *Measurement and Evaluation*. The classes of the Fall semester were mandatory for sophomores majoring in Liberal Arts and Social Sciences. Three instructors (A, B, C) including a head-instructor (A) taught the 8 classes. All the 8 classes scheduled a simultaneous final at the end of the course, and shared the same class materials including instructional videos, textbooks, and syllabus. The instructional videos were pre-recorded PowerPoint presentations with the head-instructor talking, with content based on a book also written by the head-instructor. There were a total of 34 video clips covering 11 instructional topics in the corresponding 11 instructional weeks (refer to the videos 01_1 to 11_4 in Appendix A).

On the orientation day of the first week, the importance of the weekly assignments of instructional video watching before class were emphasized, particularly because students were asked to create and complete class projects within groups based on the contents of the assigned videos. During class, interactions in small groups of 4 to 6 students were greatly encouraged. The groups were engaged in discussions on team projects and SPSS exercises in Zoom breakout rooms. A non-mandatory quiz of 4-5 short questions was presented for each week in LMS. Students were told that the quizzes would serve as formative assessments and the quiz scores did not count toward grades.

In total, 21,589 rows of video watching activities as well as 5,107 rows on board-posts readings were recorded in the log file. As many of the students indicated that they used the double-speed option of the LMS in video watching, this study used 50 % of the video length as a criterion. If a student watched a video 50 % of the length or more, the student is counted to have completed watching the video, and vice versa.

As the first research question was to investigate students' video watching behaviors at an instructional unit level, this study counted the frequencies of each video, separating before/ after and attempted but incomplete/ completed video watching. Specifically, 4 variables were created for each video: BI (incomplete attempt before class), BC (complete watching before class), AI (incomplete attempt after class), and AC (complete watching after class). Six Aggregate variables were also obtained for comparison purposes to previous research: BI, BC, and B (before-combined (I+C)) for before class counts; and AI, AC, and A (after-combined (I+C)) for after class counts.

The response variable of this study was final. The final test consisted of 35 multiple-choice items, and was given simultaneously to all the 242 students at the last week of the course. There were 5 students who missed the final, and those students' data were excluded from further analysis. The background and response variable were merged to the variables from LMS data, which resulted in the final dataset of 157 predictors of 237 students.

4. RESULTS

4.1 Students' Video Watching Behaviors

Table 1 summarizes the descriptive statistics of students' instructional video watching behaviors. The 6 groups of cells present the summary results of the aggregate variables. Students watched the videos more often after class than before class. Throughout the course students on average attempted to watch and completed watching each video about 1.03 and 1.08 times after class, respectively, while the values dropped to 0.20 and 0.23 before class (Table 1). The mean values smaller than 1 indicate that the students on average did not watch all the videos. Attempts and completions combined (I+C), students on average clicked about half of the videos before class (0.42), but they clicked each of the videos more than twice after class (2.11).

The range of students' video watching frequencies was quite wide. Some students clicked none of the videos after class (AI min= 0.00), while others after class clicked and finished watching each video as many as 4.20 (AI max= 4.20) and 2.47 times (AC max= 2.47), respectively. The maximum frequencies of before class watching were also less than those of after class, 1.38 and 1.00 for incomplete and complete watching, respectively.

4.2 Machine Learning Results

4.2.1 RMSE and Selection Counts

RMSE (root mean square error) was the prediction measure of the response variable of this study. The RMSE averages of Enet and Mnet were 5.58 and 5.69 with SDs of 0.50 and 0.46, respectively.

Consistent with literature [28, 22], Mnet always selected fewer variables than Enet. Of note, 103 and 94 predictors were selected out of 157 at least once with Enet and Mnet, respectively. This signifies the importance of running multiple iterations and employing selection counts, particularly when the research purpose is variable selection via regularization [25, 26]. In other words, employing selection counts considers the bias resulting from random data-splitting in model building.

Applying 25 or more selection counts resulted in 33 and 21 predictors for Enet and Mnet, respectively. A total of 19 and 3 predictors were selected at least 1 out of 2 runs of Enet and Mnet, respectively. Four predictors were selected with 3 out of 4 runs of Enet, but there was no such predictor with Mnet and no predictor was selected in all the 100 iterations.

4.2.2 Selected Variables

This study on log data analysis presents the summary of predictors selected 50 or more for Enet and 25 or more for Mnet in Table 2. Due to space limit, part of the results are discussed. Student gender and grade were selected important. When the other variables were held constant, male students had lower final score than female students. Interestingly, on-grade students, sophomores, tended to have lower scores. Students' attitudes toward measurement and evaluation (attitudes) also resulted in higher scores.

Table 1: Students' Before and After Watching Frequencies per Video

	I (incomplete)				C (complete)				I+C (combined)			
	M	SD	min	max	M	SD	min	max	M	SD	min	max
B (before class)	0.20	0.18	0.00	1.38	0.23	0.08	0.06	1.00	0.42	0.21	0.08	1.62
A (after class)	1.03	0.78	0.00	4.20	1.08	0.38	0.00	2.47	2.11	1.00	0.06	6.24

Among variables extracted from log data, the total number of clicks on SPSS material postings (spss.sum) and the numbers of quiz-taking (test.M and test.P) were important predictors to final. More clicks on SPSS postings lead to higher scores on final. Specifically, one more click on the SPSS material increased students' final scores by 0.11 and 0.16 for Enet and Mnet, respectively. Similarly, although students knew that the scores on quizzes did not count toward the final grade, simply taking the quizzes increased the final scores regardless of the device (mobile or PC). Students who watched the instructional videos mobile (lecture.M) also tended to have higher scores in final.

Among the 142 variables on video watching, 12 to 13 variables were selected as important depending on the regularization method (Table 2). Findings from the 13 selected variables are as follows. First, the very first video turned out to convey crucial information in predicting students' achievement, although it covered the easiest contents on formative assessment. The more the students completed watching the first video before class (BC01_1), the higher their final scores were. Specifically, one more completed watching of the first video before class increased students' final score by 0.57 in Enet and by 0.68 in Mnet. By contrast, the more the students completed watching the first video after class (AC01_1), the lower the final scores were. One more completed watching of the first video after class decreased final scores by 0.45 and 0.53 in Enet and Mnet, respectively. This (AC01_1) was the only AC variable of negative relation to the final.

Second, with the exception of AC01_1, the other AC variables (e.g., AC03_1, AC03_2, AC04_3, AC09_3, AC10_2, AC11_4) had positive relations with the final. The selected AC variables covered either the earlier technical contents or the most difficult concepts at the end. Particularly, the earlier technical contents included the first SPSS practice (AC03_1, AC03_2) and Ebel and Angoff standard setting (AC04_3). Cronbach's alpha (AC09_3), reliability with SPSS (AC10_2), and the relationship between reliability and validity (AC11_4) covered the most difficult concepts in the last weeks of the course. Students who completed watching these videos multiple times after class were more likely to obtain higher final scores.

Third, the relationship of AI variables to the final seems to depend on the class progress. Students who attempted but failed to complete watching the video on Ebel and Angoff standard setting covered in the fourth instructional week had lower scores on final (AI04_3). By contrast, incomplete watching of some videos on the last topic (covered in the last instructional week) were positively related to the final (AI11_2 and AI11_4). Of note, both AC and AI variables on video 11_4, the last video, had positive correlation coefficients.

Table 2: Coefficients of Selected Predictors by Regularization

	variable	Enet			Mnet		
		mean	SD	#	mean	SD	#
1	gender	-0.54	0.35	65	-0.8	0.48	36
2	on-grade	-0.61	0.22	75	-0.75	0.31	56
3	test.M	0.34	0.12	62	0.48	0.15	38
4	test.P	0.23	0.10	75	0.31	0.15	49
5	lecture.M	0.01	0.01	51	0.02	0.02	30
6	attitudes	1.31	0.49	80	1.65	0.58	61
7	spss.sum	0.11	0.05	57	0.16	0.08	37
8	BC01_1	0.57	0.26	77	0.68	0.35	50
9	AC01_1	-0.45	0.17	68	-0.53	0.30	38
10	AC03_1	0.26	0.16	52	0.39	0.28	25
11	AC03_2	0.34	0.22	59	0.46	0.29	31
12	AI04_2	-0.19	0.08	67	-0.23	0.13	40
13	AC04_3	0.40	0.26	52	0.55	0.34	28
14	BI06_2	-0.46	0.18	54	-0.59	0.23	34
15	AC09_3	0.29	0.19	68	0.39	0.29	44
16	AC10_2	0.44	0.24	66	0.61	0.32	44
17	AI11_2	0.38	0.18	52	0.61	0.29	27
18	AC11_4	0.29	0.21	58	0.42	0.29	35
19	AI11_4	0.33	0.16	65	0.40	0.21	37
20	on-semester				1.39	1.09	25
21	AI04_3				-0.21	0.13	27

Note. # indicates the number of selection in 100 iterations.

5. DISCUSSION

This study predicted students' final scores with as few as 19 to 21 predictors out of 157 with regularization techniques. Of note, the prediction models of this study are explainable, as we employed regularization, which is based on linear regression. Specifically, Enet and Mnet were employed to handle multicollinear data. Surprisingly, the prediction models differentiated lower-performing students as early as the first instructional week, right after the orientation week. Instructors now can invest their efforts in intervention without waiting until a quiz or an exam. Completing difficult videos multiple times after class also lead to higher scores in the final. Moreover, mere attempts to watch them after class also increased the scores.

Despite its importance in FC, it has been a foggy area whether students completed the pre-class activities or not and whether the pre-class activities lead to desired outcomes. This study also contributed to partly uncover what was going on behind the curtain of FC. The students on average completed at most 1/5 of the videos before class. Stronger links need to be established between pre-class assignments and in-class team projects.

ABSTRACT

Undergraduate college students have substantial flexibility in choosing the order in which they take courses, since most courses either have no prerequisites or only a single prerequisite. However, the specific order that courses are taken can have an impact on student performance. This paper describes a general methodology for assessing the impact of course sequencing on student performance, as measured by course grades, and applies this methodology to eight years of undergraduate academic data from Fordham University. The results demonstrate that certain course orderings are associated with improved student grade performance. This study introduces a methodology, new metrics, and a publicly available data-processing tool that can be applied to any student course-grade data set to measure course sequencing effects. The results can be used to inform student decisions, modify course recommendations, and even modify course prerequisites.

Keywords

Data mining, education, course sequencing, student performance

1. INTRODUCTION

Undergraduate university students have substantial flexibility in choosing what courses they take and when they take them. Course sequencing is usually enforced only by a modest set of course prerequisites. This study examines the impact of different course sequences on student learning outcomes, as measured by course grades. The data used in this study includes eight years of undergraduate student grade data from Fordham University. Prior studies on course sequencing have generally been quite limited. Similar research has focused more on course selection, the optimal set of courses for a student to take to maximize performance or time to graduation [4, 5], than on course sequencing. Studies that focused on course sequencing were limited to a single discipline, such as communications [7] and psychology [2]. Our study considers all undergraduate courses within the university, including sequences that span disciplines. Prior studies also only considered how early courses predict performance in later courses, whereas our study does not have this restriction and focuses instead on maximizing overall student performance.

Our study considers the impact of sequencing on pairs of courses. This simplifies the analysis and reduces the risk of finding spurious correlations. The grade performance of students taking each pair of courses in the two possible sequential orderings is measured, with the goal of identifying the ordering that yields the best overall performance (concurrent registrations are excluded from the analysis). Comparing the grade performance for the two sequences required the development of new metrics, which we consider to be one of the contributions of this research. The methodology described in this study, along with the metrics that are introduced, are embodied in a publicly available software analysis tool [6].

Every possible course-pair sequence is considered as long as there are a sufficient number of students to provide reliable results. However, our analysis focuses primarily on course sequences within certain departments and groups of departments. This focus is due to our affiliation with a Computer Science department and the current focus on STEM (Science, Technology, Engineering, and Mathematics) education that is driven by national interests and the needs of industry. We also examine course pairs that include both humanities and STEM courses, because we are interested in the role that a liberal arts education has on STEM education.

There are many factors that can impact instructor performance [8], such as class size, course workload, and time of day of a class [1]. These factors also will impact student performance and hence can interfere with our ability to draw clear conclusions about course sequencing effects. In the present study, we normalize the grade data at the course section level to account for different instructor grading schemes, but do not address the other confounding factors. Our expectation is that the large number of course sections associated with most courses will limit the impact of these factors.

There are several uses for the course sequencing analysis described in this paper. The most obvious is that this information can be used to improve recommendations provided to students concerning beneficial course orderings. When these benefits are substantial enough, official course prerequisites can be modified. Beyond these direct applications of the work, the sequencing results can provide insight into the relationships between courses, and this can be used to inform academic policies. For example, if Course A is not generally considered relevant to Course B, but nonetheless leads to improved student performance in Course B, then one might want to recommend Course A to students who must take Course B.

2. METHODOLOGY

This section describes the data set used, the data preprocessing and transformation that is necessary to convert the data into a form suitable for analysis, and the evaluation metrics that measure the impact of course sequencing.

2.1 Initial Student Course-Grade Data Set

The initial data set describes the grade performance of each undergraduate student in all course sections with at least five students. Each of the 473,527 data set records, which collectively cover 24,969 distinct students, identify a student, a course

Tess Gutenbrunner, Daniel Leeds, Spencer Ross, Michael Riad-Zaky and Gary Weiss "Measuring the Academic Impact of Course Sequencing using Student Grade Data". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 799-803. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

(including the course section and semester), the instructor, and the student's grade in the course. Although we aggregate the information to course level, section information is used to normalize student grades. Unfortunately, the initial data set cannot be made publicly available due to strict student privacy laws.

2.2 Data Preprocessing and Transformation

The analysis conducted in this study is based on pairs of courses. From the initial student course-grade data set, we compute and maintain information for each course sequence A→B and B→A, where A and B represent arbitrary courses. For each of these sequences, we maintain a list of all students taking the two courses in the corresponding order, and the grades they receive in each course. The particular section each student enrolls in is also tracked, so that grades can subsequently be normalized at the section level. The transformation of the data from the student course-grade level to the course-pair sequence level, and the generation of our evaluation metrics, are accomplished using our publicly available Python-based tool [6].

In this study, a course pair is analyzed if it meets two conditions. The first condition ensures that the percentage of students taking the sequence in each direction exceeds *MinCSP*, the Minimum Course Sequence Percentage. For this study, *MinCSP* is set to 30%, which ensures that both orderings are taken at least 30% of the time. This excludes abnormal situations where a particular course sequence is rarely taken, such as when a student takes an introductory class in their senior year or retakes a failed course outside of the normal order. The second condition ensures that at least a minimum number of students, *MinCount*, aggregated over all course sections, takes the courses in each order. *MinCount* is utilized to ensure that the sample size is sufficient to generate reliable results. For this study *MinCount* is set to 50 students.

Table 1 specifies how many course pairs remain after these conditions are applied. The conditions are applied sequentially, with *MinCSP* applied before *MinCount*. The values in the rightmost column reflect the number of course pairs actually analyzed. Table 1 displays the number of course pairs for the entire data set, as well as for the five course subsets that are of particular interest to us. Our university has no engineering school, so the STEM courses are offered by the Biology, Chemistry, Computer Science, Mathematics, Natural Sciences, Physics, and Psychology departments. The Humanities courses include all courses from the African and African American Studies, Anthropology, Art History, English, Philosophy, Theology, and Visual Arts departments.

Table 1. Number of course pairs for different course subsets

Data Set	Threshold		
	None	MinCSP=30%	MinCount=50
Full Data Set	81,327	21,461	1,939
Computer Science	850	253	14
Mathematics	392	92	23
Mathematics and CS	1,724	490	51
STEM	12,055	3,000	291
STEM & Humanities	27,303	6,646	684

2.3 Evaluation Metrics

Several metrics are used to analyze the impact of course sequencing on student performance. These metrics are based on lower-level metrics, which are introduced first. Ultimately, we want to see how the mean grades for each course in a course pair are impacted by course order in order to determine the optimal ordering and net benefit in grade performance.

The first step computes the mean grades for each course in a course pair for each of the two orderings. Because instructors vary widely in their leniency when assigning grades, all grades are normalized at the course section level using z-score normalization, as described by Equation 1. In this equation x_i represents the grade of student *i* in the course section, μ represents the mean section grade over x_i, and σ represents the standard deviation of the section grades.

$$Z_i = (x_i - \mu) / \sigma \quad (1)$$

For every course pair <*A*, *B*> we determine the average normalized grade for each course based on each ordering. Specifically, we compute $\mu_A(B \rightarrow A)$, $\mu_A(A \rightarrow B)$, $\mu_B(A \rightarrow B)$, and $\mu_B(B \rightarrow A)$, where the subscript of μ denotes the course for which the normalized mean is computed and A → B indicates that course A is taken before course B (and vice versa for B → A). As an example, for the course pair <*Math I*, *English I*>, $\mu_{Math\ I}$(*English I*→*Math I*) represents the mean normalized grade in *Math I* for students who took *Math I* after *English I*.

These normalized means are used to compute the difference in mean normalized grades (DNG). Two DNG values are computed for each course pair <*A*, *B*> since the difference in normalized mean grades is computed for each course. Equations 2 and 3 define these values, where $DNG_{A:B}$ is the difference in mean normalized grade for Course A when Course A is taken after course B rather than before course B, and $DNG_{B:A}$ is the difference in mean normalized grades for Course B when Course B is taken after course A rather than before course A. We compute the difference using the order noted in the equations, because we generally expect a course to perform better when it is taken second and anticipate that most DNG values will be positive.

$$DNG_{A:B} = \mu_A(B \rightarrow A) - \mu_A(A \rightarrow B) \quad (2)$$

$$DNG_{B:A} = \mu_B(A \rightarrow B) - \mu_B(B \rightarrow A) \quad (3)$$

The DNG equations measure the benefit of taking two courses in a particular order, but do not reflect the net benefit of one ordering over the other (if both DNG values are positive then the difference between the orderings will be reduced). We therefore compute the order benefit, OB, which is the net difference in DNG values of one ordering over the other. The OB is defined relative to a specific course ordering, as indicated in Equation 4. The OB value will be calculated for both possible orderings, but we will only list the one that is positive, which indicates the optimal course ordering.

$$OB_{A \rightarrow B} = DNG_{B:A} - DNG_{A:B} \quad (4)$$

We work through an example using <*Math I*, *English I*>, assuming the following statistics:

$\mu_{Math\ I}(English\ I \rightarrow Math\ I)$ = 0.40
$\mu_{Math\ I}(Math\ I \rightarrow English\ I)$ = -0.05
$\mu_{English\ I}(Math\ I \rightarrow English\ I)$ = 0.40
$\mu_{English\ I}(English\ I \rightarrow Math\ I)$ = -0.10

Assuming *Math I* takes on the role of Course A and *English I* Course B, using Equation 2, $DNG_{A:B}$ = 0.40 – (-0.05) = 0.45, and using Equation 3, $DNG_{B:A}$ = 0.40 – (-0.10) = 0.50. Applying Equation 4, we get $OB_{A \rightarrow B}$ = 0.50 – 0.45 = 0.05. These results are summarized in the first row of Table 2. The assignment of the two courses to A and B is arbitrary, so we can reverse them, which corresponds to the course ordering in the second row of Table 2. Then, using Equation 2 and Equation 3, we get $DNG_{A:B}$ = 0.50 and $DNG_{B:A}$= 0.45, which yields an OB value of 0.45 – 50 = -0.05. The values of $DNG_{A:B}$ and $DNG_{B:A}$ in Table 2 are flipped when we

reverse the roles of A and B (compare rows 1 and 2). This is logically and mathematically required given the definition of the DNG metric, so the OB value of one ordering must equal the negative of the other. The results in Table 2 show that taking *Math I* and then *English I* yields an overall improvement in normalized grades of 0.05, whereas taking the courses in the reverse order yields a net deterioration of 0.05.

Table 2. Example of a course pairing

Course A	Course B	$DNG_{A:B}$	$DNG_{B:A}$	$OB_{A \to B}$
Math I	English I	0.45	0.50	0.05
English I	Math I	0.50	0.45	-0.05

3. RESULTS

This section provides selected results from our analysis, with a focus on the difference in normalized grades for different course sequences. Order benefit is our primary metric, as it summarizes the net benefit of a particular course sequence over the alternative, but DNG is also informative since it specifies the amount of benefit in taking one course before the other. For example, it is possible for two competing sequences to have identical positive DNGs, leading to a zero order benefit. Top order benefit results are presented for course sequences restricted to: Computer Science, Math, Math and Computer Science, STEM, STEM and Humanities, and "All Courses" across all disciplines. We posit explanations for some of the results based on our knowledge of the domain.

The top three order benefit values for computer science courses are displayed in Table 3. Note that while the sequence *Computer Algorithms* → *Data Mining* has the highest OB value, based on the $DNG_{B:A}$ values, taking *Data Communications and Networks* after *Data Mining* yields a slightly greater improvement than taking *Data Mining* after *Computer Algorithms*. The key difference is that taking each of those pairs of courses in the opposite order (i.e., $DNG_{A:B}$) yields very different results. The two negative $DNG_{A:B}$ values in Table 3 indicate that the corresponding courses yield worse results when they are taken second. Specifically, students in *Computer Algorithms* perform worse when they take it second. We generally would not expect this to occur. This result may stem from weaker students who delay taking *Computer Algorithms*.

Table 3. Computer Science courses with largest order benefit

Course A	Course B	$DNG_{A:B}$	$DNG_{B:A}$	OB
Computer Alg.	Data Mining	-0.110	0.233	0.343
Data Structures	Computer Organization	-0.073	0.103	0.176
Data Mining	Data Comm. & Netwks.	0.101	0.235	0.134

A plausible explanation for the first entry in Table 3 is that *Data Mining* utilizes some knowledge of *Computer Algorithms* and hence taking *Data Mining* second is beneficial. While the same reasoning could be applied to the reverse ordering, the negative DNG indicates no benefit for that ordering, possibly because *Data Mining* does not teach the basics of computer algorithms. With respect to the entry in the second row of Table 3, the benefit of foundational mathematics and algorithmic knowledge provided by *Data Structures* is apparent in the somewhat more application-oriented *Computer Organization* course.

Table 3 shows negative $DNG_{A:B}$ values are smaller in magnitude than positive $DNG_{B:A}$ values — a finding replicated in subsequent tables. The presence of negative $DNG_{A:B}$ values may be an artifact of our focus on course pairs with the highest overall order benefit, because order benefit is maximized when $DNG_{A:B}$ is negative.

Table 4 shows the results for three sequences of mathematics courses. The third entry is the easiest to explain. *Business Finite Math* and *Finite Math* cover similar material, but the former covers more basic material. Students are not generally expected to take both courses, but if they do, they most likely will take the more basic one first. *Discrete Math* provides a background in formal proofs, which appears to benefit from advanced mathematical experience (*Multivariable Calculus I*) and to provide benefit to advanced study of calculus (*Multivariable Calculus II*).

Table 4. Mathematics courses with largest order benefit

Course A	Course B	$DNG_{A:B}$	$DNG_{B:A}$	OB
Discrete Math	Multivar. Calc II	-0.056	0.252	0.308
Multivar. Calc. I	Discrete Math	-0.041	0.249	0.290
Business Finite Math	Finite Math	-0.024	0.145	0.169

Most computer science programs require several mathematics courses, but the specific impact of the math courses on computer science courses is not well understood. Table 5 explores the relation between the two departments, restricting the sequences to include one math course and computer science course. One of the more notable results is the entry in the first row. Both courses teach finite mathematics, but *Structures of Computer Science* is offered by the Computer Science department and is intended for non-majors, while *Finite Math* is offered by the Mathematics department. *Structures of Computer Science* also devotes several weeks to cover simple programming assignments, thereby further reducing the time spent on the mathematics content. For these reasons, it is reasonable to conclude that the sequence with the high OB value corresponds to taking the more basic course first. It is also noteworthy that *Calculus I* has a very positive impact on taking programming courses (*Computer Science I* and its lab) and *Structures of Computer Science*. Thus it appears that increased mathematical sophistication does have a positive impact on computer science and computer programming. This is especially interesting because the mathematical material in *Calculus I* has only a tangential relationship with computer science. Most computer science programs require calculus, and our empirical data justifies this requirement.

Table 5. Math and CS courses with largest order benefit

Course A	Course B	$DNG_{A:B}$	$DNG_{B:A}$	OB
Structures of CS	Finite Math	-0.002	0.429	0.431
Calculus I	CS I	-0.035	0.338	0.373
Calculus I	CS I Lab	-0.012	0.252	0.264
Calculus I	Structures of CS	-0.010	0.213	0.223

Table 6 displays the remaining results for the three groupings of sequences: STEM courses, mixed STEM and humanities courses, and all courses without any restrictions. The first entry under the STEM category shows a benefit in taking *Applied Calculus I* after *General Chemistry I*. This ordering is typical for students on the Pre-Health track who wish to go to medical school, which may explain the high order benefit, since these students are generally motivated to achieve high grades. Furthermore, under the STEM category we find a benefit for *Learning (Psychology)* followed by *Multicultural Psychology*. The first psychology course in this sequence is a 2000 level course while the second is a 3000 level course, indicating yet again that there is a benefit from taking a more advanced course in the same discipline second.

Looking at the STEM & Humanities courses, students who took *Organic Chemistry I→ Intro. to Cultural Anthropology* did significantly better in both classes, as demonstrated by the magnitudes of the DNG values (the negative $DNG_{A:B}$ indicates *Organic Chemistry I* does worse when taken second and hence performs better when taken first). The same pattern is replicated with an even higher OB when considering the *Organic Chemistry Lab*. Pre-Health students tend to take *Organic Chemistry* very early in their college career and may dominate that particular course ordering.

The first row under the "All Courses" category displays the sequence *Spanish Language & Literature → Christian Hymns* with a very high order benefit. Students performed best in each of the two courses when taking them in the specified sequence. This may be due to the fact that Spanish literature is heavily influenced by Christianity, and therefore provides important background for students who plan to take *Christian Hymns*. Explanations for the other entries may require consultation with faculty from the associated departments.

Table 6. STEM, STEM/Humanities, All courses with large OB

4. CONCLUSION

The research described in this study introduced a methodology and set of metrics for assessing the impact of course sequencing on student performance. The analysis of our results focuses on several disciplines, such as Computer Science and Mathematics, as well as higher level groupings, such as STEM courses. Many of the results demonstrate that there is a substantial benefit with a particular sequencing of courses, such as taking *Finite Math* after *Structures of Computer Science* or taking *Computer Science I* after *Calculus I*. Our methodology and metrics are implemented in our Python-based software tool [6], which can be used by other researchers.

The course sequencing results in this paper can be used to assist with course recommendations and can be used to inform, and even modify, course prerequisites. For example, our results show a larger than expected benefit of taking calculus before a programming course; additional analysis and data will be needed to see if this extends to a broader set of mathematics courses, but if it does, then new prerequisites perhaps should be added. The results in this study also provide insight into the inter-relationships between courses and disciplines.

Many of our observed results can be explained based on our knowledge about college education and domain knowledge of specific disciplines. However, in some cases explanations are not readily available. Our search for explanations of why one sequence may outperform another can also benefit from additional domain knowledge, as our knowledge is mainly limited to computer science. Course syllabi could also prove to be useful. It would also be very interesting to apply our methodology to data from different universities, and we hope to do this in the future. It would be informative to see if the course sequencing patterns present in our university hold elsewhere. Although our university is relatively large, in many cases the number of students taking some pairs of courses was relatively small, and this informed our relatively low *MinCount* threshold of 50. With more data, we could increase this threshold, which would diminish the impact of factors like instructor effectiveness.

Our methodology normalizes for some external factors, such as different instructor grading schemes, but does not account for all factors that can impact student performance. In particular, we suspect that some course sequencing results are due to certain populations of students (e.g., Pre-Health students) taking courses in one particular order over another. In future work we do plan to consider some of these factors and modify our evaluation to isolate their impact. In cases where that is not feasible, we will at least provide summary statistics to assess the influence of these factors. For example, since we suspect that academically stronger students sometimes take courses in a different sequence than weaker or less motivated students, we can compare the overall GPAs of students taking the courses in each course ordering and note when they exhibit a statistically significant difference. Alternatively, we can normalize for overall student GPA, something that we are currently doing in a study on instructor effectiveness.

One final area that we plan to pursue is better evaluation of our results. One way to do this is to utilize statistical significance testing. Given the number of potential patterns we can find with the large number of pairs of courses, we may need to set our p-value quite low. We may be able to improve this situation by limiting our course interactions to courses within a single department or between related fields (e.g., Biology and Chemistry). We can also validate our results by partitioning the data into a training and test set and subsequently verifying if the patterns found in the training data hold for the test data. In this regard, the differences in student performance can be viewed as predictions, so the standard training and test set evaluation methodology applies.

The data utilized in this study is itself a valuable resource. Our research group has analyzed this data in a variety of ways to provide additional insights. Two studies have used this data to group/cluster courses and analyze the interrelationships between courses. One of these studies uses course co-enrollments to form the clusters and to identify hub courses [9], while the other uses the correlation between students grades as a similarity metric to cluster the courses [3]. Both of these studies used their respective notions of similarity to form networks of courses, and then analyzed these with existing network analysis techniques.

Mining Course Groupings using Academic Performance

Daniel D. Leeds, Tianyi Zhang, Gary M. Weiss
Department of Computer and Information Science
Fordham University, New York, NY
{dleeds, tzhang130, gaweiss}@fordham.edu

ABSTRACT

This study computes the correlation of student grades between pairs of courses in a large university. Course network graphs are then generated, where courses are represented as nodes and courses are connected if they have a high degree of grade correlation. Graph mining and network analysis tools visualize the course networks, identify course clusters and course cliques, and compute informative network statistics. Results are analyzed for pairs of courses and courses grouped by academic department or program of study. Strong course similarity groupings are observed within scientific disciplines, between pre-health courses, and within subfields of computer science. No prior study using this notion of course similarity has been conducted.

Keywords

Educational, Clustering, Correlation, Network graphs

1. INTRODUCTION

This paper describes a method for grouping and analyzing courses based on similar student performance, where similarity is measured between pairs of courses using the Pearson correlation of the grades assigned to students who take both courses. A graph is then formed that represents courses as nodes, and has edges between course-pairs when the student grade correlation is above a specified threshold. The resulting graph is then analyzed using a variety of graph analysis techniques, to provide insights into the relationship between individual courses and course groupings. Data preprocessing steps are described to handle confounding factors, such as differing instructor grading schemes. The methodology is encapsulated in a software tool that was developed for this study and is publicly available [5]. This study utilizes eight years of undergraduate student course grade data from Fordham University. The results show that there are strong connections between pre-health courses and courses within subdisciplines of computer science, and that courses that teach specific skills are much more highly connected to other courses than introductory survey courses.

The knowledge gleaned from this research can be used to influence curriculum design and academic policies. For example, if a student performs poorly in the first course within a set of highly correlated courses, then they are likely to encounter future difficulty; therefore, they could be asked to repeat the course or be offered academic assistance. Results from this study have many possible applications, but as is the case with descriptive data mining tasks, it may take some time to discover some of them. However, we feel that the course correlation networks that we generate and the various metrics that we introduce are themselves key contributions, which will lead to further research in educational data mining. This study is unique in that no other analysis of university courses is based on a notion of similarity that relies exclusively on student performance. One study, which is superficially similar, measures course similarity based on student course co-enrollments [7]. That study, also conducted by our research group and based on the same data set, uses this much more traditional notion of similarity to perform similar analyses; namely course network graphs are generated and then analyzes using existing network analysis methods and metrics.

2. DATASET DESCRIPTION

Eight years of student-course records were obtained from three of Fordham university's undergraduate colleges, where each record describes the performance of a student in a course section. This study restricts the data and analysis to: pre-health courses required for medical school admission, popular university core curriculum courses, and Computer Science and Psychology courses (a detailed analysis would not be possible if courses from all 83 majors were included). Computer Science and Psychology courses were included due to our affiliations with those departments, while core curriculum courses were chosen because of their prominence in our university and their diversity (students complete more than twenty core courses covering philosophy, history, foreign languages, performing arts, mathematics, and science). Pre-health courses are included because they cover many key introductory STEM courses. This study will be expanded to other disciplines in the future.

Table 1 summarizes the data and its distribution across the course categories. The core courses contribute more than half of the total course sections and are largely responsible for the data covering $20,797$ students. Each record corresponds to one student in one course section and includes the following features: *student ID*, *final grade*, *department name*, *course number*, *course title*, *semester*, and *section number*.

Table 1: Distribution across Course Categories

Course Category	Records	Sections	Courses
Computer Science	14,137(13%)	705(15%)	53(39%)
Psychology	18,017(17%)	966(20%)	67(50%)
Core	62,005(58%)	2,706(56%)	8(6%)
Pre-Health	13,087(12%)	434(9%)	7(5%)
Total	107,246	4,811	135

The final grade uses a 4 point scale and most courses will have many sections. Student privacy concerns prohibit us from sharing the raw data, even though the student identifier values have been anonymized; however, the course correlation matrix central to our analysis is available [6].

3. DATA PROCESSING

An overview of the process for measuring similarity between courses is provided in Section 3.1, and the individual steps are described in successive subsections. The code that implements these steps is publicly available [5].

3.1 Overview

The initial data set contains records that describe the performance of each student in a each course section. A variety of preprocessing steps are executed, as summarized in Fig. 1. A course correlation matrix that measures the similarity of each pair of courses using the Pearson correlation of student grades is generated in Step 7. The course network graphs, modularity clusters, and course cliques are then generated from this correlation matrix, as described in Section 4.

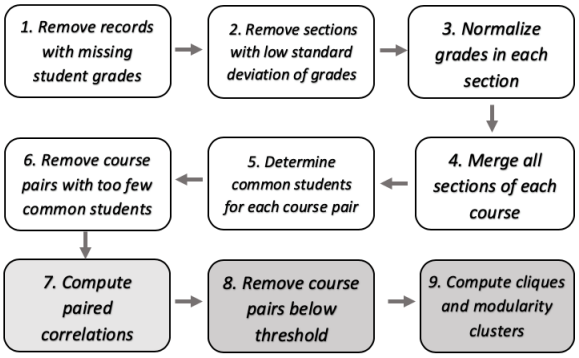

Figure 1: Overview of data processing steps

3.2 Initial Data Cleaning (Steps 1 and 2)

The first step removes records that do not have numerical grades, such as courses taken pass/fail. Some instructors sometimes assign students very similar grades, which makes it difficult to assess the similarity of courses based on grades. For this reason, Step 2 removes course sections where the standard deviation (σ) of student grades is below a specified threshold. This requires aggregation of the student course records to the section level, which yields $4,811$ sections. Fig. 2 provides the distribution of standard deviation values across these sections, and also provides a curve that shows the number of records and percentages of sections that are kept for each standard deviation threshold value (for each value we discard the sections with a lower threshold). Based on Fig. 2 we consider the values of 0.20, 0.30, and 0.40 to be reasonable candidates that maintain the majority of course sections. We ultimately selected a threshold of 0.30, which drops 6% of the sections and eliminates 6 courses (which are not left with any sections).

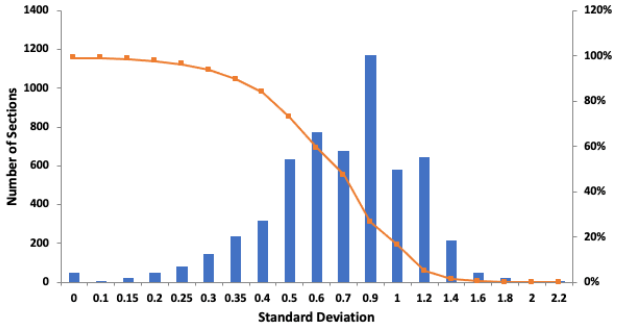

Figure 2: Distribution of grade standard deviation

3.3 Grade Normalization (Step 3)

Instructors may be easy or hard graders, and these differences will cause problems with grade correlation when a course is taught by multiple instructors. This issue is remedied by applying z-score normalization to the grades in each course section, which substracts the mean section grade from each grade and then divides it by the standard deviation of the section grades.

3.4 Generate Course-Pair Grades (Step 4-6)

Step 4 aggregates the data from the section level to the course level, which may combine dozens of course sections, spanning many years. Step 5 then forms pairs of courses, keeping on the grade data from students common to both courses. Course pairs are formed from every course that remains after application of the $\sigma = 0.3$ threshold in step 2. Step 6 then filters the course pairs that do not have at least 20 students in common, to ensure that the grade correlation is meaningful. This results in the removal of $4,585$ (25%) of the remaining course pairs.

3.5 Compute Paired Correlations (Step 7)

The final preprocessing step computes the Pearson correlation [2] between the remaining course pairs, which generates the correlation matrix that is central to our analysis. A small sample of the correlation matrix is provided in Table 2. The complete correlation matrix is publicly available [6]. Entries in the correlation matrix are not impacted by order, so values above the diagonal are omitted. Null values occur when a course pair does not have enough common students. In Table 2 we see that, as expected, there is a high correlation (0.94) between *Discrete Structures* and the associated lab. There is also a strong correlation (0.81) between *Computational Neuroscience* and *General Physics I*, which may be due to the heavy use of mathematical modeling of physical systems in both classes. *Bioinformatics* and *General Physics I* exhibit a low correlation (0.19), perhaps reflecting a heavier practical programming focus in the bioinformatics course. It is surprising that *Discrete Structures* and *Computer Algorithms* have a relatively low correlation (0.37), since they both require similar mathematical reasoning skills. This suggests that the *Discrete Structures* may not be preparing students sufficiently for future coursework.

Table 2: Representative Course-Pair Correlations

	Disc Struct	Disc Lab	Web Prog	Comp Neuro	Comp Alg	Bioinf	Gen Phys-I
Disc Struct	1						
Disc Lab	0.94	1					
Web Prog	–	–	1				
Comp Neuro	–	–	–	1			
Comp Algs	0.37	0.33	0.41	–	1		
Bioinfor	–	–	0.79	0.47	0.24	1	
Gen Phys I	–	–	–	0.81	–	0.19	1

4. RESULTS

This section describes the results derived from the course-pair correlation matrix. Section 4.1 covers the correlation results between individual course pairs, Section 4.2 covers the cliques within the course correlation graph, and Section 4.3 analyzes the course correlation network graphs.

4.1 Analysis of Course-Correlation Pairs

The distribution of Pearson course-pair correlations is displayed in Fig. 3. The leftmost bar is due to correlations between a course and itself. The top 25% of course-pair have a correlation greater than 0.5. The course network correlation graphs in Section 4.3 are generated using a threshold of 0.5.

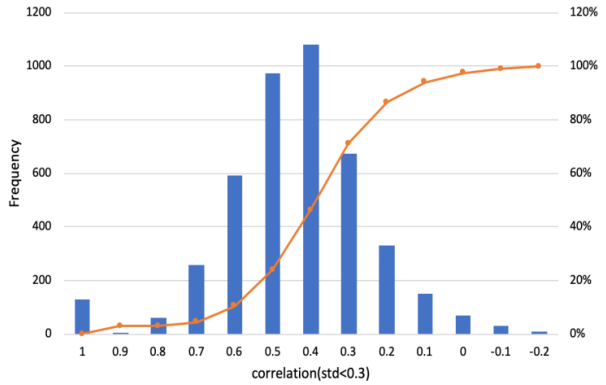

Figure 3: Distribution of course-pair correlations

Table 3 lists course pairs with correlations > 0.75. The top three entries cover matching lecture and lab courses, which is unsurprising since they cover complementary material. More than 80% of the entries are contained within an academic department, although there are interesting inter-departmental entries. The link between *General Physics I* and *Computational Neuroscience* was previously discussed and involves mathematical modeling. The link between *General Chemistry Lab II* and *Computer Algorithms* is not obvious, but both involve designing and applying a precise sequence of instructions. *Philosophy of Human Nature* shows an interesting connection with *Infant and Child Development*, potentially establishing a link between Philosophy and Psychology. The Philosophy class's link to *Scientific Computing* is more difficult to explain, although it may be related to the interdisciplinary nature of *Scientific Computing*.

4.2 Clique Results

A k-clique is a set of k nodes that are each directly connected to each other by an edge. Table 4 shows the number of cliques of each size in the course correlation network graph for correlation thresholds (ρ) of 0.55, 0.55 and 0.6. The table

Table 3: High Correlation (ρ) Course-Pairs

Course 1	Course 2	ρ
Discrete Struct II	Discrete Struct II Lab	0.96
Comp Sci II	Comp Sci II Lab	0.95
Comp Sci I	Comp Sci I Lab	0.93
Gen Phys I	Comp Neuro	0.81
Intro Bio I	Intro Bio Lab I	0.79

Intro Robotics	DataComm & Networks	0.76

shows that increasing the correlation threshold even slightly dramatically reduces the number of cliques, and hence we use 0.5 to retain a clear picture of course network structure. Each clique has many sub-cliques (e.g., each 7-clique has 7 6-cliques and 21 5-cliques), which we view as redundant, and hence the table excludes all sub-cliques. Cliques may span different course categories or fall entirely within one category. Table 5 shows how the cliques from Table 4 are distributed across the five course categories using $\rho = 0.5$. Cliques that do not fall within one category are included in the "Span" field.

Table 4: Number of Cliques as ρ Threshold Varies

Clique Size	$\rho \geq 0.5$	$\rho \geq 0.55$	$\rho \geq 0.6$
3-cliques	172	66	29
4-cliques	51	50	4
5-cliques	56	2	0
6-cliques	15	0	0
7-cliques	4	0	0
8-cliques	1	0	0

Table 5: Number of Cliques in Each Category

Clique Size	CS	Psych	Core	Pre-H	Span
3-cliques	46	9	0	0	117
4-cliques	11	32	0	0	8
5-cliques	14	39	0	0	3
6-cliques	0	15	0	0	0
7-cliques	0	3	0	1	0
8-cliques	0	1	0	0	0

Psychology courses form most of the large cliques with size 6 and greater. Psychology courses are more grouped together than Computer Science courses, which have many smaller-sized cliques. The 7 pre-health courses form a single clique, which suggests that performance in these courses is based on similar abilities or knowledge. Core courses lack even smaller 3 cliques. Despite their shared mission of core liberal arts training, it appears the differences in subject matter prevents similarity in course performance. No large cliques span course categories, but when $k = 3$, spanning cliques outnumber the other ones, which suggests that cliques only become meaningful at larger sizes. The largest cliques associated with the Computer Science, Psychology, and Pre-health courses are described in Table 6 of the appendix. Most of those cliques cover related courses (e.g., a 5-clique in Computer Science covers programming courses).

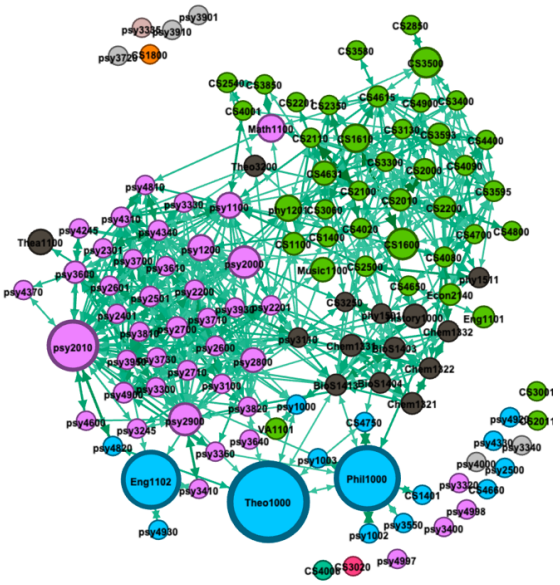

Figure 4: Network graph (all categories).

4.3 Course Correlation Network Graphs

The course correlation graphs generated with $\rho = 0.5$ were supplied to the Gephi social network analysis software [1]. Gephi partitions highly connnected nodes into modularity classes and assigns each a different color [3]. The size of each node is determined by ranking the node's "betweenness centrality," which is based on how often a node appears on shortest paths between all nodes in the network [4].

Fig. 4 shows the Gephi network that includes all courses. Nodes are labeled with a department abbreviation ("Eng" for English and "CS" for Computer Science), and 4-digit course number. Course numbers are not informative so our analysis refers to courses by title as needed. The figure shows a clear partitioning of courses between Computer Science (green, right) and Psychology (purple, left), with Pre-health courses (dark grey and below Computer Science) clustered together and forming a partial bridge between Computer Science and Psychology. While individual edges are difficult to distinguish, the figure shows that courses within a category are much better connected to each other than to courses in other categories. First-year core curriculum courses *English 1102*, *Theology 1000*, and *Philosophy 1000* are very large, indicating their large betweenness-centrality. These courses therefore often occur in the shortest paths between other courses and act as bridges between parts of the network. While these core courses do not have many connections, they connect to a diverse set of courses. *Philosophy 1000* is connected to well-connected courses from Economics, Psychology, and Computer Science, while. *Theology 1000* is connected to classes in Psychology, Pre-health (Biology), and *Philosophy 1000*. These core classes appear to be an indirect indicator of performance for classes across the university. Both classes introduce and carefully study selected core concepts in their respective fields.

Network graphs focusing on Computer Science courses and Psychology courses are provided in the appendix in Fig. 5 and Fig. 6, respectively. The modularity classes in Fig. 5 correspond to meaningful subdisciplines of Computer Science: the light-blue modularity class covers Information Science courses like Data Mining (4631); the magenta modularity class covers programming courses such as CS1 and Lab (1600, 1610), CS2 and Lab (2000, 2010), UNIX programming (3130), and Scientific Computing (4750); and the orange modularity class covers advanced courses like Algorithms (4080), Theory of Computation (4090), and Operating Systems (3595). The modularity class groupings differ from the cliques in Table 6 of the appendix, although both group the same programming courses together. Furthermore, the five largest nodes in the Fig. 5 based on betweeness centrality (*4631 Data Mining*, *4615 Data Communications*, *3593 Computer Organization*, *2200 Data Structures*, and *3300 Web Programming*) are well represented in the Computer Science cliques in Table 6. For Computer Science, high betweenness centrality reflects an abundance of both one-step and few-step connections to other courses. Within the department, it is known that a student with a poor grade in one of these classes will often struggle in the major. Most of these classes are designed to hone specialized skills within Computer Science. The key observation from the Gephi graph of Psychology courses in Fig. 6 is that the Research Methods Lab course is strongly connected with other psychology courses, while the introductory survey course is very poorly connected. This suggest that classes focused on specialized skills are more predictive of performance in advanced classes than a general survey class.

5. CONCLUSION

This descriptive data mining study defined an innovative notion of course similarity based on student performance, and then used this similarity metric to form course network graphs. These network graphs were then used to analyze the relationship between courses and course groupings. This methodology was applied to eight years of undergraduate student data at a large university.

The study established that there are many course pairs for which student performance is highly correlated. When requiring at least 20 common students, 25% of course pairs exceed the 0.5 correlation threshold used in this study, and 5% of pairs exceed 0.7 correlation. Courses with the highest correlations are often offered by the same department. In addition, multi-course clusters naturally occur, especially within subdisciplines of an academic department, such as the programming courses within Computer Science. Course clusters were identified as cliques and modularity classes within the course correlation networks. As an extreme example, all pre-health courses formed a single clique. A small number of courses with high betweeness centrality were shown to link a diverse set of topics—within one discipline or between disciplines, and those courses connecting discplines were much more likely to introduce specific skills than to provide a broad survey of an area.

This paper also introduced a methodology for generating a course grade correlation matrix from student data, and included several steps to address confounding factors such as differing instructor grading policies. This methodology is available to other education researchers through our software and associated documentation [5]. Our work presented a new way of looking at course relationships by a novel way of measuring similarity. We plan to continue to investigate this notion of course similarity and to apply it to a larger set of courses.

APPENDIX

Table 6 lists the large cliques associated with Computer Science, Psychology, and Pre-health courses. Many of the cliques have a common theme. Computer Science's second 5-clique includes three internet-focused courses: *Web Programming*, *Client Server Computing*, and *Data Communications*, while the third clique is dominated by programming courses (*Operating Systems* is an exception but includes programming projects). Psychology's 7-clique links classes covering complementary and overlapping elements of cognition; however, the 8-clique appears to span diverse topics. As mentioned earlier, the pre-health clique covers core science courses required by medical schools.

The Gephi course correlation network graph for the Computer Science is displayed in Fig. 5. The contents of Fig. 5 were describe in detail in Section 4.3 and highlighted how the different modularity classes correspond to different subdisciplines within computer science. The Gephi course correlation network graph for Psychology, which was only briefly described in Section 4.3, is displayed in Fig. 6. Meaningful subcategories are much harder to identify, but it is notable that Research Methods Lab (2010) is most strongly connected with other psychology courses, indicating a valuable skill shared across the category. This contrasts with the required introductory survey class, Psychology 1200, which has a much lower betweenness centrality. This indicates that a class focused on specialized skills is more predictive of performance in more advanced classes than a general overview class. The psychology courses with largest betweenness centrality are all represented in the cliques in Table 6. The top four courses based on betweenness centrality are: *2010 Research Methods*, *2900 Abnormal Psychology*, *2800 Personality*, and *2700 Child Development* – all courses with specialized foci. As in Computer Science, high betweenness centrality in Psychology reflects an abundance of both one-step and few-step connections to other courses.

Identifying Hubs in Undergraduate Course Networks Based on Scaled Co-Enrollments

Fordham University, New York, NY
{gaweiss, nnguyen56, kdominguezmelo, dleeds}@fordham.edu

ABSTRACT

This study uses eight years of undergraduate course enrollment data from a major university to form networks of courses based on student co-enrollments. The networks are analyzed to identify "hub" courses often taken with many other courses. Two notions of hubs are considered: one based on raw popularity and another on proportional likelihoods of co-enrollment with other courses. Network metrics are calculated to describe the course networks. Academic departments and high-level academic categories (e.g., humanities), are studied for their influence over course groupings. The identification of hub courses has practical applications, since it can help better predict the impact of changes in course offerings and in course popularity, and in the case of interdisciplinary hub courses, can be used to increase or decrease interest and enrollments in specific academic departments and areas.

Keywords

Graph mining, network analysis, educational data mining.

1. INTRODUCTION

Universities typically offer thousands of different courses across dozens of departments. The interrelationships between courses that are taken together, especially those in different departments, is often not well understood. This paper addresses this deficiency by forming course networks, connecting courses often taken by the same students. Each course is represented as a node in the graph. Several network analyses are pursued. This work also studies "hub" courses, defined as network nodes that are connected to many other nodes, resulting in a high degree count [2]. This study utilizes three popular centrality metrics to identify course hubs and compares the results when using each metric.

Network analyses utilized in this paper have been proven useful to other domains. Analysis of social networks like Facebook identify hubs corresponding to influencers with an outsized impact on other users' purchasing behaviors [3]. Network analysis metrics pursued in the present work have been applied to the World Wide Web, particularly for web searches [5, 8, 9].

Identifying and analyzing hub courses can provide concrete benefits. Courses heavily associated with other courses can be used for better resource planning, particularly when changes are made in the frequency or capacity of such courses. Furthermore, hub courses may be adjusted to drive (or diminish) student interest in an area or academic discipline. For example, there is a current need for more STEM (Science, Technology, Engineering, and Math) professionals. If a hub course is well connected to STEM courses, promoting this course may lead to increased STEM enrollments—even if the hub course is not a STEM course.

The course network analyzed in this study is based on eight years of undergraduate student course enrollment data from Fordham University. An edge connects two courses if the number of students taking both courses is above a threshold. Two types of thresholding mechanisms are considered: (1) a static threshold that is the same for all pairs of courses and (2) a dynamic threshold set to link together only courses taken together *relatively* frequently (i.e., relative to their popularity). We find the dynamic threshold shifts hub courses from humanities to STEM disciplines. Also, tighter course groupings are found within STEM and looser groupings within the humanities and social sciences. An extended version of this paper is available [12].

2. DATASET DESCRIPTION

Our study uses course enrollment data to generate a course-pair dataset, which is then used to form the course networks analyzed in this paper. This course enrollment data contains eight years of undergraduate data from Fordham University, where each record corresponds to one student in one course section. Student grades are also available and used in two of our other studies, one of which analyzes the impact of course sequencing on student grades [4], and the other that forms course networks based on the correlation of grades between courses, and then analyzes the networks [6]. This later study performs a somewhat similar analysis to the one provided in this paper, but with a very different notion of course similarity/linkage.

The course-pair dataset aggregates the course enrollment data to the course level and then extracts information about each course pair. Each course-pair record includes identifying information about two courses and the number of students that took each course and both courses (not necessarily at the same time). The department associated with each course is mapped to one of the six major course categories. The course-pair dataset contains 78,173 records, which are formed from 1,763 distinct courses. The dataset does not contain all possible pairings because pairs with fewer than 20 common students are excluded. The course-pair dataset, and the network metrics provided later, are generated from the course enrollment data using a publicly available Python-based software tool developed by our research group [10].

3. NETWORK ANALYSIS METRICS

The course-pair dataset is used to form course networks by viewing each course as a node and connecting nodes that have a sufficient number of common students. Table 1 provides the network analysis metrics used in this paper. The first three, density, diameter, and average clustering coefficient (ACC) [1], are computed

using an entire network or subnetwork. Our data shows subnetworks of courses within single departments have a higher density, smaller diameter, and higher average clustering coefficient than the network based on all undergraduate courses, because courses within a discipline are more tightly connected (see Table 2). The last three metrics are defined for each *node* in the network and can be used to help identify hubs. These metrics consist of three centrality measures: degree centrality, eigenvector centrality [11], and betweenness centrality [7]. Each measure can be used to identify a different type of hub course.

Table 1. Summary of network analysis metrics

Metric	Summary Description	Range
Density	Fraction of possible edges present.	0 - 1
Diameter	Maximum distance between any pair of nodes in network.	$\mathbf{Z}^+$
Ave. Clustering Coefficient	Fraction of pairs of neighbor nodes that are connected to each other.	0 - 1
Degree Centrality	Number of edges to node (degree).	$\mathbf{Z}^+$
Eigenvector centrality	Based on centrality of node's neighbors.	≥ 0
Betweenness centrality	Measure all shortest paths passing through node.	≥ 0

4. EDGE INCLUSION METHODOLOGY

To form a course network, each course is represented by a node, and an edge is added between two nodes if the courses, across all sections, have enough common students. Static and dynamic thresholds specify a minimum number of common students.

The static threshold is based on the number of common students between two courses, independent of how many students take each course. The distribution of common students by course pair is provided in Figure 1 in the appendix. Most course-pairs have very few common students, since few students take upper-level courses in disparate disciplines. A threshold of 20 students maintains 11% of all course-pairs with at least one student in common, and this is the static threshold utilized in this study. The static threshold is heavily biased towards popular courses, taken very frequently, even if only a few students in the popular course take specific other courses.

We also define a dynamic threshold relying primarily on the *co-occurrence rate* of courses. The dynamic threshold is determined by multiplying the co-occurrence threshold rate k by the number of students in the larger course within each course-pair. To ensure a minimum number of common students, a static threshold of 20 students is used as the floor for the dynamic threshold. The dynamic threshold, *d-thresh*, associated with two courses, C_1 and C_2, is provided in Equation 1, where C_x.students represents the number of students who have taken class C_x.

$$\text{d-thresh}(C_1, C_2) = \max(20, k \times \max(C_1.\text{students}, C_2.\text{students})) \quad [1]$$

The dynamic threshold is heavily dependent on the co-occurrence rate k, defined as the number of common students divided by the number of students in the larger course. The co-occurrence rate distribution is displayed in Figure 2 of the appendix, which shows that a co-occurrence rate threshold $k = 0.017$ discards 39% of the edges that satisfy the static threshold. This threshold is used because it leads to the most stable centrality measures while excluding the fewest number of edges. Table 5 in the appendix shows how this dynamic threshold impacts an Art History course.

5. RESULTS

This section analyzes course networks using the metrics presented in Table 1 and through the identification of hub courses. Static and dynamic thresholds are considered. Hub results are analyzed within academic departments and broader course categories. This study utilizes six course categories: Arts, Communication and Media Studies, Humanities, Modern Languages, Social Sciences, and STEM. The mapping from academic department to course category is partially provided in Table 2.

5.1 Network Metric Results

Table 2 presents the values of the previously defined network metrics for the course network and subnetworks at the department and category levels. Course categories are denoted in bold, with a subset of two selected associated departments listed below it (see [12] for the full table). The category level value reflects the median values across the member departments. The first row of data provides the values over all courses in the course network. The color of the cells reflects the magnitude of the cell value, with red (green) used for the highest (lowest) values. The colors for the departments and categories are determined independently.

The network covering all courses has a high diameter and low density compared to the subnetworks, since it includes many diverse courses that are loosely connected. Courses associated with a specific department are typically associated with a major; students within the major will take many of these courses. The dynamic threshold decreases the density, average clustering coefficient, and number of edges, while increasing the diameter.

Study of departmental subnetworks shows dynamic thresholding most dramatically decreases edges for Philosophy (52% decrease), English (44% decrease), and Theology (35% decrease), which are fields of study that include many core curriculum courses. This drop is mirrored by ACC. Conversely, the diameter maintains similar values for most departments, regardless of threshold. Overall, dynamic thresholding has a substantial impact on density and ACC of Humanities and Social Science courses, and only minimal impact on other categories, likely reflecting the core curriculum's emphasis on humanities and social science courses.

The STEM courses have much higher density and form much more dense clusters (based on ACC) than humanities courses, for both thresholds. This indicates that humanities students are less likely to take the same group of courses in their discipline. In our university, humanities majors have fewer required courses than STEM majors. Humanities departments have the highest number of nodes (distinct courses taken), closely followed by Social Science, suggesting that those disciplines allow more flexibility in course choices. The Modern Languages category also has a relatively high density and ACC. Language courses, like science courses, typically rely on prerequisite course requirements for proper student preparation.

5.2 Hub Analysis

Hubs play a special role in network structures and play an important role in understanding and utilizing the information in course co-enrollment networks. Table 3 identifies the top-17 hubs using the median of the ranks of the three centrality metrics, "Combined Rank". The top half of the table provides the top-7 hubs when using the static threshold, while the bottom half provides the top-7 for the dynamic threshold. Note that the best combined rank when using the dynamic threshold is 3—no course consistently ranks above third on all the centrality metrics. While only the combined rank for the static (dynamic) threshold is used

Table 2. Summary course network statistics based on category and selected departments

to select the entries in the top (bottom) half of the table, both combined ranks are provided to help compare differences between the thresholding mechanisms. Courses exhibit very different ranks for the two thresholds.

The first few entries for the static threshold in Table 3 vary only slightly depending on which of the three centrality metrics is used. The first four entries cover core curriculum requirements that can only be satisfied by a single course. Most of the remaining top hub courses also satisfy a core requirement, but can be satisfied by several courses. The very few STEM courses listed are introductory and satisfy a core requirement (e.g., *Finite Mathematics*). Thus, we see that hubs identified using the static threshold are based on raw popularity. Most courses identified using the dynamic threshold also satisfy a core requirement, but often many courses can satisfy the requirement. There are no courses that appear in the top-7 lists for both thresholds. For static threshold hubs, most connections to other courses may be incidental, due to so many students taking the popular course.

Table 3. Top-7 static and dynamic course hubs

Table 3 allows further comparisons among the centrality metrics. When using the static threshold, course ranks are quite consistent across all the centrality metrics. This ensures that the combined rank is also highly correlated with each of the individual metrics, and that the degree centrality is usually equal to the combined rank. This correlation is weaker when examining the dynamic threshold; degree centrality sometimes differs substantially from the combined dynamic rank; *Calculus II* has degree 7 and combined rank 19. Nonetheless, degree centrality is still generally close to combined rank and is identical in 5 of the first 7 cases.

We focus on degree centrality as our metric for identifying hubs under both thresholds. This is attractive since degree centrality is the simplest and most common metric for identifying hubs. We utilize a degree count threshold of 200 to identify hub courses. This retains all entries in Table 3, which have degree count of at least 245 [12]; the underlying data ensures that a degree count of 200 will retain the top fifty courses associated with each metric).

Table 4 shows the distribution of hub edges between the six course categories using a degree centrality threshold of 200, helping to consider connections across categories. The table displays the percentage of total hub edges from one category (row) to both hub and non-hub courses in another category (column), for each threshold. The percentage of total edges, as well as the actual number of edges, associated with each category (row), are also provided. A color scale is applied to the rows to highlight where the hub connections are directed (red is high percentage and green low percentage). For example, the first row indicates that, using a static threshold, 5% of all Arts hub courses are connected to other Arts courses and 14% are connected to Communication courses. Furthermore, Arts courses have 1,520 edges, comprising 5% of all edges in the course network.

Table 4 shows that for both thresholds, Humanities, STEM, and Social Sciences have the most hub edges, while Arts, Communications, and Modern Language have many fewer. Notably, the static threshold associates more edges with humanities courses than STEM courses (35% to 27%), whereas the dynamic threshold

Table 4. Percent distribution of hub edge linkage by course category (hubs with degree ≥200) with edge info

Category	Static threshold								Dynamic threshold							
	Arts	Comm	Hum	Lang	STEM	SocSci	#Edges	%Edges	Arts	Comm	Hum	Lang	STEM	SocSci	#Edges	%Edges
Arts	5	14	27	7	26	22	1520	5	5	9	21	10	36	20	650	5
Comm	11	24	22	7	20	15	1426	5	8	27	19	9	21	15	954	7
Hum	10	12	31	6	21	20	10892	35	6	11	20	10	33	21	2758	19
Lang	10	16	28	5	18	23	3219	10	9	17	23	5	22	24	1773	12
STEM	5	8	27	7	32	20	8479	27	5	6	24	8	36	21	5543	39
SocSci.	7	10	25	8	25	25	5543	18	3	6	23	10	29	29	2717	19

reverses this trend (19% humanities to 39% STEM). Most core curriculum requirements are associated with humanities and the dynamic threshold has an outsized impact removing courses that are hubs simply due to their popularity.

It is especially notable that more edges link humanities to STEM courses than to other humanities courses. Examining the underlying data, we find that the humanities courses *Introduction to Cultural Anthropology*, *Introduction to Physical Anthropology*, and *Introduction to Art History* all connect to STEM hub courses. Similarly, most connections for courses in the Anthropology and Art History departments go towards the Biological Sciences and Natural Science departments. While *Introduction to Physical Anthropology* is part of the Natural Science major requirement, it also satisfies a science core curriculum requirement for non-Science majors. It is interesting to observe this course's popularity with Science students. The course is a general survey of the biological focus of Anthropology.

Also notable is that Communications and Social Sciences have more links to themselves than to any other category, for both static and dynamic thresholds, even though these categories do not have as many total links as other categories. The Languages category have mostly internal links, and an intermediate number of edges overall for both thresholds.

Social Science hubs in Table 4 have a significant number of connections to STEM courses, commensurate with connections back towards Social Science. Most of the connections to STEM refer to courses in Biological Sciences, particularly from the Psychology course *Foundations of Psychology*. This course is a requirement for the Psychology major but is not part of the core curriculum. This course also has a significant number of connections with the Natural Science department. Overall, the number of connections from non-STEM to STEM courses when using the dynamic threshold is a bit of a surprise. Conversely, STEM hubs made many connections to the Social Science category in Table 4; these connections are largely directed towards the Economics department, which requires a strong mathematical base.

6. CONCLUSIONS

This study analyzed course network graphs using eight years of undergraduate course-grade data from Fordham University. General network statistics and course hub statistics were generated using a publicly available Python-based tool created by our research group [10]. Network structure and hub identity are strongly influenced by the definition of edges between courses, and whether static or dynamic threshold were applied to course co-enrollments. We gain important insights on relations among courses, departments, and categories, and on metrics naturally applied to characterize these relations.

All three common network centrality metrics (degree centrality, betweenness centrality, and eigenvector centrality) identify a similar set of hub courses using static thresholding to define edges. However, the metrics behave much less similarly when dynamic thresholding is used, requiring careful consideration in future analyses. Nonetheless, degree centrality yields a reasonable approximation of the other two metrics for both thresholds, favoring its future use to study course co-enrollment networks.

The static and dynamic thresholds yield very different course networks and hubs. Static thresholds place more emphasis on course popularity, highlighting courses that uniquely satisfy a core requirement. The dynamic threshold reduces, but does not eliminate, popularity bias. Due to the many mandatory humanities core courses, and the variety of core options in STEM, the dynamic threshold substantially shifted apparent hub focus from Humanities to STEM. Future analyses of course relations and discipline relations must continue to carefully weigh the influence of popularity or the mandatory nature of courses. For both thresholds, STEM courses have the highest density and form tightly connected clusters, while humanities courses have the opposite behavior; this is likely due to the more extensive use of prerequisites in STEM disciplines in our university.

Our analysis also identified large numbers of edges between the different course categories. Edge distributions shifted between thresholds, favoring humanities for the static threshold and STEM for the dynamic threshold. Study of courses forming individual edges provided additional insights. The strong connection between humanities and STEM courses was driven by humanities courses like *Introduction to Physical Anthropology*, which has a strong STEM component; the connection between social sciences and STEM was driven by courses like *Foundations of Psychology* which is linked to STEM courses in Biology (Psychology students must take several biology courses).

This study provides a better understanding of course co-enrollment patterns, suggesting directions for valuable practical applications. Strong models of co-enrollment patterns can help with course planning and ensuring enough of course sections are offered. Our course networks reveal valuable details and quantitative relationships among courses. This work is a foundational step in better understanding course co-enrollments.

There are many ways in which this work can be extended and improved. The dynamic threshold could incorporate underlying probabilities of each course being taken, so courses are linked only where their co-occurrence is much more likely than chance. We also can consider additional methods for clustering courses. Future analyses may extend to course ordering information. It may be useful to reduce the influence of popular departments in repeated analysis of category-level network patterns. More fundamentally, our present results may be validated by partitioning the underlying student enrollment records into distinct subsets, to create training and testing data for our network models.

APPENDIX

Figure 1 shows the distribution of common students by course pair (each bin covers a range of common students). The orange curve is a cumulative curve that corresponds to the y-axis values listed to the right (varying between 0% and 80%) and represents the percentage of course-pairs that are *maintained* for each common student threshold value (e.g., a threshold of 20 maintains 11% of all course-pairs with at least one student).

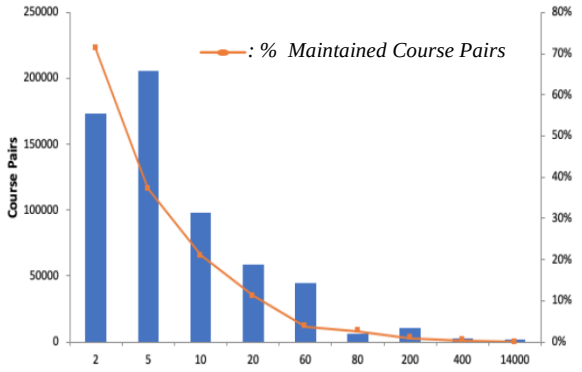

Figure 1. Distribution of common students by course-pair

The dynamic threshold is heavily dependent on the co-occurrence rate *k*. To help set this value appropriately, Figure 2 shows the distribution of course-pairs for each co-occurrence rate, for the course pairs that satisfy the static threshold of 20. The co-occurrence rate is the number of common students divided by the number of students in the course with more students. The co-occurrence rate distribution is heavily skewed to the smaller values, just as the number of common students was skewed to the smaller values in Figure 1. The bar at the far right at x=1.0 is associated with course pairs with the same course in both positions and should be ignored. After some experimentation we decided on a co-occurrence rate threshold $k = 0.017$, which is the value that leads to the most stable centrality measures while excluding the fewest number of edges. The orange curve, which shows the fraction of edges discarded, indicates that this value of *k* discards 39% of the edges that satisfy the static threshold.

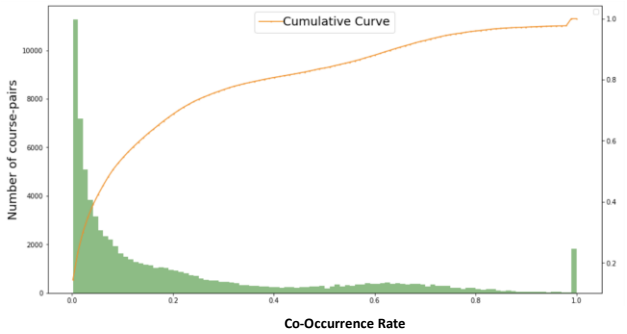

Figure 2. Co-Occurrence Rate Distribution

To illustrate the dynamic threshold, we apply it to the course *Art History Seminar*, which has 123 students. There are 22 courses that share at least 20 students in common with this course, satisfying the static threshold. However, 9 courses have fewer common students than the computed dynamic threshold, and hence are pruned. Half of these 22 courses are displayed in Table 5, and five of these, denoted in **bold**, are pruned since the number of common students is less than the dynamic threshold. As anticipated, the courses affected by the dynamic threshold have a large number of students (third column). In this example, every course that satisfies the static threshold, but is pruned by the dynamic threshold, fulfills a core curriculum requirement.

ABSTRACT

This study leverages natural language processing to assess dimensions of language and discourse in students' discussion board posts and comments within an online learning platform, Math Nation. This study focusses on 1,035 students whose aggregated posts included more than 100 words. Students' wall post discourse was assessed using two linguistic tools, Coh-Metrix and SEANCE, which report linguistic indices related to language sophistication, cohesion, and sentiment. A linear model including prior math scores (i.e., Mathematics Florida Standards Assessments), grade level, semantic overlap (i.e., LSA givenness), incidence of pronouns, and noun hypernymy accounted for 64.48% of the variance for the Algebra I end of course scores (RMSE=13.73). Students with stronger course outcomes used more sophisticated language, across a wider range of topics, and with less personalized language. Overall, this study confirms the contributions of language and communication skills over and above prior math abilities to performance in mathematics courses such as Algebra.

Keywords

Student performance, performance prediction, discussion posts, linguistic features

1. INTRODUCTION

Discussion boards have emerged to be among the most beneficial features of online learning platforms. Some of the positive outcomes obtained include greater student involvement and improved academic performance [1-5]. Discussion boards have been implemented to achieve a number of educational goals, namely, to supplement course resources, evoke creativity and motivation, facilitate interaction between teachers and learners, and for class management or administrative purposes [6-9]. Student engagement and collaboration within discussion boards are critical towards their success. Indeed, students' language used within these discussion boards has been linked to positive learning outcomes [10-12]. This creates a pressing need to further understand the language used by students when collaborating with each other or engaging with their teachers within informal online academic settings.

1.1 Language and Math Success

While empirical evidence shows mixed results in the correlations between language proficiency and academic success (i.e., some found significant correlations and some none), proponents have articulated that language proficiency, and more importantly - communicative competence significantly influence success in math [13]. The dimensions of language that have been found to specifically influence math achievement include linguistic complexity, language control, and vocabulary usage [14].

A number of studies have demonstrated links between language and performance in math [10, 11, 15]. There are strong links between language skills and the ability to engage with math concepts and problems. For instance, success in math is partially based on the development of language that affords children the ability to participate in math instruction in the classroom as well as "engage quantitatively with the world outside the classroom" [16]. Similarly, strong math skills are presumed to interact with language ability to understand numbers and symbols [17]. Linguistic skills may be one of the key factors that relate to math ability. For instance, Cummins identified language difficulties in second language speakers as a key obstacle in solving math problems [18]. Articulating and representing cognitive processes in math domains is especially challenging for students with lower literacy skills. Successfully solving verbal analogies and mathematical word problems, in particular, demand certain levels of linguistic fluency and reading comprehension skills, which can be barriers to success.

More specific to discourse in online discussion boards, substantial work has been done to characterize the language used within online discussion forums [19-24]. This research indicates that linguistic features distinguish subject matter experts from nonexperts and are predictive of student learning outcomes. In social questioning and answering sites (e.g., Quora), linguistic features such as word usage, average number of words, subjectivity of words, and word complexity have been found to be markers of expertise [19]. Discourse analyses conducted on online discussion boards show that linguistic characteristics are predictive of student learning performance [20]. To name a few, the complexity of syntactic structures, cohesion, emotion words, modal verbs, and words that provide additional information or make claims when elaborating are significant predictors of students' performance [20-24].

1.2 Current Study

This study examines students' discussion wall posts for an entire academic year within an online Algebra tutoring platform, Math Nation, developed by the University of Florida Lastinger Center for Learning [25-29]. Math Nation is an interactive and comprehensive math teaching and learning platform that provides video tutorials and online resources aligned to the Mathematics Florida Standards (MAFS). Most relevant to the current study, Math Nation also features an online discussion forum called Algebra Wall where students can collaborate with other students, teachers, and study experts. Wall posts (see Figure 1 for a sample discussion thread) from 3,277 students, Math Nation study experts, and Algebra teachers were collected for the period August 1, 2018 to July 31, 2019, including comments within more than 14,000 threads.

Our objective in this study was to further examine the extent to which the linguistic features of these posts were predictive of End of-Course (EOC) Algebra performance, over and above their scores Math scores from the previous year. Providing information concerning students' potential EOC performance is important because it has the potential to augment stealth assessment of students' abilities such that the instructor or the tutoring system can intervene and provide scaffolding when necessary.

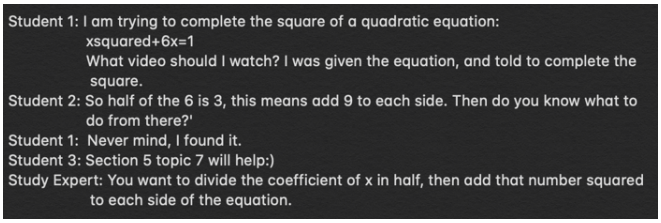

Figure 1. Sample Discussion Thread

2. METHODS

2.1 Participants

The participants included 3,277 Algebra students from the different Florida school districts in grade levels 7, 8. and 9 who participated in the Math Nation discussion board for the academic year August 1, 2018 to July 31, 2019. The majority of these students were white (n = 2,464, 75%). This study focusses on 1,035 students in this larger sample whose aggregated posts that included more than 100 words because NLP indices are not reliable with small language samples, and many of our indices (e.g., lexical diversity) require a minimum of 100 words [32]. Those who included more words in their posts had significantly higher FSA scores, $t(3275) = 5.79$, $p<.001$ ($M_{\leq 100\ words}$,= 354.08, SD = 16.83; $M_{>100\ words}$,= 357.75, SD = 16.89); and EoC scores, $t(3275) = 8.12$, $p<.001$ ($M_{\leq 100\ words}$,= 522.66, SD = 22.99; $M_{>100\ words}$,= 529.67, SD = 22.93). As such, number of words in posts are strong indicators of future and current math performance; the purpose of this study is to examine language beyond number of words.

*2.1.1 **Prior Math and Algebra I EoC Scores***

Students' mathematics performance was measured using Algebra I End-of-Course (EoC) assessment (M=524.88; SD=23.20; Range = 425-575), which is a high-stakes exam required by the Florida Department of Education [30] for high school graduation. Mathematics Florida Standards Assessments (FSA) scores (M=355.24; SD=16.93; Range = 269-393), from the previous year were included as proxy baseline scores indicative of Math preparedness [31]. The FSA math scores are often used as a baseline measure of Algebra skills or preparedness because they are strongly related to the students' Algebra I EoC scores. Indeed, the relation between these two tests was strong in the current study ($r=0.76$, $p<0.01$). Controlling for gender, grade level and district did not result in significant variations in the correlation between the Math FSA score and the Algebra I score (i.e., r = .73 - .76). Table 1 shows the mean scores for both the FSA Math and Algebra I exams as a function of grade level and gender.

Table 1. Algebra performance

	Math (FSA) Score from Previous Year (Mean / SD)	**Algebra I Score (Mean / SD)**
Grade 7 (n =440)	362.89 (15.74)	539.31 (19.02)
Grade 8 (n = 520)	355.39 (16.04)	525.58 (20.75)
Grade 9 (n = 75)	343.92 (17.95)	501.49 (26.49)
Male (n = 429)	359.92 (16.79)	531.55 (23.25)
Female (n = 606)	356.21 (16.80)	528.33 (22.62)

2.2 Natural Language Processing Tools

We assessed students' Math Nation Wall discourse using two linguistic tools, namely Coh-Metrix [32] and SEANCE [33], which report linguistic indices related to language sophistication, cohesion, and sentiment. Use of these two tools was motivated by prior work relating academic performance in mathematics to these features of language in online forums and discussion boards [20-24].

2.2.1 Coh-Metrix

Coh-Metrix provides multiple levels of linguistic analysis that include indices at word level and sentence level, indices related to connections between the sentences, and discourse relationships between the texts and their mental representations. Coh-Metrix has been used to analyze different forms of text in the English language that are written to communicate messages to readers, including those within tutoring sessions, chat rooms, email exchanges and other forms of informal conversation [34, 35]. In the current study the Coh-Metrix indices that estimate psycholinguistic measures, word information, syntactic patterns, syntactic complexity, situation model, lexical diversity and other descriptive indices were used to specifically investigate the linguistic profiles of discourse in the Math Nation Wall posts.

2.2.2 SEANCE

The Sentiment Analysis and Cognition Engine (SEANCE) calculates sentiment indices for a text using pre-developed word vectors that measure sentiment and pre-existing sentiment, social positioning and cognition dictionaries. One particular advantage of SEANCE is that accounts for the presence of negations in the texts (e.g., *not sad*, would not be assessed as negative). Yoo and Kim found positive emotions reported by SEANCE to be strong predictors of success [35]. SEANCE has also been previously used to model math identity and math success [12]. In another study, Crossley et al. demonstrated using SEANCE that math performance was related to the use of fewer words related to respect [11]. Similarly, we used SEANCE in the current study to assess the extent to which sentiment expressed within the discussion posts was related to math performance.

2.3 Data Preprocessing and Feature Selection

The dataset was checked for multicollinearity as it reduces the precision of the estimate coefficients and makes it difficult to assess the relative importance of the independent variables in explaining the variation caused by the dependent variable. Highly correlated features (r >= 0.90) were removed from the analysis. In case two or more attributes were found to be highly correlated, the attributes with the greater number of pairwise correlations were removed. The dataset was further filtered such that features with more than 20% values were missing and those with zero and nearly zero variance were also removed.

The analysis initially included 124 variables (92 Coh-Metrix features, 20 SEANCE Component Scores, and 12 variables related to student factors). After preprocessing and feature selection, 12 linguistic indices, and 4 student variables were included in subsequent analyses. The 12 features represent cohesion and sentiment measures, whereas the 4 non-linguistic indices represent demographics and performance data.

3. RESULTS

The purpose of this study was to assess the degree to which linguistic features of students' language within the Math Nation Wall posts predicted EOC performance compared to other more traditional measures such as demographics and prior math performance. To this end, three linear models were examined using different combinations of candidate predictors of math performance (i.e., non-linguistic features, linguistic features, and the combination of both the non-linguistic and the linguistic features). The necessary assumptions for testing the regression models were met by examining model residuals for all three models. Figure 2 provides the sample diagnostic plots for the residual analysis of the full model. The residuals versus fitted graph reveal no pattern, show a constant variation, and depict linearity. The normal Q-Q plot also shows normal distribution of the residuals. The remaining 2 plots do not depict any non-linear behavior nor any influence of homoscedasticity. These models were also validated using 10-fold cross-validation which rendered the best fit models in terms of RMSE performance.

3.1 Non-linguistic Predictive Model

The non-linguistic features included in this regression model were the students' gender, grade level, and FSA math scores of the previous year (see Table 2). Using only the FSA math scores as a candidate predictor the resulting model accounted for 58.64% of the variance. Using the FSA math score, gender, and grade level, grade level also emerged as a significant predictor but gender did not. The model with the FSA and grade level as predictors accounted for 63.12% of the variance of the EoC scores. No significant interactions between grade and gender emerged.

These results suggest that the Math FSA score depicting prior performance in mathematics and the grade level significantly contributes to Algebra EoC performance, providing adequate proxies for students' baseline performance prior to the course.

3.2 Linguistic Predictive Model

The primary purpose of this study is to examine the degree to which features of the language used by students in the wall posts are predictive of students' Algebra EoC scores over and above baseline proxies provided by FSA performance and demographic variables.

We conducted a multiple linear regression analysis predicting Algebra I scores using the 12 linguistic indices discussed in Section 2.3.

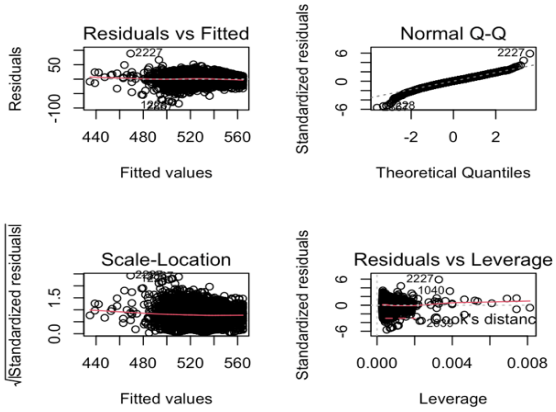

Figure 2 - Diagnostic Plots for linear regressions

Table 2. Linear model including Non-linguistic Features

	Estimate	S.E.	*t*
Using Math FSA only as candidate predictor			
Math FSA Score	1.040	0.027	38.30
Intercept	157.778	9.721	16.23
Using Math FSA, grade and gender as candidate predictors			
Math FSA Score	0.949	0.027	35.052
Grade	-8.395	0.745	-11.262
Gender *	1.000	0.884	1.131
Intercept	253.855	12.691	20.003

Notes: Gender is not significant (p = 0.258); All other p< 0.001. Random-effects were estimated with school district (level 1) in a nested mixed-effects model, resulting in a negligible amount of variance account by the school district (3.67%). Hence, the final models were constructed without district.

Table 3. Linear model including Linguistic Features

	Estimate	S.E.	*t*
Semantic overlap (givenness) of each sentence	-75.698	15.150	-4.997
Incidence of Pronouns	-0.159	0.024	-6.732
Hypernymy for nouns	5.617	0.976	5.758
Intercept	527.486	7.343	71.838

Note: p-value at < 0.001

After the 10-fold cross validation, the best-tuned model accounted for 10.64% of the EOC variance with an RMSE = 21.73. Table 3 reports the coefficients of the significant linguistic. Students whose posts include higher noun specificity (hypernymy) also tended to have higher Algebra I EoC performance. Moreover, lower degrees of sentence givenness and pronoun incidence also emerged as indicators of Algebra I EoC performance. These results imply that the posts by better performing students were structured in such a way that they used more specific terms for concepts or topics (higher noun hypernymy), less personal (lower pronoun incidence), and included queries or responses with greater amount of elaboration on topics that varied across posts (lower sentence givenness/newness).

3.3 Combined Model

The combined model included the significantly predictive features from both the non-linguistic and linguistic models (i.e., FSA score, grade level, LSA givenness, incidence of pronouns, and hypernymy of nouns). This model accounted for 64.48% of the variance for the Algebra I EoC scores with an RMSE of 13.73. The results are summarized in Table 4.

The findings revealed that the full model with the combined linguistic and non-linguistic features performed only slightly better than the baseline model in predicting Algebra I scores (i.e., 63.1% vs. 64.5% of the variance). An ANOVA was conducted to compare the fitness of both regression models, comparing the non-linguistic model to the model with the linguistic predictors. The results indicated that the more complex model with the additional linguistic predictors better captured the variance of the Algebra I EoC scores than the baseline model, $F = 20.879$, $p < 0.001$. We also used Akaike information criterion (AIC) model selection to select the best fit model between the non-linguistic model and the model with the linguistic predictors. The model with the linguistic predictors emerged as the best-fit model carrying 100% of the model weight (AICc weight = 1) and having lower AICc (AICc full model = 8,357.60; AICc baseline model = 8394.72) in predicting Algebra I EOC performance.

These results replicate prior studies [10,15] suggesting students' language fluency and use within Math discussion boards provide valuable information regarding students' potential performance at the end of the year. Importantly, these features can be captured dynamically as the course progresses, and in the absence of other information, such as prior course scores and demographics.

Table 4. Linear model for Combined Features

	Estimate	S.E.	t
Math FSA score	0.902	0.027	32.889
Grade	-8.432	0.731	-11.533
Hypernymy for nouns	2.919	0.617	4.730
Semantic overlap (givenness) of each sentence	-27.529	9.594	-2.869
Incidence of Pronouns	-0.044	0.015	-2.929
Intercept	264.302	13.502	19.575

Note: all $p < 0.001$

4. CONCLUSION

In summary, the results reported in this study confirm prior studies that have suggested that the students' math course scores, and in this case Algebra 1 EoC scores, can be significantly predicted by language, in particular hypernymy, pronoun incidence, and lower semantic overlap between sentences. Students with stronger course outcomes used more sophisticated language, across a wider range of topics, and with less personalized language.

Students' math scores from the previous year served as a proxy for baseline math performance, or prior math skills. As expected, prior math skills provided the strongest predictors of the EoC Algebra I scores. Students' grade level also emerged as a significant (negative) predictor of the Algebra I EoC performance. The students self-select as to when they would take the Algebra I course. As such, higher ability students tend to take Algebra I in middle school whereas lower ability students tend to take the exam later in high school, and thus grade was negatively related to scores.

Hypernymy (specificity) of nouns, an indicator of language fluency, contributed to the prediction of EoC performance such that a higher degree of hypernymy or specificity the words used in the discourse was related to higher EoC scores. Further, the discourse of higher performing students can be characterized as less personal as depicted by lower pronoun incidence. In addition, higher performing students' posts had lower overlap between posts, and more new information as depicted by the lower givenness/new LSA index.

We assume that students' engagement in online discussions reveals some aspects of their mental representations or understanding of the academic content. In turn, the linguistic features of their language can serve as proxies for underlying literacy and math skills. The linguistic features that pertain to language fluency suggest that students' posts were reflective of their ability to communicate more effectively and use terms more specific to the academic content.

Notably, linguistic features depicting sentiment did not emerge as significant predictors of Algebra I EoC performance. This could be attributed to the academic nature of the discussion such that students' discourse tends to be more domain-related and less personal in nature. Yet, there is a strong tendency in the NLP literature to focus on sentiment in language. This study indicates that when other features related to language sophistication are considered, sentiment may not emerge as a significant predictor of performance.

There are multiple implications from this work. The first is relatively obvious: literacy and language skills contribute to students' math performance. Language skills aide in student' comprehension of math and their ability to communicate regarding math. In turn, they are more likely to succeed. As such, providing literacy instruction is important: to enhance students' performance in language courses (ELA), but also for performance in content courses (science, history) and mathematics courses. Second, these results suggest that it behooves educators to consider literacy and communication skills, and provide instructions as concretely and coherently as possible [36-38].

Third, within the context of online platforms, these results further confirm the potential of leveraging linguistic and semantic features of students' posts as indicators of potential course performance. It might be assumed that language is not an important indicator of math; and yet, multiple studies have demonstrated that the linguistic features are powerful proxies for students' underlying skills and knowledge across a variety of contexts. Our future studies will consider other features of language (e.g., rhetorical features, lexical features) as well as examining students' language use across various times during the course. Whereas this study solely examined aggregated posts at the end of the course, our future work will examine the number of posts necessary to significantly predict performance. Dynamic, online predictions are necessary in order to intervene, provide appropriate scaffolding to the students, and usable information for the mathematics instructors. Linguistic dimensions of the production of online discourse and their association with academic performance is a promising field of research. As such, linguistic profiles of discourse have strong potential to inform instructional and pedagogical design of collaborative learning environments such as Math Nation.

ABSTRACT

How do students respond to feedback in a reading platform? In this study we examined students' (n = 670) reading and SRL behaviors after receiving feedback from their teachers. First, we examined the extent in which students revised their responses after receiving feedback. Second, we examined the association of reading and SRL behaviors with student scores after feedback. Third, we examined relationships between the type of feedback received (i.e. teacher comments) and subsequent student behaviors. We found that students who revised their answers more had greater score improvements. Teacher feedback in writing conventions was shown to produce fewer reading and SRL behaviors when compared to other types of feedback. The number of reading events was correlated with improved scores, although the effect size was small. These findings suggest that teacher feedback can help students employ reading and SRL behaviors and improve their reading comprehension under the right conditions. We discuss recommendations and possible design implications for online reading platforms.

1. INTRODUCTION

Feedback can improve students' performance [38] and Self-Regulated Learning (SRL) behaviors [10]. However, students must understand feedback in order to apply it [48]. Feedback gaps occur when students receive but do not act upon feedback [24], and may be caused by lack of clarity [9], students' misunderstanding of feedback application [55], and the feedback paradox [61] (i.e., students do not address feedback despite understanding its importance). Researchers have recently emphasized the actionability of feedback as one factor to change students' actions and behaviors [12]. This concept remains largely underexplored [34].

To address the feedback actionability gap, researchers have analyzed how students act upon receiving feedback by examining students' perceptions [37, 50] and analyzing student behavior, including timely response to feedback [34], the effect of different types of feedback on the same question [27], and students' learning strategies usage [43].

Effat Farhana, Andrew Potter, Teomara Rutherford and Collin F. Lynch "Feedback and Self-Regulated Learning in Science Reading". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 820-826. https://educationaldatamining.org/edm2021/

We examine students' feedback response behavior in science reading. Science reading skills are of critical importance, but challenging for students to master [63]. Science reading can be enhanced through the application of SRL skill [15, 47]. To investigate SRL and science reading, we conducted our analysis on middle school science readings and questions from an online learning platform, Actively Learn (AL). We answered three research questions:

RQ1. How do students' scores vary after receiving feedback?
RQ1.1. To what extent do students change their answers after receiving feedback?
RQ2. How does students' reading and SRL usage vary upon receiving feedback?
RQ3. Is feedback type associated with subsequent reading and SRL behaviors?

2. RELATED WORK

2.1 SRL and Reading

SRL refers to four regulatory processes during learning: goal setting, self-monitoring, self-evaluating, and applying strategies [65]. Self-regulated learners use self-monitoring skills to monitor their tasks [69] and can judge their learning outcomes in light of their goals [68]. Self-regulation is associated with academic performance [49, 66]. SRL researchers have proposed theories and models (e.g., Pintrich's SRL framework [49], Zimmerman's Cyclic model [66]) to explain learners' SRL behaviors. In this study, we adopt Winne and Hadwin's model [56, 58] to measure students SRLs from students' log trace data within AL, as it has proven a useful framework for similar research [4].

SRL-based reading interventions have been effective in improving middle school reading in experimental studies [54]. Computer-based learning environments (CBLEs) can integrate SRL instruction via features to help students foster SRL skills. Examples of CBLEs that are rooted in models of SRL and have been shown to support reading comprehension and SRL behaviors for reading include iSTART [44-45], nSTUDY [4], and ReaderBench [18-19]. In this study, we examine the web-based platform Actively Learn (AL), which uses platform features that promote SRL (Section 3.1).

2.2 Sequence Mining

Sequence mining techniques can identify students' learning behaviors [2, 29]. For example, *n*-gram sequencing techniques have been applied to a game-based learning platform to identify students' problem-solving behavior [2] and to study associations between students' academic performance and transition behavior among multiple platforms [29].

In this study, we are focused on what SRL activities students engage in on the AL platform *after* they receive feedback on a prior submission. In this analysis we applied an approach used by Sheshadri et al. [52] to examine sequence behaviors across platforms. In this approach we aggregated distinct SRL and question submission actions within AL and then examined the frequency and sequence of the activities prior to a resubmission.

2.3 Feedback

Providing feedback and opportunities for students to respond to feedback is one way teachers can assist their students in reading to learn tasks in STEM domains [42]. However, feedback quality can influence students' responses [53]. Hattie and Timperley [31] characterized feedback at four levels: the task (i.e., how well the student accomplished a task), processing (i.e., the processes required to complete the task), self-regulation (i.e., how students choose and implement self-regulatory strategies to accomplish a task); and the self-level (i.e., personal evaluations). Feedback effectiveness is also moderated by the amount of information provided; different types of feedback should be considered as separate constructs [60]. Prior studies have also shown that timely engagement with personalized feedback was associated with academic success for undergraduate students [34] and may also prompt more engaged learning activities when compared to general feedback [43].

Corrective and self-regulatory feedback given to students after answering comprehension questions in response to texts in a digital environment can enhance SRL behaviors and performance [39, 40]. In an experimental study, students who received self-regulatory feedback made more text searches and included more textual info in their responses when compared to students who received less informative or no feedback [39]. A follow-up study replicated these findings and also demonstrated that requiring students to select relevant text information before re-submitting answers led to improved SRL behaviors [40]. Taken together, these studies suggest that corrective and self-regulatory feedback can improve SRL behaviors and reading performance when students are tasked with re-submitting answers to comprehension questions with digital texts.

However, it can be challenging for teachers to provide timely and informative feedback at scale [31, 53]. A prior study on feedback comments of science assignments [8] indicated that feedback that did not provide a correct answer was only helpful if students knew where to find the correct answer; more informative feedback was required when students lacked background knowledge Prior research also suggests that timely engagement with feedback, particularly personalized feedback, was associated with academic success for undergraduate students [34]. Written comments can provide an effective means for providing feedback on science content [8] and in digital reading comprehension tasks [39, 40]. In this study we examined how teacher feedback comments within the context of a digital science reading comprehension related to students' SRL behaviors.

3. Actively Learn (AL) Platform

AL is an online K-12 reading platform for multiple disciplinary subjects. AL catalogs curriculum-integrated readings that teachers can assign as in-class or homework assignments. Teachers can also add their own content as assignments. AL assignments contain text-embedded questions that can be multiple choice (MCQ) and short-answer (SA), including open ended questions and fill-in-the blanks. Teachers can give feedback on students' answers to questions by scoring questions on a scale from 0-4 and writing comments.

We adopted Winne and Hadwin's SRL model in our study. Winne and Hadwin's model has four phases: task defining (**Phase 1**), goal setting (**Phase 2**), enacting tactics and strategies (**Phase 3**), and metacognitively adopting strategies (**Phase 4**). We primarily focus on students' usage of SRL tactics/strategies within AL (**Phase 3)** and adapting reading and SRL (**Phase 4)** upon receiving feedback. Our study is grounded in the Winne and Hadwin model, as its focus on the events underlying SRL [57] fits the retrospective analysis of student interaction data within our study. Furthermore, we focus on three types of SRL events that are consistent with prior literature situated in Winne and Hadwin's model: annotating [3, 41], highlighting [59], and vocabulary lookups [5].

3.1 Dataset Preparation

The present study was conducted with middle school physical science data collected from AL in 2018. The initial dataset contained 17,886 student records from 1,033 classes. First, after data cleaning, we included classes containing 10-60 students (n = 14,925 students). Second, we identified student submissions on which they received feedback. This reduced dataset included 1,819 unique students, 3,867 questions, and 5,373 submissions. Third, we applied the following filtering criteria: 1) a student submitted a question multiple times, 2) received at least one instance of feedback, and 3) re-submitted after receiving feedback. The trimmed dataset, which included student empty submissions, contained 670 unique students in 113 classes, 58 teachers, 156 assignments, 1,072 questions, and 2,502 submissions. All questions in our dataset are SA questions.

4. METHODOLOGY

We describe our methodology for each RQ in this section.

4.1 RQ1 Methodology

To answer RQ1 we measured students' score differences by calculating the difference between the first and last submission scores when students made multiple attempts after receiving feedback. We observed three categories of submissions: score increased in the last submission, score decreased in the last submission, and score was unchanged in the last submission.

To assess whether students were addressing teachers' feedback, we calculated similarity between subsequent answer submissions of a question. We hypothesized that changes in submitted answers would result in a greater score difference in a question. Thus, we measured the cosine similarity between subsequent submissions of a question. Specifically, we calculated cosine similarities between ith and (i-1) th submissions, for i => 2 attempts and took the average. We took all submissions because we wanted to assess how students' changed their answers upon receiving feedback, and how those changes impacted their final scores.

To encode students' responses into vector representations, we used the Universal Sentence Encoder (USE) [15]. The USE can take a word, a sentence, or a paragraph as inputs and encodes into a fixed length vector of 512 values. We then used a Deep Averaging Network (DAN) model with USE to encode questions and question-dependent texts into vectors [15]. DAN averages unigrams and bi-grams of word embedding to construct sentence embedding. Moreover, to evaluate how the answer modifications were connected to score differences, we calculated Spearman correlation between mean cosine similarities and score difference.

4.2 RQ2 Methodology

To answer RQ2, we coded student actions within the AL system as either an answer submission, reading event (R), or SRL event, such as annotating (A), highlighting (H), or vocabulary-lookup (V). The AL system does not define explicit student sessions.

Therefore, we adopted a data-driven approach from prior research to define session [36, 52]. First, we aggregated students' assignment actions and timestamps into a unified transaction log. We then plotted histograms of two consecutive action sequences to estimate the intervals between consecutive actions within an assignment. Based on our exploratory analysis we selected 30 minutes as a "session" cutoff. Any student actions exceeding 30 minutes were defined as a new session. After defining session cutoffs, we split all student actions within an assignment by session. Next, we counted SRL events ***before*** a student's resubmission of the question received feedback.

We then applied a four-level hierarchical linear model (HLM) to predict the last score of a question. HLM is commonly used in educational research [24, 50] to account for nested data [62]. Our HLM model included questions at level-one, assignment ID at level-two, student ID at level-three, and teacher ID at level-four. Fixed effect variables included students' first score on questions and features of SRL usage during attempting questions. All grouping variables were modelled as random intercepts.

4.3 RQ3 Methodology

To answer RQ3, we categorized teacher feedback comments using deductive analysis, which is a method for analyzing content using a predefined model based on prior research [23]. Our deductive analysis categories were adapted from Hattie and Timperley's [31] feedback categories, which have been used in prior research [1, 30]. Our model was also influenced by Shute's [53] review of formative feedback, and Bruno and Santos' [8] combined inductive and deductive coding scheme of teacher written comments in a science classroom context for task and processing-level feedback. We established five a-priori feedback categories using these models. The feedback categories included feedback on the task and processing [31] that (i) asked a student to either provide a correction to a response or to (ii) provide an explanation of a response [8], (iii) self-level feedback, (iv) and SRL behaviors. We also created a category for feedback that only addressed (v) conventions (e.g., spelling, grammar).

The SRL behavior category included teacher comments that referred to the SRL reading behaviors described in the previous section. SRL feedback has been defined as high-information feedback about task performance and suggestions for employing self-regulation strategies to monitor cognitive processes, self-evaluate performance, and strategy development to improve performance [31, 60]. We defined SRL feedback more broadly to include teacher comments that provided feedback on referring to the text to make revisions to an answer, annotating or highlighting the text, or to look up a vocabulary term. This definition is more appropriate within the context of AL, in which teachers leave brief comments on comprehension questions. Prior research has also defined SRL feedback in this context as feedback that includes knowledge about when to refer to the text [39] and which text information is relevant for completing the task [40].

Two members of the research team trained on coding comments using a sample. All differences in training were resolved by discussion. One researcher then coded all teacher feedback comments (n = 1,441). A second researcher independently coded 23% of this sample. Inter-rater reliability (IRR) was calculated using Cohen's kappa and was found to be acceptable ($\kappa = 0.74$, $p < 0.001$). We then applied a nonparametric Kruskal-Wallis test to identify if reading and SRL behaviors varied significantly among feedback categories.

5. RESULTS

In the following subsections we discuss our results for each RQ.

5.1 RQ1 Results

We calculated the average cosine similarities between subsequent submissions (sim_score) and score difference (d) with and without empty student submissions. A higher sim_score indicates that the submitted answers are more similar to each other. The frequencies of six different score difference categories and question counts (n) are: **-2** (n = 4), **-1** (n = 53), **0** (n = 187), **1** (n = 474), **2** (n = 252), **3** (n = 87), and **4** (n = 15). Total questions = 1,072. The Spearman correlation test between score difference (d) and mean cosine similarities (sim_score) was (coefficient = -0.315, $p < 0.001$). The negative coefficient indicates when the mean cosine similarity score decreases, the score difference increases. In other words, the more changes are present in students' subsequent answers, the greater the score difference.

Score Increased Descriptive statistics in this category are: 828 unique questions, 1,963 submissions by 543 students. First attempt score ranged from 0 to 3 with a mean 1.41. Last attempt score varied from 1 to 4 with a mean 2.98. We found that the positive score change groups have increased by 1, 2, 3, and 4 points. In these four groups, sim_score has a lower median value compared to the rest. This observation indicates that students with greater score increases had submissions that differed more than their original answers, as represented by a lower sim_score. We examined student submissions with identical responses (sim_score = 1) but an increase in final score (n = 40) submissions.

Score Decreased. This group includes 57 unique questions with 124 submissions by 49 students. First attempt scores ranged from 1 to 4 with a mean 1.58. Last attempt score varied from 0 to 3 with a mean of 0.51.

Score Unchanged. Descriptive statistics for this category are: 187 unique questions, 415 submissions by 165 students. First and last attempt scores have the same statistics in this category. First and last attempt scores ranged from 0 to 4 with a mean 1.69.

5.2 RQ2 Results

Standardized effect sizes were calculated using the formula, ß = (B*SDx)/(SDy) [50]. First attempt score had the highest predictive power (B = 0.32, ß = 0.28, $p < 0.001$). Only reading was a statistically significant positive predictor. Highlighting behavior was negatively associated with the last score.

5.3 RQ3 Results

Feedback comments were coded as requiring either a correction (n = 654), explanation (n = 565), a SRL behavior (n = 134), addressing conventions (n = 77), and self-level feedback (n = 11). SRL events after receiving feedback and before resubmission were identified. Kruskal-Wallis test results indicated statistically significant differences across the five feedback categories for reading ($p < 0.001$), highlighting ($p = 0.007$), and vocabulary lookup events ($p = 0.006$). Annotating text was not significant.

We conducted post-hoc analyses using Dunn's pairwise tests with Benjamini-Hochberg correction for features with statistically significant results. Effect size (r) is reported using a nonparametric test, Cliff's-Delta. Results indicated that students were less likely to engage in reading after conventions feedback when compared to SRL behavior feedback ($p < 0.001$, r = 0.25), corrective ($p < 0.001$, r = 0.28), and explanation feedback ($p < 0.001$, r = 0.29). The Kruskal-Wallis test assessed whether the group with non-zero entry (i.e., SRL Behavior) was statistically

different from the ones with all zero entries. We found statistically significant differences between SRL Behavior and corrective feedback (p = 0.002, r = 0.009) and explanation feedback (p = 0.001, r = 0.009). Students were more likely to look up vocabulary words after corrective over explanation feedback (p = 0.003, r = 0.021).

6. DISCUSSION and CONTRIBUTIONS

Scholarly Implication: Student Response to Feedback

RQ1 results show that students' who modified their answers had greater score differences, which is consistent with prior findings on automated feedback [39, 40, 64]. We found that teachers at times scored revised responses lower than students' initial score. When examining students' responses, we found students sometimes submitted the identical answer or an empty answer ("No response") despite the teacher asking for explanation or suggesting additional correction. This phenomenon in which students do not address teacher feedback is known as the ***"feedback gap"*** [24]. Students might not respond to feedback if they find it difficult to decipher [9], lack study habits [20], or erroneously believe it does not apply to them [28]. One limitation of the present study is that it is not equipped to determine the reason for lack of student response.

Our HLM analysis from RQ2 shows that reading events and initial scores were statistically significant predictors of last scores. However, SRL variables such as annotation, highlighting, and vocabulary lookups were not statistically significant predictors. We also found that highlighting was underutilized by students and that self-level feedback was not commonly employed by teachers.

Feedback comments categorized as focusing on correction, explanation, and SRL behaviors were associated with more reading events during student revisions when compared to feedback about conventions. We expected SRL feedback to produce more reading events and SRL behaviors than other categories based on prior research with automated feedback, because these comments directed students to revisit the text to revise their answers [39, 40]. However, SRL feedback did not produce statistically significant differences in student behaviors compared to correction and explanation feedback. One reason for this finding might be that these feedback categories had similar amounts of information; the level of feedback informativeness may have a greater impact on student performance and behavior [60]. Corrective (e.g., "Protons cannot be gained or lost") and explanation feedback provided did not explicitly direct students to revisit the text or use an AL feature, but perhaps these behaviors were implied perhaps these behaviors were implied during a task-oriented reading assignment with explanation feedback comments such as: "Great definitions but you need to explain why phase changes are considered physical changes.". This might explain why vocabulary look-ups were more common in corrective and explanation comments when compared to SRL (e.g., "Go back and reread paragraph 9 and reanswer. Might help you to plug some numbers into the equation to see how the inverse relationship works.") and conventions feedback ("Capitalize the first word in a sentence."). Conversely, perhaps the SRL feedback could more effectively influence reading events and SRL behaviors if teachers provided more explicit information that helped students decide when and how to revisit the text to revise an answer [39] or required students to select relevant information from the text to support their answer [40]. SRL feedback may have directed students to relevant portions of the text based on relatively greater highlighting behavior after SRL feedback, but this effect size was small, and highlighting was not positively related to score change, calling into question the value of this behavior.

For Teachers: Feedback Quality

Our analysis also showed that teacher comments were generally short and contained limited information. It may be possible for teachers to improve the quality and effectiveness of their feedback by providing more SRL feedback [60, 31], and by avoiding self-level feedback and comments about conventions, which were shown to not support student performance in the present study. To optimize feedback from teacher comments and increase student feedback uptake, teachers should support students in understanding feedback comments and evaluation criteria [13], which may require greater elaboration within comments and potentially instruction outside of AL.

Design Implications: Automated Feedback Affordances

Feedback can improve performance [38], but poor feedback can hinder student learning [31]. Middle school teachers may not have enough time to provide quality and timely feedback to all students, particularly when providing feedback to open-ended questions that require source-based explanations [6]. Although automated feedback may assist teachers in providing quality and timely feedback without increasing their workload [6, 14], challenges remain in building platforms to provide such feedback within the context of source-based science questions. For example, AL science questions are often constructed responses that require connecting information from different paragraphs. The state-of-the-art NLP research to automatically infer information from paragraphs in reading comprehension is still in early stage [22, 35]. One possible design for automated support would be to collect other teachers' feedback on the same question in the AL platform and provide suggestions to the teacher.

Design Implication: Supporting Feedback Actionability

Some students were not responsive to feedback as indicated by their submission of an empty answer or re-submission the same answer. One solution to increase actionability could be pointing to additional learning materials in an automated feedback setting [33]. For example, Broos and colleagues [7] designed a button "***Okay, what now?***" in a dashboard to provide actionable feedback. Students could click the button to view extra reading content. Similarly, a nudge can be implemented in AL—***"Are you sure you want to submit that empty answer?"***

7. CONCLUSIONS

This study has two main contributions to reading and SRL research: (i) empirically evaluating students' response changes to short answer questions upon receiving feedback and (ii) measuring the association of students' reading and SRL with five feedback categories. Our findings show that students who revised their answers demonstrated statistically significant differences in their scores. We also observed that teachers mainly provided corrective feedback followed by explanatory and feedback related to SRL behavior. Students exhibited more reading behavior upon receiving these types of feedback than convention-related feedback. These results may aid educators in writing feedback comments to students for maximal impact.

ABSTRACT

Active involvement of new community members is essential for Q&A platforms such as Stack Overflow, to make the platform efficient and more inclusive. However, more than half of Stack Overflow users contribute only once and disappear. This decreases the diversity of viewpoints and experience on the platform. This paper aims to identify factors that can discourage users from active participation after their first or second post. We collected a dataset of the responses to questions posted by new users (answers, comments, upvotes, downvotes) and analysed the tone of the feedback and its impact on the users' ongoing participation. We considered as new users those who registered to Stack Overflow for the last two years before the data collection and classified then into three groups based on the number of their posts (low, medium and high number of posts) on Stack Overflow. The differences in the responses between the three user groups have been validated by performing one-way ANOVA and Pearson's chi-square test. Based on these results we trained a machine learning model using a SVM classifier which predicts whether a user is likely to post or not with an accuracy of 88.69 %. Our work contributes to identifying and quantifying the potential underlying factors behind the decline in participation and dropout of new users on Stack Overflow.

1. INTRODUCTION

Stack Overflow (SO) is one of the most popular Q & A based platforms for programmers, having over 50 million monthly visitors[7], over 16 million questions[19] and 19 million answers[11]. SO has detailed guidelines for posting questions and some fundamental standards for providing feedback to the questions. Expert users who have been using Stack Overflow for a long time are rewarded with badges and reputation [14]. In order to garner a high reputation on the site, the user must be active on a regular basis on the SO platform and their questions must have many positive responses. However, novice users may not have the correct vocabulary or expertise to formulate a technical question. As a result, they may end up getting negative responses such as "stupid question" or "This is such common issue, just google". Such negative responses to posts may discourage users to limit or seize their contributions to the platform. This kind of users make up for almost half the users of the platform [18]. Unsolved questions in SO have seen an exponential growth over the years [16] and they continue to be an issue for new users who seek help. Studies have shown that online trolling and negative responses worsen over the active time of a user in a community [8] and 77% of users tend to ask for help on the SO platform only once [13]. In this paper, we identify and validate the factors which impact the state of participation of the new users on Stack Overflow. "New users" are those who have been registered to SO for less than 2 years until August 2019 (when the dataset was created). We selected and analysed five features from the SO post responses to understand how getting little to no response and negative responses is related to users posting behaviour. Based on our findings, we built a machine learning classifier to predict posting status of users in SO.

2. RELATED WORK

The Stack Overflow or SO platform has turned into a valuable resource for both skilled and amateur programmers for glitches, bug and any code related problems. Managing such a large user base has been a challenge and an ongoing topic for investigation and research from different perspectives. Anderson et al. [3] explores the correlation between user reputation and quality of answers and its impact on the design of the site. Asaduzzaman et al. [4] mines the unanswered questions in SO to reveal the underlying factors that lead to questions remaining unanswered, such as title length, askers' score, post length etc. Alharthi et al. [2] investigates sev-

eral factors that impact the quality of questions in SO and predicts the score of the question, which indicates its overall quality. Similar idea of prediction has been explored in Shao et al. [17] developed a prediction model which analyses the latent context of a question and recommends an answer for the user. Calefato et al. [6] developed a framework based on successful questions on SO to provide an evidence -based guideline for programmers to write better questions in SO. Grant et al. [12] explores the use of badge, to motivate users. When a question has better wording and quality, it attracts more users and the user gets upvotes which in turn helps the score. Adaji et al. [1] investigates specific social support strategies that influence users to contribute in SO More recent studies have focused on the behavioural and personality traits of SO users as well, in order to target the emotional aspects of the users who ask questions [15, 5]. The novice or infrequent users who just started out face some level of criticism or neglect by the more experienced users on SO, a phenomenon related to maintaining community boundaries by hazing. Hazing is a psycho-social phenomenon where the newcomers in a tightly knit group face backlash and elitist attitude (which is sometimes borderline abusive)[9]. Slag et al. [18] discusses the difficulties encountered by "one day flies", users who post only once in their profile's lifetime and do not contribute to the platform afterwards. Our work further investigates the effect of the factors identified in [18] by providing statistical and empirical validation to the hypothesis proposed in [18].

3. RESEARCH QUESTIONS AND DATASET

Since we wanted to compare the responses of the posts, not the nature of post itself, we eliminated two of Slag et al. [18] factors: duplicate questions and uncommon tags. Instead, to further investigate the features of questions asked by such inactive users, we added five new factors: the number of upvotes on a question (Up Votes), the downvotes (Down Votes), the number of comments on a post (Comment Count), the reputation of users (Reputation), and the types of comments on a post (Comment Texts). We chose to add reputation since it affects how a user's posts is perceived by other users. We aim to answer two research questions:
"1. Do these factors have any quantifiable relation to the frequency of posts of users in Stack Overflow?"
"2. Can we predict whether a user will drop out and stop posting?".

3.1 Data Collection

We collected data from Stack Exchange Data Explorer [1], an open source tool to collect publicly available data from Stack Overflow. We used Stack Exchange Data Explorer to collect information about users who created their profile on Stack Overflow in 2017.

For our work, we chose to consider only the questions posted by users as their contribution. We collected the number of answers, comments, upvotes, downvotes, view count given against (received by) each post of a user and the user's reputation. We decided to analyze the mean values of these features for each user so that we can consider all of them in a normalized form since the distribution of responses is not equal for all users. In order to determine the overall tone of a comment, we inferred the polarity of the comments from the text of the comments through sentiment analysis on the text by using TextBlob on all the comments received by a user. Polarity generally falls within the range of -1 to 1 where -1 refers to a very negative sentiment, 0 refers to a neutral sentiment and 1 refers to a very positive sentiment. We categorized this range into five different groups as shown in Table 1.

[1]https://data.stackexchange.com/stackoverflow/query/new

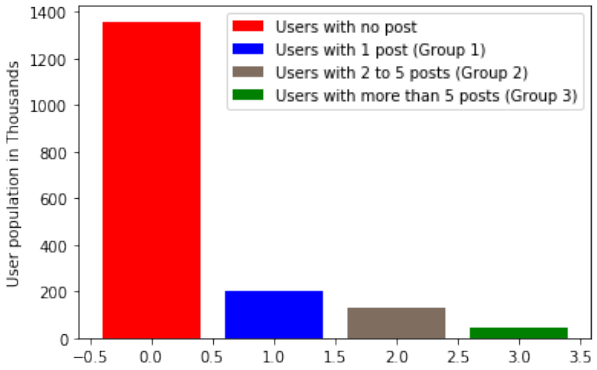

Figure 1: Distribution of users population (in thousands) based on the number of posts they made on Stack Overflow

Table 1: Group based on overall polarity of the comment

Group	Description
1 (Highly negative)	If -1 <= polarity <-0.5
2 (Moderately negative)	If -0.5 <= polarity <0
3 (Neutral)	0
4 (Moderately positive)	If 0 <polarity <= 0.5
5 (Highly positive)	If 0.5 <polarity <= 1

3.2 Target user groups

The users were categorized into the following groups based on the number of questions they posted from January 2017 to June 2019: group 1 (users who posted a question once), group 2 (users who have posted from 2 to 5 times), group 3 (users who have posted more than 5 times). The distribution of user population according to the number of posts they made in their lifetime on SO in out collected data is depicted in the figure 1. We aim to identify such users by analyzing their past experiences on SO. In our prediction model, described in Section 5, for predicting the future behavior of a user, group 1 is labelled as the negative class whereas groups 2 and 3 are combined into a single category as the positive class. Therefore, the labeled classes considered for this study are:

1. Negative class: Users who will discontinue making any contribution to Stack Overflow after their first post.

2. Positive class: Users who will continue contributing to the platform.

4. DATA ANALYSIS

	View Count	AnswerCount	CommentCount	Reputation	DownVote	UpVote	Polarity
View Count	1	0.32	0.41	0.1	0.3	0.51	0.24
AnswerCount	0.32	1	**0.86**	0.1	**0.59**	**0.68**	**0.67**
CommentCount	0.41	**0.86**	1	0.11	**0.57**	**0.61**	**0.79**
Reputation	0.1	0.1	0.11	1	0.08	0.24	0.1
DownVote	0.3	**0.59**	**0.57**	0.08	1	**0.52**	0.53
UpVote	**0.51**	**0.68**	**0.61**	0.24	**0.52**	1	0.49
Polarity	0.24	**0.67**	**0.79**	0.1	**0.53**	0.49	1

Figure 2: Distribution of users population (in thousands) based on the number of posts they made on Stack Overflow

The data analysis of feature selection, validation of metrics and prediction model is provided below.

4.1 Feature Selection

From the data collected from SO, we performed Pearson correlation analysis to find out how strongly each feature is related to another. The results of correlation analysis for the features are shown in figure 2. Following the Cohen's classification system [10], only the largest relationships i.e. where the correlation coefficient r>0.5, have been considered to be significantly correlated. From figure 2, it is evident that the correlation coefficient of comment count, answer count, downvote, upvote, and polarity are significant i.e. greater than 0.5. Therefore, for our feature analysis, these five features are selected as the final metrics for next stage.

4.2 Feature Distribution in User Groups

To answer the research question: Do these features have any quantifiable relation to the frequency of posts of users in Stack Overflow?, we analyzed their statistical differences among the three user groups. We used a one-way ANOVA test and Pearson's chi-square test to establish the statistical evidence of the differences in terms of the features among the three user groups.

All of the five features are plotted against the number of posts from users. And the plotting is done for each of the three target user groups to observe the difference of plots in each groups. The sections below provide in-depth description of each of the features on all three user groups.

4.2.1 Number of Answers against Number of Posts

Figure 3 depicts the distribution of average number of answers against the number of posts from each user from the target group of users on SO. The mean number of answers among three groups are: 1.10 (group 1), 3.31 (group 2) and 15.70 (group 3), which indicates that users in group 3 receive significantly more responses to their posts compared to users in groups 1 and 2. The p-value in one-way ANOVA test indicates significant statistical difference among the three groups in terms of the mean number of answers they receive against their posts ($F(2,375196) = 678.8$, $p = .000$).

4.2.2 Number of Comments against Number of Posts

The mean number of comments among three groups are: 2.22 (group 1), 6.60 (group 2) and 30.00 (group 3), which indicates that the mean number of comments significantly increases with the increasing number of posts in each group. Moreover, it is also evident from figure 4 that users who posted less (no more than five times) exhibited a higher tendency of receiving no comments from other users. The result of one-way ANOVA test indicates significant statistical difference between the groups than within the groups in terms of number of comments they receive against their posts ($F(2,375196) = 187.3$, $p = .000$).

4.2.3 Number of Upvotes against Number of Posts

The graphs show the relation between the average number of upvotes with the number of posts in Figure 5. The mean upvotes in group 1 and 2 are significantly lower than group 3 (0.696, 1.853 and 8.877 respectively), which indicates that the posts made by the users of group 3 are more appreciated and receive higher number of upvotes than the posts made by the users who are less active. One-way ANOVA result indicates significant statistical difference among the three groups in terms of number of upvotes they receive against their posts ($F(2,375196) = 17.15$, $p = .000$)

4.2.4 Number of Downvotes against Number of Posts

From figure 6, it can be observed that the mean number of downvotes in group 1 and group 2 (0.548 and 1.309 respectively) are lower than that of group 3 (4.17). This means that the users who are posting more questions are also getting fewer downvotes. This is an important and surprising observation since a higher number of posts could have also led to increased number of downvotes, which turns out to not be the case. One-way ANOVA result indicates significant statistical difference between the groups than within the groups in terms of number of comments they receive against their posts ($F(2,375196) = 473.04$, $p = .000$).

4.2.5 Comment Polarity against Number of Posts

Table 2: Percentage of each comment polarity category received by the user groups

	User Group		
Polarity Group	1	2	3
1 (Highly negative)	0.2%	0.1%	0%
2 (Moderately negative)	20.1%	20.7%	13.6%
3 (Neutral)	24.4%	11.7%	1.3%
4 (Moderately positive)	48.4%	67.2%	85.1%
5 (Highly positive)	1.1%	0.3%	0%

The result of cross tabulation in Table 2 revealed that users from group 3 received zero highly negative comments, and the least proportion of moderately negative comments. They also received the highest proportion of moderately positive comments (85.1%). On the other hand, the users of group 1 received the lowest amount of moderately positive comments(49.5%) among the user groups. It can be concluded from Table 2 that with the increase in the number of posts made by the users, there is an increase in the positive comments and decline in the negative remarks received by the post owners. Lastly, the result of Pearson's chi-square test establishes the statistically significant relationship between the polarity of comments and the user groups ($\chi^2(8, 297447) = 20310.29, p = 0.000$).

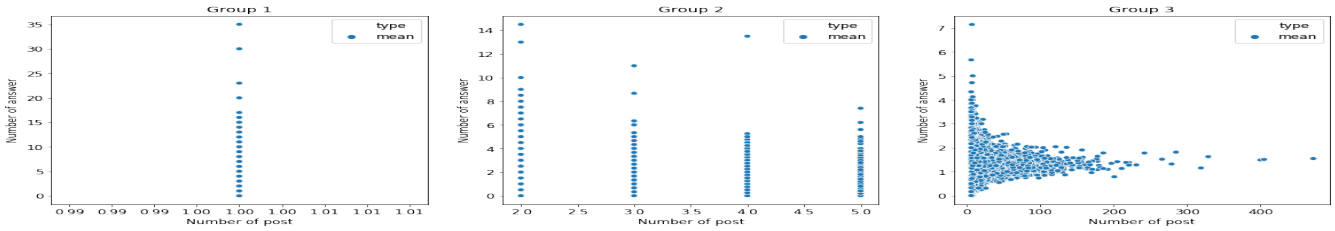

Figure 3: Distribution of average number of answers against number of posts among three user groups

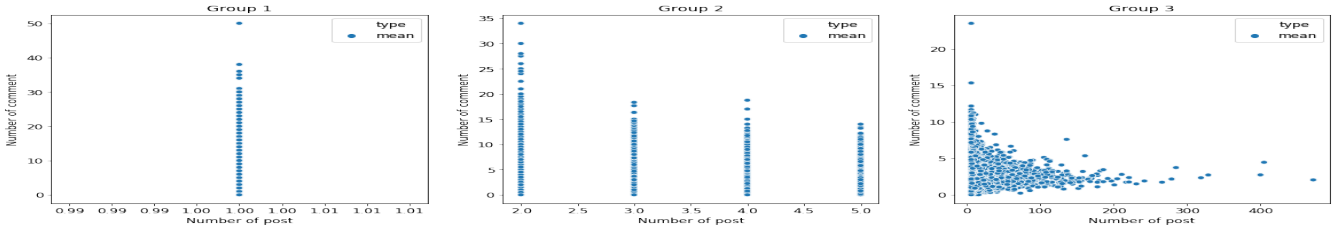

Figure 4: Distribution of average number of comments against number of posts among three user groups

	Name	Measure
Features	Mean answer	Scale
	Mean comment	Scale
	Mean upvote	Scale
	Mean downvote	Scale
	Mean polarity	Scale
Target	User Class	Nominal

Table 3: Attributes of the dataset employed in the SVM classifier

Classifier	Accuracy	Precision	Recall
SVM	0.8869	0.9875	0.7635

Table 4: Prediction model performance per evaluation metric

5. PREDICTING USER PARTICIPATION

Based on the findings from correlation analysis and statistical testing of factors influencing users post frequency, we developed an actual prediction model to answer the second research question. In order to develop and train our model, we took advantage of a popular supervised machine learning algorithm called support vector machines (SVM). Table 3 describes the features and target groups employed in our model. We divided the original data set into training set representing 80% of the data and testing set representing the remaining data. By using the five features, we divide our users into two classes: likely to post and not likely to post. The performance of our prediction model i.e. how well it predicts the user class is evaluated using the metrics: accuracy, precision and recall. Our model performs significantly well and yields a high score in terms of all three metrics as illustrated by Table 4.

6. IMPLICATIONS AND FUTURE WORK

From our data analysis, we observed that a low number of answers and comments, a high number of downvotes and negative comments, and a low number of upvotes are more prevalent in the posts of users who have posted fewer times compared to the users who have higher number of posts. Since these users are receiving negative remarks and downvotes even with fewer posts, this may play a role in discouraging them from seeking help again from SO. In the light of this discovery, we trained a SVM classifier model with the five special features and divided the users into two classes: users who will post in the future and users who will not. The model has shown good performance with high accuracy and effectiveness.

Previous works which mostly focused on how users can ask better questions or build a better profile to attract more answers to their questions. The novelty of our study is to identify infrequent users and find a possible factor underlying their withdrawal, so that the community owner/ moderator can make the platform more welcoming and less hostile for them. Our study has some limitations as well. We could not consider the number of deleted questions of a user as one of the factors that could contribute to users' decline in posts since Stack Exchange Data Explorer does not provide that data. The research also lacks a qualitative analysis from feedback of infrequent or absent users. Therefore, as part of our our future plan, we will attempt to explore the user modelling of infrequent posting through a targeted qualitative user study of SO users.

7. CONCLUSIONS

More than half of the users in Stack Overflow tend to ask for help on the platform only once and never post again. In this paper, we identified five main features / metrics which we hypothesized to be related to the inactive status of users. We collected the responses to posts in SO for users who have their SO profiles for 2 years (2017 to 2019) and selected five factors with strong correlation. Ours statistical analysis supports our hypotheses and validates the effect of these factors having a significant correspondence to users' posting frequency. Using these factors as selected features, we trained a machine learning model that predicts whether or not a user will post in the Stack Overflow platform, based

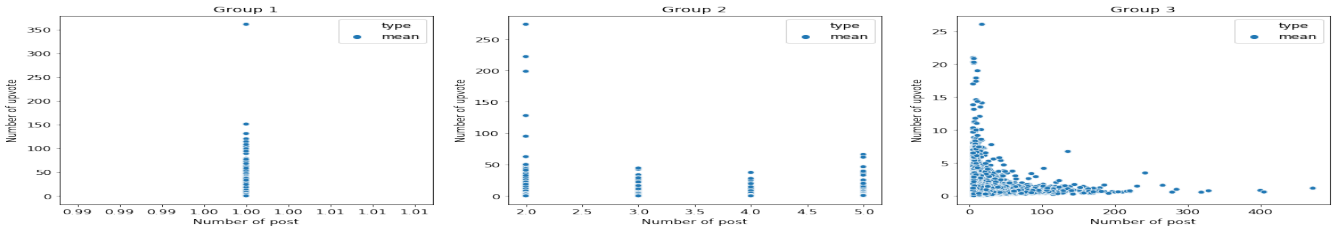

Figure 5: Distribution of average number of upvotes against number of posts among three user groups

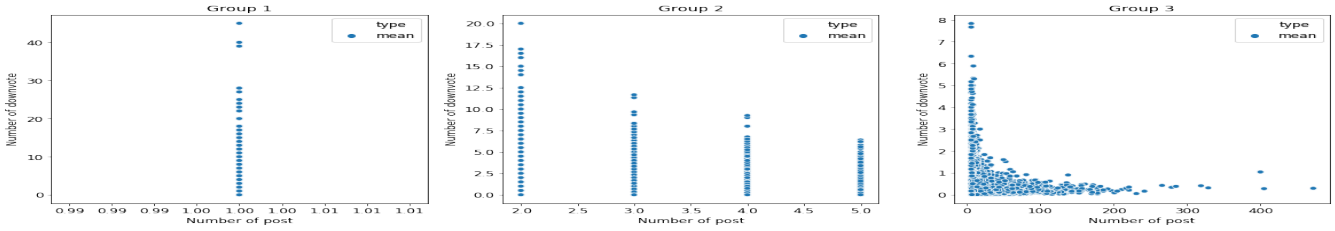

Figure 6: Distribution of average number of downvotes against number of posts among three user groups

on the responses their posts received till now. This prediction can identify users who have reduced their posting in SO and face lack of encouragement and thus can benefit from a positive nudge, help or mentorship. The significance of the contribution of our analysis and prediction model is that it can help to provide more equitable treatment of newcomers, and thus increase the diversity of the SO community.

SimGrade: Using Code Similarity Measures for More Accurate Human Grading

Sonja Johnson-Yu, Nicholas Bowman, Mehran Sahami, and Chris Piech
Stanford University
{sonja, nbowman, sahami, piech}@cs.stanford.edu

ABSTRACT

While the use of programming problems on exams is a common form of summative assessment in CS courses, grading such exam problems can be a difficult and inconsistent process. Through an analysis of historical grading patterns we show that inaccurate and inconsistent grading of free-response programming problems is widespread in CS1 courses. These inconsistencies necessitate the development of methods to ensure more fairer and more accurate grading. In subsequent analysis of this historical exam data we demonstrate that graders are able to more accurately assign a score to a student submission when they have previously seen another submission similar to it. As a result, we hypothesize that we can improve exam grading accuracy by ensuring that each submission that a grader sees is similar to at least one submission they have previously seen. We propose several algorithms for (1) assigning student submissions to graders, and (2) ordering submissions to maximize the probability that a grader has previously seen a similar solution, leveraging distributed representations of student code in order to measure similarity between submissions. Finally, we demonstrate in simulation that these algorithms achieve higher grading accuracy than the current standard random assignment process used for grading.

similarity, code embeddings, embeddings, assessment, grading, human, simgrade, grade

1. INTRODUCTION

Free-response coding questions are a common component of many exams and assessments in programming courses. These questions are popular because they give students the opportunity to show their understanding of course material and demonstrate their coding and problem-solving skills [16]. However, the flexible nature of these problems introduces unique challenges when it comes to grading student responses, which are compounded in situations where the scale of the course necessitates a team of graders working together ("group grading"). The difficulty of consistent application of grading criteria by a group of graders stems from the incredible diversity of student submissions that are generated for free-response coding questions. In particular, it has been previously shown that the space of different student solutions to free-response programming problems follows a long-tailed Zipf distribution [18]. For this reason, it is challenging to develop automated systems for grading and providing feedback and thus human grading remains the gold standard for grading such free-response problems. However, even a team of human graders with extensive experience can struggle to consistently and accurately apply a single, unified criteria when grading. This is problematic as it can result in negative impacts on students in the form of incorrectly assigned grades and inaccurate feedback. Our goal in this paper to explore the frontier of techniques improving the process and outcomes of the exam grading experience.

Our main insight in developing improved approaches for grading is that *it is easier for graders to grade in a consistent manner if they are able to grade similar submissions one after another.* First, we examine historical data to provide concrete evidence of a relationship between grader accuracy and the similarity of previously graded submissions to the current submissions a grader is grading. Then, we propose algorithms that group and order similar submissions in different ways to minimize grader error. Finally, we show that these algorithms perform better than current baseline methods for grading. This work's primary contributions are:

1. Reporting of grader errors in a CS1 course
2. Using historical data to demonstrate the potential benefits of similarity-based grading
3. Three algorithms for grading using code similarity

1.1 Related Work

Autograding One commonly used approach to scale grading is the use of autograders [6]. While useful for comparing program output for correctness or matching short snippets of code, autograders are more problematic for free-response questions in exam settings. In such contexts, the subtlety of understanding that human graders provide is often essential to providing appropriate feedback to students and properly assessing the (partial) correctness of their solutions. While promising, fully autonomous AI solutions are not ready for

Sonja Johnson-Yu, Nicholas Bowman, Mehran Sahami and Chris Piech "SimGrade: Using Code Similarity Measures for More Accurate Human Grading". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 833-837. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

grading CS1 midterms [14, 11, 18, 12] especially for contexts with only hundreds of available student submissions [17].

Grading by Similarity The idea of grouping and organizing student submissions in order to improve grading outcomes has been previously proposed for a variety of problem types. Merceron and Yacef [9] use vectors that encode students' mistakes in order to group together students who make similar mistakes when working on formal proofs in propositional logic. Gradescope, designed by Singh et al. [15] offers functionality for grading similar solutions, which is currently most effective on multiple-choice-type questions. This approach has also been applied to short answer questions, as explored by Basu et al. [2], as well as math problems, as demonstrated by Mathematical Language Processing [8]. In this paper, we identify "similar" student responses on free-response programming questions to improve grading quality.

Code Similarity In order to define similarity metrics for student code submissions, we apply techniques for generating numerical embeddings for student programs. Henkel et al.what [5] created abstracted symbolic traces, a higher-level, light-syntax summary of the programs, and embedded them using the GloVe algorithm [13]. Alon et al. [1] pioneered code2vec, an attention-based embedding model specifically used to represent code. Recently, further advances have been made to improve code embeddings by training contextual AI models on large datasets from Github [7]. For this application, we favor simpler unsupervised embedding strategies that do not require human-generated labels by adapting the popular NLP technique Word2vec [10], in which "word" representations are derived from surrounding context.

1.2 Dataset

Our analysis focuses on the student submissions and grader logs from four exams for an introductory programming (CS1) course taught in Python. The breakdown of summary statistics across the four exams is presented in Table 1. As a note, a "submission" is defined as one student's written answer to one free-response problem – thus, the total number of submissions for a given exam is roughly the number of students times the number of coding problems on the exam. In total, we analyze 11,171 student submissions across 1,490 students. Additionally, we have grading logs for every student submission, which consists of information about the grader, the criteria items applied, the final score, and the amount of time that the grader spent on the submission. 199 graders contributed to grading these four exams. As discussed below, the same student submission is sometimes graded by more than one grader for validation purposes. Thus, our dataset contains 14,597 individual grading log entries.

Our grading data comes from a grading software system that randomly distributes student submissions to graders. Among the standard student submissions for grading, this software also inserts "validation" submissions that have already been graded by senior teaching assistants. Every grader assigned to a specific problem will grade all "validation" submissions for that problem. The presence of these special submissions creates opportunities for assessing grader performance, both relative to their peers and relative to "expert" performance.

Exam #	# Students	# Submissions	# Graders
1	533	3,731	53
2	259	1,813	52
3	247	2,470	51
4	451	3,157	43
Total	1,490	11,171	199

Table 1: Exam Grading Dataset Summary Statistics

2. NATURAL GRADING ERROR

While anecdotal experience of grading inconsistency is a common trend in our experience as educators, our first focus is to quantify the inconsistencies present in historical grading sessions in a rigorous manner. In particular, our analysis focuses on the aforementioned "validation" submissions that were specially handled by the grading software and assigned to every grader working on a specific problem. As a result, we had a subset of the grading logs for which we knew both the true grade (as defined by an expert) and the "validation" grade assigned by each grader. Plotting these values against one another is shown in Figure 1, which reveals troubling inconsistencies in the grades assigned by graders. With an RMSE of 7.5 (i.e., average error of 7.5 percentage points per problem), we see that grading error is significant, nearly on the order of what would translate to a full letter grade. Linear regression on this plot yields an R-squared coefficient of 0.947 indicating that while the error may be high, the direction of errors is generally unbiased. In other words, there is not systematic over/under-grading. Rather, the grading errors tend to be randomly distributed around the true grade. Thus, the rest of this paper focuses on methods for decreasing this demonstrated inconsistency (absolute error) in human grading.

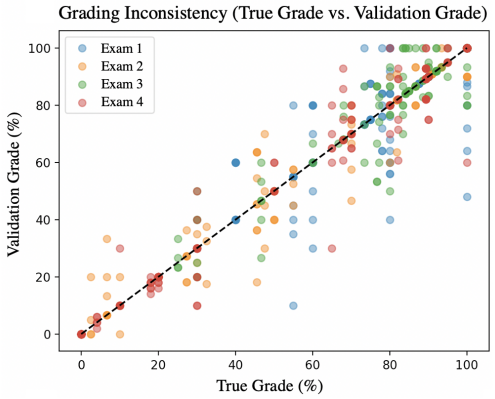

Figure 1: True grade assigned by expert vs. validation grade assigned by human grader

3. METHODS

In this section, we will first outline methods for answering key questions about the problem of improving human grading using similarity scores. Then, we will present three novel algorithms for improving human grading.

3.1 Can code similarity be accurately captured?

We generate program embeddings for all student submissions in our corpus. Word embeddings are an established

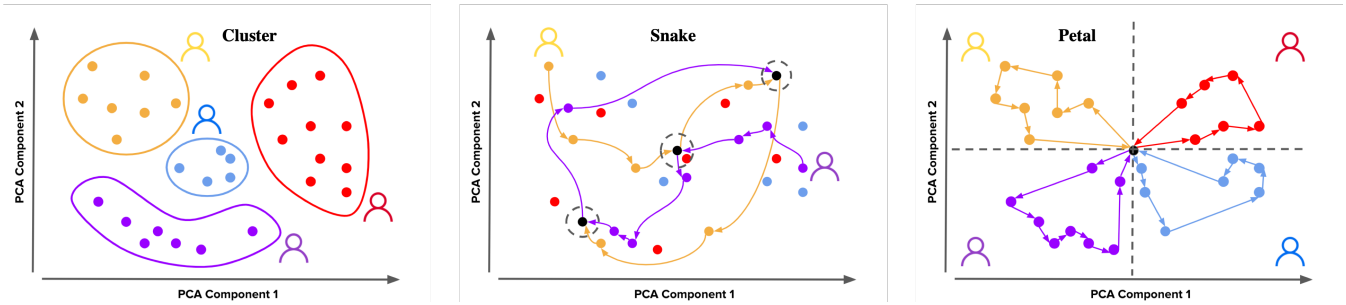

Figure 2: Submission assignment via three algorithms: Cluster, Snake, Petal

method of encoding semantics in human language [10, 13, 3, 3], and these same techniques applied to code accomplish similar results. Algorithms for generating embeddings are constantly evolving and improving; to avoid over-optimization at the embedding generation stage, we chose to employ the simple baseline Word2Vec algorithm. We then demonstrated that our embeddings are semantically significant using zero-shot rubric sampling [18]. For details, see the Appendix[1].

3.2 Does similarity influence grader accuracy?

We hypothesize that graders score submissions more accurately when they have recently seen a submission similar to the current submission. To test this hypothesis, we analyze grading data for four exams. First, for each grader, we generate a "percentage grading error," which is an average of their absolute percent deviation from the correct answer on all validation submissions that they graded. Then, for each of the validation submissions that a grader evaluated, we sort their personal grading logs by time and look at the window of three submissions leading up to each validation submission they graded. To quantify similarity of the validation submission to recently graded submissions, we take the maximum of the cosine similarity between the current validation submission and the three previous submissions. We plot the maximum similarity between a validation submission and the previous submissions against a grader's percentage grading error in order to identify the relationship between a grader's history and accuracy. Then we can infer a formula that approximates the relationship between previous submission similarity and percentage grading error.

3.3 Algorithms to assist human grading

We compare four algorithms for assigning submissions to graders: (1) Random, in which submissions are randomly assigned to graders, with five "validation" submissions interspersed for assessing grader bias. This is the status quo and serves as the baseline. (2) Cluster, in which each grader is assigned to a cluster of highly similar submissions. (3) Snake, in which each grader is randomly assigned a set of submissions and is shown the submissions greedily by nearest neighbor. (4) Petal, in which the dataset is divided into "petals" and all graders begin in the same place. Figure 2 provides a visualization of (2), (3), and (4). Detailed explanations of the algorithms are in the Appendix[1].

[1]https://compedu.stanford.edu/papers/appendices/SimGradeAppendix.pdf

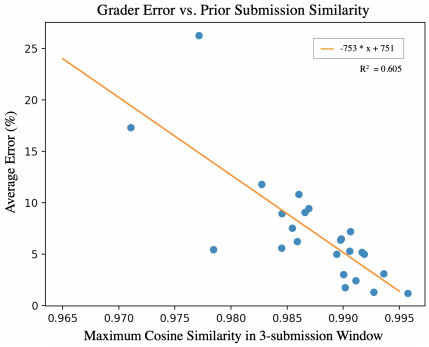

Figure 3: Relationship between grader accuracy and similarity in 3-submission window prior to validation submission

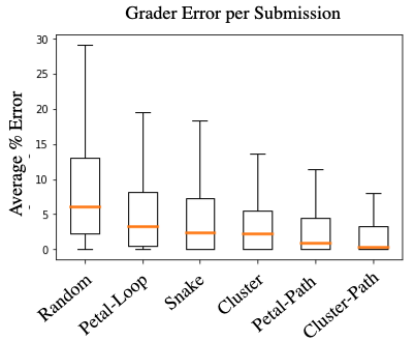
3.4 Algorithm evaluation

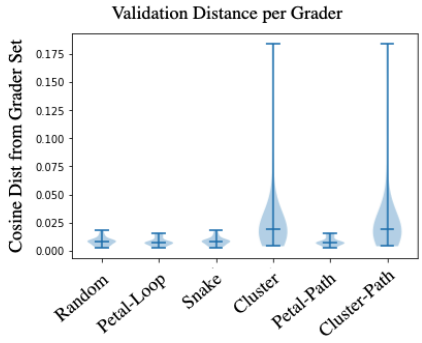
To evaluate the performance of the different algorithms, we simulate grading for a 444-person six-problem exam and ten graders, using real student programs from an actual exam. Details about the selection of validation submissions are in the Appendix[1]. When running the simulation, we infer percentage grading error by examining the similarity of the previous three submissions to the current submission. While we emphasize grader error as the most important metric for assessing an algorithm, a secondary consideration is how naturally validation submissions integrate with the rest of a grader's assigned submissions. Ideally, a validation submission is not "out-of-distribution" with respect to the other submissions that a grader is assigned. Otherwise, a grader will be able to tell when they are being evaluated for grading accuracy. To assess how "out-of-distribution" the validation submissions are, we examine how dissimilar the validation submissions are from the non-validation submissions assigned to a grader. Specifically, for each validation submission, we measure the distance between the validation submission and the nearest non-validation submission assigned to that grader. We average over the five validation submissions in order to get the mean minimum distance from validation to non-validation for a grader, which will be higher if one of the validation submissions is out-of-distribution.

4. EXPERIMENTAL RESULTS

4.1 Similarity scores are meaningful

Embeddings are semantically significant because similarity between embeddings corresponds to similarity between sub-





Algorithm	Grading Error (%)	Validation Dist (cos)	P-Value
Random	10.2	0.0084	-
Petal-Loop	6.1	0.0080	0.07
Snake	6.2	**0.0068**	0.10
Cluster	3.9	0.028	< 0.005
Petal-Path	3.9	0.0080	< 0.01
Cluster-Path	**2.7**	0.028	< 0.005

Figure 4: Left: Average per-submission grading error for each algorithm, Center: Distance of validation submissions from normally assigned submissions, Right: Summary performance statistics, including comparison to random baseline.

mission feedback labels, as described in the Appendix[1].

4.2 Similarity influences grading

Graders score assignments more accurately when they have recently seen a submission similar to the current submission they are grading. From our analysis of historical data, we find that when there is a high similarity between the current submission and at least one of the previous three submissions, the percentage grading error is low. Conversely, when the similarity between previous submissions is low, the percentage grading error is high. We find a linear relationship between the maximum similarity of the previous three submissions and the percentage grading error as shown in Fig. 3, with $R^2 = 0.605$. Given that the grading process involves the numerous uncertainties that come along with human involvement, we believe this correlation coefficient shows a statistically significant relationship between historical similarity and grader accuracy. While the linear relationship between historical submission similarity and percentage grading error is a simplifying assumption, it is the best assumption we can make given evidence provided in Fig. 3.

4.3 Improved accuracy by algorithm

We compare six algorithms for assigning submissions to graders and selecting an order in which a grader will view a submission in Figure 4. We apply the equation of the linear relationship shown in Figure 3 to the similarity of submissions as ordered for evaluation by different algorithms in our experiments. This equation allows us to predict grader accuracy when using the orderings provided by different algorithms. We find that implementing a path ordering on a clustered assignment of graders to submissions yields the lowest mean error of 2.7% (bold-ed in Fig. 4), while the other algorithms all show an improvement over the baseline 10.2% grading error. We utilize bootstrapping [4] over 100,000 trials in order to get the p-values that indicate the significance of the difference in means between the baseline algorithm and the other algorithms (see table in Fig. 4).

4.4 Validation viability by algorithm

When comparing the cluster, snake, and petal algorithms, we observe that the cluster-based algorithms are most likely to have validation submissions that are "out-of-distribution," with a mean validation distance of 0.0277. All other algorithms have substantially lower mean minimum distances.

5. DISCUSSION

Overall, we saw that all of our novel proposed algorithms for assignment of submissions to graders provided improvements over the random baseline in simulation. In general, we saw that path-based algorithms (petal-path and cluster-path) had lower grading error than their non-path counterparts because they are designed to optimize for maximum similarity between consecutive submissions that a grader grades. In particular, the cluster-path algorithm yielded the lowest grader error in simulation due to its strong tendency to assign very similar submissions to graders. On the other hand, the snake algorithm provided the most optimal average distance to validation submissions, which may be important for a smooth experience for a real-life grader. Finally, we saw that the petal algorithm offered a balanced trade-off between these two extremes – while not optimal in either metric, it can be a good choice when both metrics (grading error and validation submission distance) are equally important for designing a grading experience. For a more in-depth discussion of our observed results, see the Appendix[1].

6. CONCLUSION

Through analysis of historical exams, we demonstrated that there is inconsistency between true scores and grader-assigned scores. In doing so, we introduce a new task and associated measure, *grading correctness*. Moreover, we found experimental support for our hypothesis that graders are able to assign scores to exam problems more accurately when they have previously seen similar submissions. In turn, we proposed the use of code embeddings to capture semantic information about the structure and output of programs and identify similarity between submissions. Using similarity of code embeddings in conjunction with historical grading data, we demonstrate in simulation that graders are indeed able to score submissions more accurately when they have previously seen another submission similar to it. We propose and compare several algorithms for this task, showing that it is possible to achieve a significant increase in grading accuracy over simple random assignment of submissions. Future extensions of this work include (i) improvements on code embeddings and (ii) deployment of the grading algorithms in an operational system to allow more direct experimental comparison of grading accuracy. The use of such algorithms show promise for improving accuracy, and in turn fairness, in evaluations of student performance.

ABSTRACT

In distance education and some computer-assisted learning scenarios asking for help when needed is important. Some students do not ask for help even when they do not know how to proceed. In situations where a teacher is not present, this can be a serious setback. We aim to find an approach to learn about students' help-seeking behaviour by studying sequences of actions that end with the student asking for help. The goal is to be able to recognize those students who need help but fail to ask for it and offer them assistance. We propose to include the temporal context of user-platform interaction and suggest an ensemble model to learn from both general and personal tendencies.

Keywords

Adaptive systems, time series, educational data mining, personalized education

1. INTRODUCTION

Researchers have found help-seeking to be important in learning scenarios and observed that some students do not reach for help when they need it [4, 25]. When a teacher is not always present, and the student needs some level of self-discipline, not asking for help might be problematic as the student could end up wheel-spinning [18] or abandoning the task. The longitudinal nature of student-platform interactions leads us to think that taking into account the temporal context could be useful for analysing help-seeking behaviour. There is literature on help-seeking including temporal data, and some works have focused on performance prediction or have centred on specific knowledge topics. However, we have not found work that focuses on the behaviour around help-seeking actions, including temporal data and independent of student knowledge and task content. In this Master Thesis, we propose to represent student-platform interactions as sequences of actions, study whether sequential patterns exist in students' help-seeking behaviour and explore whether a prediction model could identify students that need help but do not ask for it.

2. RELATED RESEARCH

Time series studies are very common in natural sciences and some social sciences. Studies that make use of time series data can also be found in the field of educational sciences [5, 8, 9, 13, 14, 15, 17, 29]. We have reviewed existing works on both help-seeking behaviour and time series data analysis. In section 3 we highlight the specific differences between the works exposed here and what we propose to do.

2.1 Help-seeking behaviour

Knowing when to ask for help is important [4, 11]. [10, 11] agreed that it could improve resilience and efficacy. According to [10], help-seeking has been studied for years but the rise of new technologies opens new research opportunities on help-seeking in these new contexts.

Some works have focused on detecting specific situations that are known to be problematic. For instance, in classes where the teacher has more students than desired, it might be difficult for them to identify students who need help or are stuck. [18] developed a method using machine learning (ML) models to automatically predict wheel-spinning and decide how to intervene. [4] attacked both problems of asking for help too much and not enough by negotiating with the student. Rather than using ML models, they predefined a set of heuristics. A slightly different situation was studied by [32]. Their goal was to find a connection between student procrastination (i.e. intentionally delaying work) and their activities within different learning materials. They used data from a massive open online course (MOOC) platform and found two main study strategies: students who delayed work worked intensively for short periods followed by long pauses, while students who did not delay usually split the tasks into subtasks and worked more constantly but less intensively.

Other works have focused on knowledge tracing [6, 7, 24], however, we will not be considering student knowledge but their behaviour and interaction with the educational system.

2.2 Pattern recognition and sequence prediction

To cluster categorical sequences, one needs to define the function or method used to compare the sequences pairwise, that is, how to measure the distance between them. [5] analyzed activity frequency through the length of different online courses to study if different activity patterns were related to student performance. They used agglomerative hierarchical clustering (AHC) with the Levenshtein distance. [17] used a similar approach and found patterns in group problem-solving strategies analysing group behaviour of students working on interactive tabletops. [8] also used AHC with the Levenshtein distance and found 3 groups of similar study state sequences using data from a drill-and-practice learning environment in college mathematics.

[13] found that a large subgroup of MOOC participants might have been engaging by watching video lectures without doing the assignments. Their methodology consisted in constructing, for each student, vectors of states representing their engagement trajectories through the course. They computed the distance between trajectories by assigning a numerical value to each label and calculating the L1 norm.

[14] proposed a method that would capture the clusters' number and size evolution over time. They transformed log data sequences into Markov chain models. Then, they computed the pairwise similarities by computing the expected transition probabilities using the stationary distribution over the actions. They used the Jensen-Shannon divergence and the Hellinger distance between the expected transition frequencies of the Markov chains (more details in [21], as cited in [14]). They used k-means with an evolutionary clustering method that tracks the evolution of the similarities over time by smoothing the similarity matrices ([31] as cited in [14]). [9] also modelled student behaviour using Markov chains. They randomly generated Markov chain priors and assigned each sequence to the prior most likely to generate it. Then, each prior would be updated to the Markov chain generated using its associated sequences. These last two steps were repeated until less than 5% of the sequences would change their prior. As they stated, this method is similar to k-means but with the clustering being dependent on the Markov chains instead of on a similarity measure performed directly on the sequences.

[29] was able to detect unprofitable learning experiences and predict student performance by using time series data. They used dynamic time warping (DTW) to measure the distance between sequences and performed hierarchical clustering to find clusters. DTW was proved to be useful; however, to the best of our knowledge, it is not suitable for categorical sequences but only for numerical ones and has therefore been ruled out as a possible approach to our specific problem.

Artificial neural networks (ANNs) are known to be useful for a vast variety of tasks. When it comes to time series, the most used ones seem to be recurrent neural networks (RNN) and long short-term memory networks (LSTM). RNNs' main limitation is their difficulty to work with long sequences due to a vanishing gradient problem [12]. While LSTMs solve this issue, they usually take quite a long to train and have difficulties in capturing long-term dependencies in long sequences [12, 30]. Finally, a novel approach called transformer networks was introduced by [30]. This approach introduces what the authors called an *attention mechanism*, which solves the long-term dependency problem in LSTMs. [2] used LSTMs in a multi-module system to analyse the relationship between intent and user actions in interactive systems. [16] used time-aware LSTMs (T-LSTM), a special type of LSTM that can handle time irregularities, to model student knowledge state in continuous time. They conducted an empirical experiment and discovered that they outperformed regular LSTMs, logistic regression and recent temporal pattern mining (RTPs). [15] used RTPs along with support vector machine (SVM) and logistic regression to predict student performance and detect the need for intervention using students' answers to programming exercises. They were able to classify students within only 1 minute into the exercise.

3. EXPECTED CONTRIBUTION

To our knowledge, this would be the first work to use student-platform interaction data in form of sequences of actions to predict help-seeking behaviour while being independent of the topic being taught. Our approach differs from existing work by joining three main aspects. First, **help-seeking behaviour**: we have found works that linked the need for intervention with performance or student knowledge [6, 15, 16] instead of analyzing the behaviour surrounding actual help-seeking actions. Second, **time-awareness**: we have found works that have used cumulative data (e.g. number of attempts) to predict the need for intervention [18] but did not take into account the temporal context. Third, **topic-independence**: we have found works that did take into account the temporal context but focused on the content of student answers for specific topics [15, 23].

The approach we propose would include the temporal context, would not be dependent on the nature of the content being taught and would focus on user-platform interaction (i.e. clicking, typing, deleting, consulting theory, etc).

While this research is still in the early stages, we believe in the importance of students' affective state [26, 27, 28] and might consider including the affective context if possible. Finally, if we were to find successful results, we believe that richer predictions could be obtained by joining student knowledge information [6, 15, 16] along with the information learnt from help-seeking behaviour. However, this is out of the scope of this research.

4. RESEARCH QUESTIONS

We aim to study whether our proposal would be feasible and for that we present two research questions:

Q1 Are there temporal patterns in students help-seeking behaviour?

Q2 Can temporal student-platform interaction data be used to detect students who need help but do not ask for it?

5. PROPOSED METHODOLOGY

We will be dealing with both supervised and unsupervised problems: we will be using clustering algorithms towards answering Q1 and prediction algorithms towards answering

Q2. We propose to perform clustering (Q1) as a preliminary step to a more complex system (Q2). Clustering can lead to interpretable results and reveal information that could be useful to pedagogical experts while some prediction methods are more powerful but may act as a black box. As well as considering less interpretable methods, the system proposed in Q2 addresses personalization. We expose the methodology we intend to follow, and the methods we have considered so far.

5.1 Data

The dataset to be used is yet to be found or constructed. Efforts are being made to find a suitable dataset. Some promising options are being considered but are yet to be confirmed. Even though, the characteristics that we look for in a dataset have been defined. The dataset should contain action logs that originated from the interaction between a student and a learning platform that has some kind of help tool that the student can choose to use. Each log should include, at least: (1) action type, (2) action start time, (3) action end time, (4) student identification (anonymized) and (4) exercise identification.

Given that some actions are continuous rather than instantaneous, we will need to decide how to represent this characteristic. As an example, a student might consult the theory section of the system just for 10 seconds, or they could spend 5 minutes consulting the content. It would be desirable that those two cases were not represented in the same way and that duration was taken into account. When using Markov chains, if we consider action durations, the probabilities of staying in the same state will always be 0, and the duration would not be taken into account. To solve this, we could consider splitting the actions into time slots. We will need to take into account that some other actions might be instant actions, with practically no duration, e.g. submitting an exercise. We will need to make sure that the model we use does not undermine these actions. Finally, if possible, we might consider including *idle* actions, that is, time in which the student does nothing.

5.2 Clustering

To answer **Q1**, we encounter two main decisions: how to determine the distance between sequences and which clustering algorithm to use.

5.2.1 Distance between the sequences

The main challenge of dealing with sequential data is that they cannot be directly fed to traditional clustering algorithms. First, one needs to decide how to represent the sequences and define how to compare them. We have decided to try two methods for representing the distance between sequences: Markov chains and the Levenshtein distance. Markov chains represent a sequence by considering the probability of going from one state (i.e. action) to another. The basic form of a Markov chain only considers the current state to predict the next one. This could be a limitation and therefore n-order Markov chains could be considered. In a Markov chain of order n, n previous steps are taken into account. On the other hand, the Levenshtein distance is a type of edit distance, that is, the minimum changes required to transform one sequence into another. The Levenshtein distance considers insertions, deletions and substitutions.

5.2.2 Clustering algorithms

Taking into account existing work, we have narrowed the search for a clustering method down to two: hierarchical clustering and k-means. The main drawback of k-means is the requirement of a predefined number of clusters, which in our case is unknown. Hierarchical clustering has the advantage that the number of clusters can be chosen a posteriori, however, it can be expensive when dealing with large datasets. K-means is usually a fast algorithm, although it might depend on the chosen distance metric [19].

5.3 Prediction

Towards answering **Q2**, we propose a prediction system; its characteristics are presented in this section.

5.3.1 System structure

While we want to take advantage of how students in general behave, we want to provide a personalized learning experience. To do so, a student's personal traits and tendencies must be taken into account. Therefore, we aim to take advantage of the general traits of student behaviour while preserving the personal study tendencies of each student, thus combining an inter-subject with an intra-subject approach. To achieve this goal, we propose an ensemble system composed of three blocks. We name the system SHEmblE (Sequence analysis of Help-seeking behaviour with an ensEMBLE model for Educational systems)

Firstly, we will have a prediction model that will be trained with all the available data. We will refer to this model as the *common model* as it will be shared among all students. We expect it to be able to learn the general patterns of help-seeking behaviour if those exist.

Secondly, we will have what we call a *personal model*. Each student will have each own personal model trained with their own data, if any. We expect this model to be able to learn the personal tendencies and preferences of a student.

Finally, a third model will combine the predictions of common and personal models. We call this model the *ensemble model* and we expect it to learn how to combine the predictions the best way possible.

We will focus on students who regularly ask for help for the general model. However, from those students, we will take into account interactions that exhibit help-seeking behaviour as well as those in which the student does not need help to successfully reach their goal. Sequences from students who never ask for help will not be included as we cannot know if the student did really not need assistance, or they simply never ask for it.

We are aware that data size will be a concern regarding the personal model. Its goal is to provide individualization, and thus, we believe it is an important part of the system [1, 7, 22]. Therefore, the ensemble model could take into account the amount of data with which the personal model was trained in order to weigh the predictions properly.

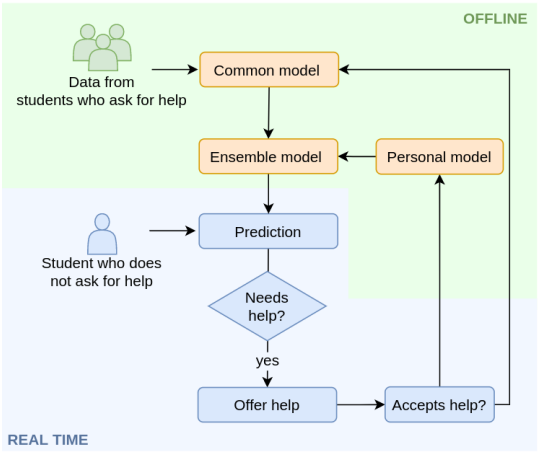

Figure 1: General schema of SHEmblE, the proposed system.

The ultimate goal, if this system was to achieve good results, would be to implement it in a real educational system. Figure 1 represents the overall structure of the proposed system. The idea would be to be able to detect, in real-time, students that need help and offer it to them. Apart from collecting logs from students that ask for help themselves, whenever we offer help we would save their response as well. The scope of this work comprises the common, personal and ensemble models, the rest could be the object of study of future research.

5.3.2 *Prediction algorithms*

Time series prediction has been the challenge of many works in literature. This work deals with categorical time series, in other words, categorical sequences. It has been narrowed down to three methods: artificial neural networks, hidden Markov models, and recent temporal patterns. As exposed in section 2, ANNs have been used in problems involving time series data and showed promising results, different types found in the literature will be considered (e.g. LSTM, T-LSTM, transformers). HMMs have also been useful for predicting and classifying action sequences. [20] found that HMMs needed fewer training samples and less CPU time while performing similar to LSTMs. Finally, RTPs [3] have been successful at similar tasks. [15] used them and managed to detect students that needed intervention only one minute after starting an exercise. While their data consisted of attributes of the students' answers' content and ours will consist of interaction data, we believe that a similar approach could be applied to our particular task.

5.3.3 *System training and evaluation*

The system we propose is going to be composed of three different models. These models will be evaluated independently and altogether. We intend to evaluate the common model by performing a variation of the leave-one-out cross-validation (LOOCV) in which in each iteration the whole data of one student is left out for validation. Regarding the personal model, the dataset will be split by the sequences' student id and for each student, a LOOCV will be performed. The performance of the personal model will be assessed by combining all the performances (eg. mean and standard deviation) and special attention will be paid to possible outliers. Finally, the ensemble model block will need to be fed the predictions of the other two models. Therefore, a whole new dataset E will need to be constructed such that:

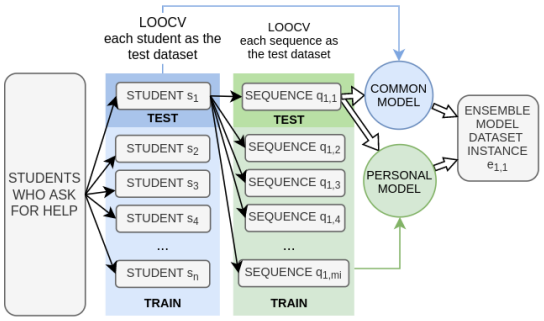

Figure 2: Graphical representation of the evaluation scheme and the generation of the dataset for the ensemble model.

- Consider the set of n students $S = \{s_i | i \in \{1..n\}\}$.
- Each student s_i has got m_i sequences $Q_i = \{q_{ij} | j \in \{1..m_i\}\}$
- The instance e_{ij} will correspond to the sequence j of the student i and will contain at least 2 features:
  - The output of the common model trained using the sequences from students other than s_i.
  - The output by the personal model trained using the sequences of student s_i other than q_{ij}.

  Moreover, additional features could be added, such as the size of the dataset used to train the personal model, given that some students might have few or no data.
- The dataset E will then have $\sum_{i=1}^{n} m_i$ rows.

Once the dataset has been constructed, k-fold cross-validation can be performed. Figure 2 shows a graphical representation of the proposed evaluation method.

6. CONCLUSIONS

We have not found works that aim to detect students who need help by analysing behaviour around help-seeking actions using time-aware user-platform interaction data. In this Master Thesis, we aim to study whether such data can be useful to predict help-request actions and propose an ensemble system that combines a shared model and a personal model so as to achieve individualization.

This work is still at a very early stage. Any feedback and ideas on this proposal are very much welcomed. Specifically, comments on the sequence representation, and the clustering and predictive model choices will be appreciated.

7. ACKNOWLEDGEMENTS

The work is partially supported by UNED's master's degree in Research in AI and the project INT2AFF funded under Grant PGC2018-102279-B-I00 (MCIU/AEI/FEDER, UE) by the Spanish Ministry of Science, Innovation and Universities, the Spanish Agency of Research and the European Regional Development Fund (ERDF).

Mixed Data Sampling in Learning Analytics

Julian Langenhagen
Goethe University Frankfurt, Germany
langenhagen@econ.uni-frankfurt.de

ABSTRACT

Technical progress facilitates collecting large amounts and new kinds of data in a wide range of areas. That enables versatile new possibilities in empirical research, especially with high-frequency data. However, researchers are confronted with the problem that not all available data have the same (high) frequency. For many common methods, it is necessary to adjust the high-frequency to the low-frequency data, resulting in a significant loss of information. In accounting research, this kind of problem exists due to the low-frequency reporting data of companies on the one hand and the high-frequency financial market data on the other. A promising solution to this problem is the innovative approach of mixed data sampling (MIDAS). Since the coexistence of low-frequency data (e.g., exam grades) and high-frequency data (e.g., learning management system usage data) is also prevalent in educational settings, this paper will discuss the first application of MIDAS in the field of learning analytics.

Keywords

time series, mixed data sampling, regression, prediction models

1. INTRODUCTION

Educational Data Mining (EDM) is a comparatively young field of research. Even though certain research methods within this area are already established, the field regularly benefits from valuable contributions from interdisciplinary research approaches [e.g., 14]. The methods used in Educational Data Mining can be divided into four different areas: prediction models, structure discovery, relationship mining, and discovery with models [2]. The focus of this paper lies on prediction models, especially on those with time-series data. Methods in this area include classifications, regressions, and latent knowledge estimation [2]. In this area, EDM researchers are confronted with a specific problem. The variety of available data sources is growing due to the use of complex learning management systems (LMS), game-based learning applications, or other digital educational tools. These sources often contain high-frequency data and therefore offer a lot of potential information. However, in the most commonly used methods in prediction models, it is usually the case that data from different samples have to be brought to the same frequency to be analyzed. This can lead to a significant loss of information. For example, data from an LMS can be gathered for every possible usage second to be used as an explanatory variable. However, there is usually a low-frequency variable on the other side of the equation, such as the exam grade or score. Accounting researchers face a similar problem. Companies usually only publish reports at a pre-defined low frequency, as financial statements or other reports are often made available only annually or quarterly. An independent variable available in corresponding research settings is, for example, the share price, which, like the data from the LMS, can be collected at a very high frequency. However, the information contained here cannot be fully included in the analysis if the variables on both sides of the equation have to be adjusted to the lowest frequency available. A solution to this problem in accounting is the method of mixed data sampling (MIDAS). As the underlying problem is comparable to typical educational research settings, this method will be examined in more detail in the following section, and then a possible application in Educational Data Mining will be discussed using the example of a concrete implementation in the context of a learning app in higher education.

2. MIDAS IN ACCOUNTING RESEARCH

The basic MIDAS model builds on a regression equation where the dependent variable is measured in a lower frequency than one or more of the independent variables [5]. The problem of the different frequencies on both sides is solved with two separate components. In the first component, each time disaggregated observation of the higher frequency variable is included separately as an independent variable. In other words, if the higher frequency data is observable N times within a period, then N separate independent variables are included in the regression. This allows the independent variable's effect on the dependent variable to evolve over the course of the examined period, even though the dependent variable was only measured once. The second component of MIDAS is the requirement of each of the N regression coefficients to follow a specific function of time that is shaped by few estimated parameters. For example, if the temporal distribution is assumed to be linear, this condition only requires two parameters, namely an intercept and a slope. This condition is the key feature of MIDAS to establish a balance between model flexibility and parsimony to be able to reasonably interpret the results. This basic model can be enhanced in many different directions, e.g., to whether certain events within the observed period have a different relationship to non-event data [5] or for the evaluation of unequally spaced temporal data [11]. MIDAS has so far been used mainly in accounting and macroeconomics research [e.g., 4, 5, 8]. The method is particularly well suited to accounting research as companies are legally obliged to publish certain economic data such as revenues and costs on a regular low-frequency cycle (e.g., quarterly or annually). Share prices, on the other hand, can generally be retrieved every second and are therefore high-frequency. The job of professional analysts is to

use this information, among other things, to predict the companies' disclosures. For forecasts based on regressions, it is usually necessary to adjust the frequency of the different data samples to the lowest frequency available. For a share price, this could result in the quarterly mean, for example. Therefore, the information within the high-frequency stock market data lost in this process represents a major challenge for analysts to optimize their forecasts. A previous study has shown that MIDAS can significantly help analysts with this challenge and improve the forecasts accordingly [6]. Building on these findings, the next section will discuss whether MIDAS can also help lecturers and researchers in education with specific predictions.

3. MIDAS IN LEARNING ANALYTICS

Prediction models belong to the most used methods in Educational Data Mining [1, 7]. Usually, the corresponding analyses are carried out with classifications or regressions [3]. The prediction of exam grades or scores is one of the most frequently investigated research questions within prediction models [13]. The dependent variables are usually the exam points (regression), the exam grade (classification or regression), or the fact of whether a student has passed or not (classification). In many cases, usage data from learning management systems are used as independent variables. This data is usually high-frequency and must be adjusted to the low-frequency dependent variables for the methods mentioned above. For example, an LMS may record all clicks within the system with precise temporal data. Still, in the above analyses, this information needs to be restricted, for example, to the total number of clicks over the entire period of use [9]. These limitations could be overcome with more sophisticated methods. For instance, it was shown that GARCH, a method from finance research, outperformed the other common methods in multi-modal learning analytics [14]. As of this writing, there is no publication in the field of Educational Data Mining or Learning Analytics that has used the MIDAS approach. This research gap should be filled with the present project. In a subsequent step, MIDAS could even be linked to GARCH to further enrich the research setting [10]. Thus, the research question of this project is whether MIDAS is suitable for predicting exam results in an educational context and how the results compare to those of already known methods in Educational Data Mining. Previous studies have shown that it is important to look not only at aggregate usage data for a given time period but also at the distribution and sequence of the corresponding data points [e.g., 9, 12]. MIDAS could make a valuable contribution to the range of methods already available, as it takes into account the high frequency of independent variables while still providing well-interpretable and thus actionable results for instructors. These results could, for example, be used to build an early warning system for students at risk of academic failure. The good interpretability of MIDAS results could make it easier for instructors to take appropriate measures compared to when using complex machine learning algorithms, whose results might be much more challenging to interpret. Such an early warning system is especially beneficial in lectures where there is little performance feedback between students and teachers in general (e.g., because there is only one final exam at the end of the semester) or due to special conditions (e.g., COVID-19). In such cases, all actors involved see the result of learning and teaching behavior only at the end of the semester through the exam result. Since it is already too late for countermeasures at this point, an early warning system with clear recommendations for action would be beneficial in such a context. Therefore, MIDAS is a promising addition to the current variety of methods and should be considered in future studies.

4. NEXT STEPS

A first application of the basic MIDAS model will be carried out in the following setting as soon as the project's data collection is completed. We developed a mobile learning app for an undergraduate accounting course at a large public university in Europe. The course is compulsory and ought to be taken in the third semester of the bachelor's program. The course is taken by approximately 600 students per semester and consists of a weekly lecture, a biweekly exercise, and biweekly tutorials (five meetings in small groups). The content of this course includes the basics of cost accounting as well as a summary of their significance and classification in the management accounting context. The primary learning material consists of a slide deck, a collection of exercises (with solutions), and a trial exam (all available as PDF files). In the evaluations of earlier semesters, students often complained that there were no contemporary possibilities to learn the subject matter. Therefore, we decided to develop an additional learning tool in the form of a smartphone app, which was launched in the summer semester of 2019. The use of the app is voluntary, and no extra credits or advantages for the final exam can be earned by collecting points in the app. The tool is available via a web version and as an app in the Google Play Store and the Apple App Store. The app's core element is a database with over 550 questions that covers all nine chapters of the course. In addition to the question types single and multiple-choice, there are also sorting and cloze text tasks. The app can be used in three modes: The chapter mode can be used to answer specific questions about a single chapter. As soon as a student has mastered the problems of one chapter, the next chapter is unlocked. In random mode, questions are randomly selected from the chapters that have already been unlocked in chapter mode. In the third mode, the so-called Weekly Challenge, users can compare themselves with other students. Once a week, they have the opportunity to answer 25 questions randomly selected from the chapters already covered in the lecture. The results are subsequently displayed in a weekly and a semester ranking. For good performances in the Weekly Challenge and other learning achievements, students can earn so-called badges, which are then displayed in their account under their self-chosen username. By answering questions (regardless of the mode), students also earn learning points and thus increase their learning level. The progress display of the individual chapters shows students how well they currently master a particular topic. The app has been specifically designed to complement the existing course and is not intended to replace other learning materials such as the slides or the collection of exercises. The app contains an individual explanation for each question which is displayed if a wrong answer is given. Thus, students can work their way through the catalog of questions independently of time and place and eliminate any gaps in their understanding without having to rely on the presence of the lecturers. This is an essential value-added for the students, especially in such a large course with approximately 600 students per semester. The collected app data consists of details about the usage behavior of each student (e.g., time of use, performance (history) regarding every question, and earned badges). At this stage, we already have four semesters of app usage, and the data set is growing as the research project is still ongoing. This is especially promising as the situation regarding COVID-19 lead to an exogenous shock. While in the years 2018 and 2019, the course was held face-to-face, in the summer semester 2020, it was

converted into a purely online lecture. Apart from the launch of the app and the switch to an online lecture, there were no teaching design changes over the course of the semesters. The lecturer and the learning materials remained constant, as well as the design and the grading of the final exam. This unique setting could provide valuable insights into the impact of COVID-19 on higher education. The starting point of the corresponding analysis would be a basic linear regression with the exam score as dependent and usage data from the app as independent variable. The exam score is measured once, while the usage data from the app could be evaluated by every second of the semester. In this setting, we face the challenge of unequal frequencies on both sides of the equation that was described before. If we would only take the sum of total questions answered by a student as the independent variable, we would miss a lot of information. The type and especially the time of usage can be decisive for the effect on the exam score. We would miss all this information with reducing the app usage on measures like total questions answered. Therefore, the MIDAS approach offers a promising possibility to extract more insights from the data set. A comparative analysis with other already known methods in Educational Data Mining or Learning Analytics, which take into account the high frequency of data, could highlight the additional benefits of MIDAS for this research area.

5. CONCLUSION AND FUTURE WORK

In this paper, it was shown that the innovative approach MIDAS could be a promising extension of the variety of methods in Educational Data Mining and Learning Analytics. Further insights will be gained by testing the approach with the usage data from our gamified learning app. Based on the findings, it will be further discussed whether the basic model of MIDAS should be extended for the use in an educational setting or whether other novel methods should be applied in this setting. Besides, it could be promising to apply the MIDAS approach to already published analyses in order to test the corresponding added value. If the results are similarly insightful as those in accounting research, MIDAS could find numerous use cases in Educational Data Mining and Learning Analytics.

ABSTRACT

Clustering is an important technique in learning analytics for partitioning students into groups of similar instances. Application examples include group assignments, students-class allocation, etc. However, traditional clustering does not ensure a fair-representation in terms of some protected attributes like gender or race, and as a result, the resulting clusters might be biased. Moreover, traditional clustering might result in clusters of varying cardinalities reducing their actionability for end user. In many applications, like group assignment, the capacity of the resulting clusters should be controllable to allow direct applicability of the resulting clusters. Furthermore, it is important to be able to explain why an instance/student is clustered into a specific cluster and/or which attributes play a crucial role in the clustering process. We believe that the aforementioned aspects of fairness, capacity and explainability are important for the successful application of clustering in the learning analytics domain.

Keywords

learning analytics, clustering, fairness, bias, explainability, capacity, actionability

1. INTRODUCTION

In education, machine learning (ML) has been used in a wide variety of decision-making tasks, for example, student dropout prediction [11], education admission decisions [25] or forecasting on-time graduation of students [16]. Recently, the incidents of discrimination in ML-based decision-making systems in education, such as grades prediction [4, 15], are an important reason for the increase of the attention to bias and fairness in ML of researchers [32]. Accordingly, the decisions made by the ML-based systems against groups or individuals on the basis of *protected attributes* like gender, race, etc. Bias in education has been studied in many aspects from different sources of bias in education [27], students' data analysis [3], racial bias [39] and gender bias [26].

Tai Le Quy and Eirini Ntoutsi "Towards fair, explainable and actionable clustering for learning analytics". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 847-851. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

However, ML-based decision-making systems have the potential to amplify prevalent biases or create new ones and therefore, fairness-aware ML approaches are required also for the learning environments.

In our research, we are focusing on the *fairness* of clustering methods in learning analytics since clustering is an effective method to analyze student data [8, 17, 28, 36]. Clustering algorithms are useful tools for partitioning students into groups of similar instances [3, 31]. Results from clustering methods are applicable in educational activities such as group assignments [10] and student team achievement divisions [37]. However, the traditional clustering algorithms do not take into account the fairness w.r.t. protected attributes like gender or race, as a consequence of focusing only on the similarity objective. Moreover, the cardinality of the resulting clusters is typically not part of the objective function and as a result clusters of very different cardinalities might be extracted reducing the usefulness of the results. Moreover, understanding the instances-to-clusters assignments, the important features for clustering and what characterizes each cluster (the so-called, cluster labels) is not always easy [33].

The aim of this research is to study the fairness, capacity and explainability requirements and challenges in the learning analytics domain and propose effective solutions that can be used by the domain experts. In this direction, we propose the concept of *fair-capacitated clustering* which extends traditional clustering focusing on clustering quality to also ensure fairness of representation in terms of some protected attribute(s) and the applicability of the resulting clusters by ensuring balanced cluster cardinalities. Such clusters can be exploited by different stakeholders in the learning environment: educators can better organize the learning activities, e.g., group assignments; students can learn better in a more inclusive and equitable environment.

In another direction, we plan to extend the *fair capacitated clustering with explainability* to give insights to the end users about how certain assignment decisions are made, what features are important for clustering and what the extracted clusters represent. Such information will allow educators to customize teaching activities to each group and improve the learning trajectory of each student, each group and the class in overall.

We believe that the results of our research are useful in other domains as well, for example business (clustering cus-

tomers in marketing studies, salesmen areas distribution), traffic (vehicle routing) and communication (network design). Moreover, our research contributes to the further development of the domain of fairness and responsible AI with new methods (for the unsupervised learning problem) and application domain (learning analytics).

The rest of our paper is structured as follows: Section 2 overviews the related work. Research questions are presented in Section 3. Section 4 describes our ongoing work on fair-capacitated clustering and preliminary results. Finally, conclusions and outlook are presented in Section 5.

2. RELATED WORK

Chierichetti et al. [7] first introduced the fair clustering problem and presented a balance measure for computing fairness in the resulting clusters. They defined "fairlet" as a small cluster preserving fairness measure, and then they apply k-Center clustering algorithm on these fairlets to obtain the final clusters. In the later studies, Backurs et al. [1] described an algorithm for the fairlets computation in nearly linear time. The problem of fair clustering with multiple protected attributes is investigated in the researches of Rösner and Schmidt [34] and Bera et al. [2].

The capacitated clustering problem (CCP) was first introduced by Mulvey and Beck [30] with heuristic and subgradient algorithms. Later, researchers proposed approaches to solve the problem in the different clustering methods. For instance, Khuller and Sussmann [19] introduced an approximation algorithm for the capacitated k-Center problem. An improved version of k-Means algorithm for CCP was presented by Geetha et al. [12] with the use of a priority measure to assign points to their centroid. Lam and Mittenthal [20] proposed a heuristic hierarchical clustering method for CCP.

Quite a few researchers, recently, are interested in the usefulness of explainable and interpretable clustering models. Chen et al. [6] proposed a probabilistic discriminative model with the ability to learn rectangular decision rules for each cluster. Saisubramanian et al. [35] offered a voting method to consider which features are meaningful for the end user. Moshkovitz et al. [29] used an unsupervised decision tree to explain k-Means and k-Medians methods.

3. RESEARCH QUESTIONS

We organize the challenges into the research questions $Q1 - Q3$ explained hereafter:

Q_1: **What is fairness in learning analytics and how to mitigate discrimination in clustering?** Fairness in education is an interesting topic researchers [5, 9, 13]. We investigate the fairness terminology in student analytics w.r.t protected attributes such as gender, race. Student performance can be considered as the protected attribute because in some cases no knowledge of the student's performance can help to prevent bias in the grading procedure [23, 24]. Related work in the fairness-aware ML area depicts a large variety of approaches that can be categorized into: i) pre-processing approaches that intervene at the input data [22]; ii) in-processing approaches that directly tweak the clustering algorithm to account for fairness [7] and iii) post-processing approaches that adjust the clustering results to ensure fairness [38]. We will mainly follow the in-processing approaches that directly incorporate fairness in the clustering process. However, such approaches depend on the clustering algorithm per se; our current work focuses on hierarchical and partitioning algorithms, in the future density-based clustering will be also investigated.

Q_2: **How to satisfy multiple objectives, namely capacity of clusters and fairness of representation on top of the (standard) cluster similarity objective?** As already mentioned, the actionability of the results is important. As a concrete example consider group assignments: groups should be comparable to allow for a fair allocation of work among students. In the capacitated clustering problem [30], they do not consider fairness, nor explainability. Likewise approaches for fair clustering also exist [7]. However, approaches that jointly consider the different objectives do not exist.

Q_3: **What is the explanation of a (fair-capacitated) clustering model and how to find it?** The importance of explainable clustering results for the end users has been already discussed. Explainability does not only allow for understanding how certain decisions are made but also allows for debugging of algorithmic decisions and corrections in case of decisions based on protected attributes like gender or race. There are different aspects to explainability in clustering: understanding how a certain assignment of an instance to a cluster was made, understanding what attributes contributed to clustering and explaining what each cluster is about (or cluster labeling). We will investigate the different aspects to allow educators to better understand the groups that are formed and to allow both educators and single users/students to understand how they fit into a particular cluster.

4. PRELIMINARY RESULTS ON FAIR CAPACITATED CLUSTERING

In this section, we present the preliminary results of our work namely *fair-capacitated clustering* [21] problem. The goal is to cluster students into fair-groups w.r.t. single protected attribute. *Gender*, typically, is chosen as the protected attribute. In other words, we would like to balance the number of males and females in the resulting clusters and our proposed methods should satisfy the size of group constraint in order to make the results more actionable.

We define the problem of (t, k, q)-fair-capacitated clustering as finding a clustering $\mathcal{C} = \{C_1, \cdots C_k\}$ that partitions the data X into k clusters such that the cardinality of each cluster $C_i \in \mathcal{C}$ does not exceed a threshold q, i.e., $|C_i| \leq q$ (*the capacity constraint*), the balance of each cluster is at least t, i.e., $balance(\mathcal{C}) \geq t$ (*the fairness constraint*), and minimizes *the objective function*. Parameters k, t, q are user-defined referring to the number of clusters, minimum balance threshold and maximum cluster capacity, respectively.

We present a two-step solution to the problem: i) we rely on fairlets [7] to generate minimal sets that satisfy the fair constraint and ii) we propose two approaches, namely hierarchical clustering (denoted by *hierarchical fair-capacitated*) and partitioning-based clustering (denoted by *k-Medoids fair-capacitated*, to obtain the fair-capacitated clustering. The hierarchical approach embeds the additional cardinality re-

quirements during the merging step while the partitioning-based one alters the assignment step using a knapsack problem formulation to satisfy the additional requirements.

We experiment our proposed methods on four educational datasets: UCI Student performance[1], PISA test scores[2], OULAD[3], MOOC[4], containing the demographics, grades and school-related attributes of students. Table 1 in Appendix A summarizes the characteristics of datasets.

We report on clustering quality (measured as clustering cost, see Eq. 1), cluster fairness (expressed as cluster balance [7], see Eq. 2 and Eq. 3) and cluster capacity (expressed as cluster cardinality). The parameters are set as follows: the minimum threshold of balance $t = 0.5$, i.e., the proportion of the minority group is at least 50% in the resulting clusters; the maximum capacity of clusters $q = \left\lceil \frac{|X| * \epsilon}{k} \right\rceil$; ε is set to 1.01 and 1.2, for k-Medoids fair-capacitated and hierarchical fair-capacitated methods, respectively.

$$\mathcal{L}(X, \mathcal{C}) = \sum_{s_i \in S} \sum_{x \in C_i} d(x, s_i) \tag{1}$$

$$balance(C_i) = \min \left(\frac{|\{x \in C_i | \psi(x) = 0\}|}{|\{x \in C_i | \psi(x) = 1\}|}, \frac{|\{x \in C_i | \psi(x) = 1\}|}{|\{x \in C_i | \psi(x) = 0\}|} \right) \tag{2}$$

$$balance(\mathcal{C}) = \min_{C_i \in C} balance(C_i) \tag{3}$$

The baseline includes well-known clustering methods with fairness-aware approaches and a traditional algorithm. **1) k-Medoids**[18]. This is a traditional partitioning technique of clustering that uses the actual instances as centers (medoids) and divides the dataset into k clusters and minimizes the clustering cost. **2) Vanilla fairlet** [7]. A vanilla fairlet decomposition that ensures fair clusters is generated, then, a k-Center clustering algorithm [14] is applied to cluster those fairlets into k clusters. **3) MCF fairlet** [7]. It is an updated version of the *Vanilla fairlet* with The fairlet decomposition is transformed into a *minimum cost flow* (MCF) problem, by which an optimized version of fairlet decomposition in terms of cost value is computed.

The preliminary results show that our approaches deliver well-balanced clusters in terms of both fairness and cardinality while maintaining a good clustering quality. In terms of clustering cost (Figure 1-a) (Appendix B), our approaches outperform the vanilla fairlet and MCF fairlet methods although they are worse compared to the vanilla k-Medoids clustering. This is obvious due to the fact that our methods have to satisfy constraints on fairness or/and cardinality. *MCF fairlet hierarchical fair-capacitated* shows the best performance due to the optimization in the merging step. As illustrated in Figure 1-b regarding to fairness, our methods are comparative to the competitors. In which, the minimum threshold of balance t is visualized as a dashed line and the actual balance from the dataset is plotted as a dotted line. In Figure 1-c, the maximum capacity thresholds q are presented by the dashed and dotted lines. Our approaches are more preeminent with a lower dispersion, in terms of cardinality. The boxplots of our methods are drawn thicker because the variation of the capacity of resulting clusters is tiny in quite a few cases. MCF fairlet shows the worst performance, followed by Vanilla fairlet and vanilla k-Medoids algorithm.

5. CONCLUSION AND OUTLOOK

The investigations of the fairness, capacity and explainability requirements in the learning analytics domain are the main goals of our research. In this paper, we present the challenges of our work with 3 research questions. The preliminary results on the fair-capacitated clustering problem show that our approaches can satisfy multiple objectives namely fairness, capacity and clustering cost. In the next step, we want to deploy the implementation of an explainable fair clustering algorithm to achieve the clarification of the assignment in a fair clustering method.

ABSTRACT

In this article, we take a look at digital social networks in education. The observation made on the campus of Norbert ZONGO University is that the digital device set up on the campus to support the learning and teaching process has not had the support of users who prefer social networks adapted to their smartphone. Most students use digital social networks for exchanges with their peers or teachers, especially with WhatsApp, Facebook about their courses. Yet these technologies are not designed for educational purposes. After a survey of 318 students to take into account the needs of students and teachers, we propose to design an educational social network. This social network will be integrated into a distance learning platform under development as part of a project. We end by presenting the software architecture of our future educational social network.

Keywords

Educational social networks, CEHL, West Africa, University

1. INTRODUCTION

A Computing Environment for Human Learning (CEHL) is a computer environment whose purpose is to lead learners to develop one or more activities favorable to the achievement of educational objectives [1]. They are used to support or encourage learners in learning. The collaborative learning environment is an example of CEHL, designed to promote certain types of interactions including argumentation, explanations, conflict resolution etc. Many more examples of CEHL exist in the scientific literature.

New research work on CEHL has emerged with the new capabilities offered by Internet and new communication and information technologies [2]. The use of social networks in education is a part of this new work. The educational platforms used to support teaching and learning are neglected in the profile of social networks including Facebook, WhatsApp etc. Yet these technologies are not designed for educational purposes.

Romaric Bassole, Frédéric Ouedraogo, Laurence Capus "Towards a Conception and Integration of an Educational Social Network into an Institutional Learning Platform". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 852-855. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

Social networks with an existing educational component often require a monthly or annual subscription and are often not designed in an institutional framework. Students feel the need to use digital platforms in their learning process, which pushes them towards these technologies that are less suited to their context.

In view of this observation, we propose to design an educational social network (ESN) better suited to the West African context. This ESN could be integrated into the new system [3] proposed by a group of researchers with a profile of West African universities.

In the rest of our work, we will present the context of our study then we will present the analysis of the needs carried out for the implementation of a new device and will end with the architecture of our future device.

2. CONTEXT AND STATE OF THE ART

In this section, we present the context of this research project. We also present a small preview on Facebook technology. We end this part by connecting social networks and computing environments for human learning.

2.1 Context

Computing Environments for Human Learning (CEHL) are used to stimulate and support learning among learners. Despite the multitude of learning / teaching platforms that exist, universities in African countries, particularly Norbert ZONGO University (previously University of Koudougou), have difficulty setting up a resource sharing platform better suited to their context. Some environments such as Moodle which is an online learning platform are being implemented in some universities in West Africa to support learning / teaching. This powerful platform is badly used or even abandoned by the first users. Teachers and students are sometimes tempted to use other technology such as WhatsApp [4]–[6] for learning / teaching purposes. To take into account their needs, researchers [3] propose to set up a system better suited to the West African context while keeping services existing.

Students see themselves using other means to share, interact with their peers and teacher. Its means are among others through social

media such as: WhatsApp, Facebook, etc. Social media are used by students as the preferred tools for sharing, communicating, photographing parts of the course / TD. Its tools, easily accessible through their smartphones, are practically used on a daily basis. Although these media have a real advantage, accessibility and flexibility of use [7], it should be noted that they are not suitable for learning / teaching. These technologies are used to create groups without the knowledge of the pedagogy managers which makes it difficult to follow up, see its contribution in improving the learning / teaching of students.

.

To have an CEHL adapted to the West African context, a project [3] is already underway to set up a digital device. Our problem comes in addition to this project but we are focusing more on social networks aspect.

2.2 Curent situation

2.2.1 Social networks

First introduced by Australian anthropologist John A. Barnes [8], a social network is defined as a set of social interactions that unite a group of individuals. These social interactions can be: friendships, family ties, professional ties or specific ties. With the advent of Internet, the notion of social network took a new turn and gave birth to the notion of digital social network. Boyd and Ellison define digital social networks as "a web service allowing individuals to build a profile or not created by a combination of content and, on the other hand, to articulate this public profile with others" [9]. The most famous social networks these days are: Facebook, Twitter, LinkedIn, MySpace etc. these digital networks have drawn the attention of researchers [4], [7], [8] to its possible use in learning / teaching.

2.2.2 Educational social networks

An educational social network is first and foremost a social network. But unlike this one, the individuals in relationships are the learners and the teachers. It is a network that enables teacher-student and student-student, one-to-one, one-to-many and many-to-many interactions. Social networks occupy an important place nowadays in society and its more and more used by young people. This trend has prompted teachers to use these networks in the classroom [4], [6], [9] including Facebook, WhatsApp, etc.

Some educational social networks have been developed to support and stimulate learning among pupils or students. We can cite:

Learndia[1] is an educational social network and interactive learning space dedicated to students. It provides students with course content and a space to simulate assessments. In February 2017, the founders announced the release of the desktop version which does not require an Internet connection.

Freasyway[2] is an international educational social network for students, institutions, independent teachers. Beyond the fact that it offers interactive teaching, this platform offers students the possibility of obtaining information on the types of procedures to be carried out with institutions.

Madabooky [10] is an educational social network targeting terminal and third grade students. Created by three young Madagascans, Tsira Louis Venceslas, Dada Manacé Sylvano and Haritiana Rabemanantsoa, after one of them failed the Baccalauréat exams many times.

These social networks all have in common the objective of stimulating learning among pupils or students. However, these networks raise two major problems:

- Cost: Access to these platforms is conditioned by a subscription to the platform for a flat fee. The cost of these platforms is a barrier for students. In addition to this, the cost of the internet connection is an issue. The questionnaire found that 87% of students use the Internet connection of mobile operators (Orange, Telecel and Moov Africa).
- Institutional scope: These educational social networks have been developed outside the institutions in charge of education (universities, colleges and high schools, training centre, institute, etc.). This causes two major problems, students do not always interact with their teachers and the syllabus may be not consistent with their own courses.

Social networks such as Facebook, WhatsApp are widely used by students nowadays. These easily accessible technologies via smartphones are now used by learners and teachers to learn/teach [5], [6], [9]. These technologies, although used by students for consultation, collaboration, sharing and production activities in their learning processes, were not designed for pedagogical purposes. Moreover, access to user data for integration with existing educational platforms such as Moodle is problematic [6]. Furthermore, these platforms cannot be linked to institutional systems set up to support learning. Finally, the question of accessibility to user data arises with these applications. Yet these data are useful for monitoring learning and for educational research. In an article entitled "How WhatsApp makes Educational Data Mining difficult in West African universities"[6], the authors posed the difficulty for researchers in the field to have educational data for their research.

Educational social networks designed to support learning are inspiring solutions but they do not address the concerns observed on the campus of the Norbert ZONGO University. The design of these educational social networks is not adapted to the system set up in the universities of Burkina Faso. The cost of these applications is a major problem.

In view of this, we proposed an appropriate solution. The following section presents our proposal.

3. PROPOSED SOLUTION

This section of our paper deals with the analysis of students' needs following a survey conducted on a sample of 318 students from public and private universities in Burkina Faso. We propose a new learning device and present its architecture.

3.1 Description of the questionnaire

To understand student practices on campus, we conducted a survey with a student questionnaire. This study concerned 318 students from public and private universities in Burkina Faso.

The questionnaire consists of four parts: student identification, access to communication and information technologies (ICT), use of ICT and use of educational platforms.

[1] https://learndia.com/

[2] https://freasyway.com/public/

The identification of the student made it possible to collect the demographic social information of the students (sex, age group, sector, university, etc.). The section, Access to ICT, allowed us to collect information on the types of electronic support available to students, on Internet access at the University and at home. The last two sections of our questionnaire concerned the use made by students of ICT and educational platforms.

3.2 Needs analysis and specifications

To better understand student practices, we conducted a survey of 318 students from public and private universities in Burkina Faso. This survey allowed us to capture the needs of the students.

Users: Teachers and students are the future users of our solution. Indeed, the network should connect students of the same class and their teachers. Also, students should be able to send invitations to other students (their elders for example). As for teachers, they should be able to send and receive invitations from their colleagues and students. An administrator should ensure the proper functioning of the system.

Analysis of student needs: The survey revealed the following student needs, namely communication, sharing, mutual support:

Communication is the major problem for students. The number of students per teacher is very high so that the students are not satisfied with explanations in class. There is not anyway to contact or ask questions of the teacher outside of the classroom. The students noted that they have class WhatsApp groups to communicate. Although they have this communication tool, their teachers are not included in these groups.

Sharing files, lessons, tutorials, exercise solutions and tutorials are also a major concern for students. The WhatsApp group serves as their tools for sharing but the storage problem is posed. The data of these groups are quickly deleted if the storage disk is full.

Mutual aid appears important when an exercise or another part of a course is misunderstood. Students use Web searches.

As a result of this analysis, our solution should be able to allow students and teachers to make the following actions grouped in this table.

Requirements specification		
Student	Teacher	Admin
▪ Manage an account ▪ Send invitations ▪ Ask questions ▪ Answer questions ▪ Share information	▪ Manage an account ▪ Send invitations ▪ Answer questions ▪ Share information ▪ Create discussion topic	▪ Manage accounts

Tableau 1:requirements specification

3.3 Functional architecture of the new device

Figure 1 shows the software architecture that we have chosen for the development of the future device.

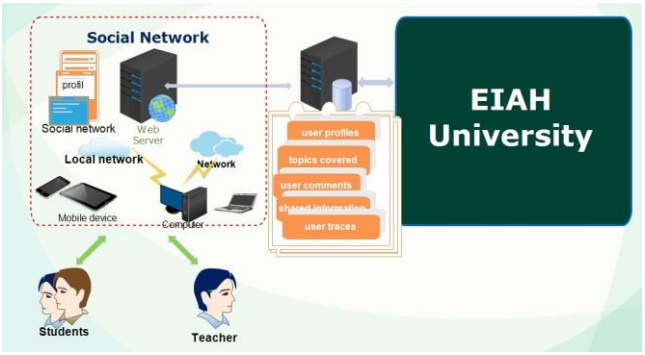

Figure 1: Software architecture

The new device complements existing platforms. This figure below presents an overview of our future system. The users will have access to the social network by Internet or by a local network. To respond to the difficulties related to the accessibility of the Internet connection on campus, students will be able to access the social network through a local network. It will be accessible via smartphones, tablets, laptops and desktops.

This device will be powered by text, audio, video, image and podcast data from students and teachers.

4. Conclusion

In this paper, we have dealt with the establishment of a social network for students from West Africa, particularly those of Burkina Faso. We have presented the background and the objectives of this research. To better understand and take into account the needs of students, we conducted a survey with a questionnaire on 318 students. The results of this questionnaire allowed us to highlight the needs and expectations of students for a better learning environment. We proposed to design an educational social network more suited to the learning context of students in West African universities. We presented the architecture of our future device. Our goal in this research is to create a free and open source platform that will create a community of researchers around this theme.

The work already done and presented in this paper is a first step of this research. The next step will concern the design of this new device. We plan to evaluate our proposed learning system at two levels: pedagogical, technical. To do this, we will enlist experts in education science to our research team.

ABSTRACT

Automated essay scoring (AES), where natural language processing is applied to score written text, can underpin educational resources in blended and distance learning. AES performance has typically been reported in terms of correlation coefficients or agreement statistics calculated between a system and an expert human examiner. We describe the benefits of alternative methods to evaluate AES systems and, more importantly, facilitate comparison between AES systems and expert human examiners. We employ these methods, together with *multi-marked* test data labelled by 5 expert human examiners, to guide machine learning model development and selection, resulting in models that outperform expert human examiners.

We extend on previous work on a mature feature-based linear ranking perceptron model and also develop a new multi-task learning neural network model built on top of a pre-trained language model – DistilBERT. Combining these two models' scores results in further improvements in performance (compared to that of each single model).

1. INTRODUCTION

Automated essay scoring (AES) is the task of employing computer technology to score written text. Learning to write a foreign language well requires a considerable amount of practice and appropriate feedback. On the one hand, AES systems provide a learning environment in which foreign language learners can practice and improve their writing skills even when teachers are not available. On the other hand, AES reduces the workload of examiners and enables large-scale writing assessment. In fact, these technologies have already been deployed in standardised tests such as the TOEFL and GMAT [7, 6] as well as in a classroom setting [26].

As English is one of the world's most widely used languages, and learners naturally outnumber teachers, AES systems aimed at 'English as a Second or Other Language' (ESOL) are in high demand. Consequently, there is a large body of literature with regards to AES systems of text produced by ESOL learners [20, 3, 5, 28, 2, 30, 1, 23, 16], overviews of which can be found in various studies [25, 22, 15].

AES systems exploit textual features in order to measure the overall quality and assign a score to a text. The earliest systems used superficial features, such as essay length, as proxies for understanding the text. As multiple factors influence the quality of texts, later systems have used more sophisticated automated text processing techniques to exploit a large range of textual features that correspond to different properties of text, such as grammar, vocabulary, style, topic relevance, and discourse coherence and cohesion. In addition to lexical and part-of-speech (PoS) n-grams, linguistically deeper features such as types of syntactic constructions, grammatical relations and measures of sentence complexity are some of the properties that form an AES system's internal marking criteria. The final representation of a text typically consists of a vector of features that have been manually selected and tuned to predict a score on a marking scale as accurately as possible, an approach which has involved extensive work on feature development and optimisation.

In contrast, the most recent AES systems are based on neural networks that learn the feature representations automatically, without the need for this kind of manual tuning [1, 23, 19, 16, 27]. Taking the sequence of (one-hot vectors of

the) words in an essay as input, Alikaniotis et al. [1] and Taghipour et al. [23] studied a number of neural architectures for the AES task and determined that a bidirectional Long Short-Term Memory (LSTM) [14] network was the best performing single architecture. With recent advances in pre-trained bidirectional Transformer [24] language models such as Bidirectional Encoder Representations from Transformers (BERT) [11], pre-trained language models have been applied for AES to achieve state-of-the-art performance [19, 16].

The B2 First exam, formerly known as Cambridge English: First (FCE), is a Cambridge English Qualification that assesses English at an upper-intermediate level. We extend a mature state-of-the-art feature-based AES system [5, 28, 2], researched and developed over the last decade using Cambridge English's FCE exam answers and their corresponding operational scores as training data. Further, we develop a new multi-task learning (MTL) neural network model built on top of a pre-trained masked language model – DistilBERT [21].

Various evaluation metrics have been used to evaluate AES systems, including correlation metrics such as Pearson's Correlation Coefficient (PCC) and Spearman's Correlation Coefficient (SCC), agreement metrics like quadratic weighted Kappa [8] (QWK) and quadratic agreement coefficient [13] (AC2), and error metrics such as Mean Absolute Error (MAE) and Mean Square Error (MSE).

We introduce novel evaluation methods that employ *multi-marked* test data, where each test item has been labelled by more than one expert human examiner, to facilitate comparison of human and AES system performance. Our methods aim to recognise that the set of examiner scores per answer represent an *acceptable range* of scores and thence we aim to evaluate AES systems against this set of scores rather than against a single gold standard score or via inter-rater agreement metrics. This is an important distinction given that expert examiner performance represents the upper bound on the AES task. To the best of our knowledge, this is the first work to perform an in-depth comparison of feature-based and neural-based AES model performance. Further, we illustrate that these models can be considered complementary, and combined to improve performance.

2. DATA

We employ a large training set, collected by Cambridge Assessment,[1] comprising almost 50,000 FCE examination scripts from 2016–20 with operational scores, as well as a newly created multi-marked test set containing 182 scripts labelled by 5 expert human examiners.[2] Each script consists of two questions, and responses are scored using 4 fine-grained assessment scales: content, communicative achievement, organisation and language. Each scale provides a score between 0 and 5 inclusively, and the overall score is calculated by summing over these 4 individual scales to provide an answer score in the range 0–20. For this AES task, we employ the overall 0–20 score to train and test models.[3]

The full training set contains almost 100,000 individual responses to over 50 different prompts, all labelled with a score in the range 0–20, but with an uneven distribution strongly concentrated around 14 (the score expected by an average learner having attained the B2 level for which the exam is designed). In order for the multi-marked test set to include as wide a range of responses as possible, 182 scripts (each consisting of two answers) were sampled to provide a more uniform distribution of scores in the range 16–40 as well as a certain number of lower scores (scripts with scores 0–15 are rarely seen since they correspond to a level far below the one required to pass the exam); the 364 individual answers show a relatively uniform distribution of scores above 8. Similarly, a more balanced training set of just under 15,000 answers was extracted from the full training set by excluding supernumerary scripts from the middle of the scale; u400.[4] The resulting distributions can be seen in Figure 1.

3. METRICS

3.1 Traditional Metrics

Yannakoudakis & Cummins [29] investigated the appropriateness and efficacy of evaluation metrics for AES including

[1] https://www.cambridgeassessment.org.uk/

[2] The operational score, combined with 5 examiner scores, results in 6 scores per answer in the test data. In contrast, the training data contains a single operational score.

[3] Previously, Yannakoudakis et al. [28] worked at the script level (i.e. across two answers) and therefore used scores in the range 0–40.

[4] Note: u400 was selected to be uniformly distributed at the script-level; with 400 randomly selected (maximum) scripts for each script score level 0–40.

SCC, PCC, QWK and AC2 under different experimental conditions. They recommend AC2 [13] for evaluation and reporting SCC and PCC measures for error analysis and system interpretation. Therefore we report these three evaluation metrics (AC2, SCC, PCC), as well as RMSE which we consider operationally desirable; it penalises larger errors more than smaller errors.

Ke & Ng [15] provide a survey of AES system research and popular public corpora employed in evaluation. Most public corpora contain a single human annotator score and evaluation is limited to considering this score the gold standard thence evaluation aids in comparison of AES systems but it is not possible to determine a reasonable upper bound on the task.

The CLC-FCE dataset [28] and the Automated Student Assessment Prize (ASAP) corpus, released as part of a Kaggle competition,[5] include scores assigned by four and two human annotators, respectively. For these, multi-marked corpus evaluation can be performed against a single reference score by taking an average of the scores [1, 16].[6] Alternatively, agreement between the AES system and (each) human expert can be compared to inter-rater agreement performance (which represents the upper bound the task) [28, 19]. Yannakoudakis et al. [28] calculate the average pair-wise agreement across all markers (human examiners and AES system) to produce a single (comparable) metric for SCC and PCC.We perform inter-rater and rater-to-AES pair-wise evaluations for SCC, PCC, AC2 and RMSE in our experimentation, and determine the average performance across the 5 expert human examiners.

3.2 Multi-marked Metrics

We also employ a novel evaluation method whereby scores are only considered to be erroneous if they fall outside the *acceptable range* of scores, as defined by the set of expert human examiner scores considered. We consider two score ranges: i) the range of 5 expert examiner scores (*ALL*) and ii) a narrower range (*MID3*) where we remove the top and bottom scores (for each test item). In addition, we report performance achieved for each of these ranges after removing a single examiner's score from the range, in turn, so that we can compare the performance of each expert examiner against the AES models.

Given a score range, we report the accuracy (percentage of scores that fall within the range) and a novel RMSE variant; RMSE^{R}, which considers the size of the error as equal to the distance between the score and the range. For example, if a score falls above the range we calculate the error as the difference between the score and the highest score in the range.

3.3 RMSE_c Graphs

Operationally, the best performing model may not necessarily be one that achieves the highest performance value based on single metric such as AC2. Rather, a model that performs well *across* the assessment scale is preferable. Further, it is possible for models to achieve similar (single) metric performance but exhibit very different performance distributions across the scale (cf. uniform vs non-uniform distributions with the same average).

Baccianella et al. [4] argued that macro-averaged metrics, including macro-averaged root mean squared error (RMSE^{M}), are more suitable for ordinal regression tasks. RMSE^{M} is calculated by averaging over RMSE_c (RMSE determined for each score c on the assessment scale). That is, RMSE_c is RMSE calculated over the subset of test items that are labelled c. They argue that macro-averaged metrics are more robust to test set distribution given the average results in equally weighting the error rate for each label in the assessment scale. Therefore, we report the RMSE^{M} metric.

We also want to explicitly analyse how a model performs across the assessment scale. Therefore, we employ individual RMSE_c measures, for each reference score c (0–20), and produce novel graphs; RMSE_c graphs, where the score (c) is plotted on the x-axis and the RMSE_c value is plotted on the y-axis. We also produce RMSE^{R}_c graphs, where we calculate RMSE_c values based on our novel RMSE^{R} variant.

4. AES MODELS

4.1 Feature-based

In this work, we extend a mature feature-based AES model [5, 28, 2]: a ranking timed aggregate perceptron (TAP) model trained on a set of features shown to encode the information required to distinguish between texts exhibiting different levels of language proficiency attained by upper-intermedite learners. Features include ones that can be extracted directly from the text (word and character n-grams) or a parsed representation (PoS n-grams and parse rule names), as well as various statistics (PoS categories, lengths, readability scores, use of cohesive devices, etc.) and error estimations (rule-based and corpus-based). We also include features that measure congruence between question and answer (similarity between embeddings for different parts), but that is not the focus of this paper.

Unlike for models used in previous work, the n-gram features have been filtered to exclude ones that encode punctuation without context; this forces the model to focus on other, possibly more relevant, aspects of the text and at the same time removes the possibility of artificially inflating model scores by adding superfluous punctuation characters. The models trained on the full and u400 training sets will be referred to as the TAP and TAP_1, respectively, in the following.

4.2 Neural Network

In recent years, fine-tuning pre-trained masked language models like BERT via supervised learning has become the key to achieving state-of-the-art performance in various natural language processing (NLP) tasks. These models often consist of over 100 million parameters across multiple layers and have been pre-trained on large amounts of existing text data to capture context-sensitive meaning of, and relations between, words. Following [19, 16], our neural approach builds upon this, where we use pre-trained DistilBERT as

[5] https://www.kaggle.com/c/asap-aes

[6] For ASAP, the *resolved* score is often employed, which is calculated as the average between the two human examiner scores (if the scores are close), or is determined by a third examiner (if the scores are far apart).

Table 1: Average inter-rater and rater-to-AES performance (Ex1–Ex5)

	Op	Ex1	Ex2	Ex3	Ex4	Ex5	TAP	TAP_1	NN	TAP+NN	TAP_1+NN

	TAP	TAP_1	NN	TAP+NN	TAP_1+NN
RMSE	1.70	1.72	1.58	1.56	**1.52**
$RMSE^M$	1.70	1.34	1.55	1.54	**1.33**

the basis for our neural network model and add additional layers on top to perform supervised tasks. We choose DistilBERT for practical reasons – it retains 97% of the language understanding capabilities of BERT, while reducing parameter size by 40% and decreasing model inference time by 60% [21].

We treat AES as a *sequence regression* problem and construct the input by adding a special start token ([CLS]) to the full text:

$$[\text{CLS}], w_1, w_2, \ldots, w_t, \ldots, w_n \tag{1}$$

This representation is then used as input to the output layer to perform regression.

Compared with feature-based models, for neural network models to be effective, they need to be trained on a large amount of annotated data. MTL allows models to learn from multiple objectives via shared representations, using information from related tasks to boost performance on tasks for which there is limited target data [18, 10, 31, 9]. Instead of only predicting the score of an essay, we extended the model to incorporate auxiliary objectives. The information from these auxiliary objectives is propagated into the weights of the model during training, without requiring the extra labels at testing time. Inspired by the linguistic features used in the feature-based AES systems, we experimented with a number of linguistic auxiliary tasks, and identified the dependency parsing as the most effective one.

The neural AES model is developed as a MTL neural network model trained jointly to perform AES and Grammatical Relation (GR) prediction. Model weights are shared among these two training objectives. The final layer for the AES objective is a fully connected layer that performs regression (i.e. scoring head), while another linear layer is introduced to perform token-level classification to predict the type of the GR in which the current token is a dependent (i.e. classification head). The overall loss function is a weighted sum of the essay scoring loss (measured as MSE) and the dependency parsing loss (as cross-entropy):

$$\text{Loss} = \lambda\,\text{Loss}_{\text{AES}} + (1-\lambda)\text{Loss}_{\text{GR}} \tag{2}$$

During training the whole model is optimised in an end-to-end manner. We refer to the neural MTL model trained on the full training set as the *NN* model in Section 5.

5. EVALUATION

To facilitate comparison between AES systems and human examiners, we employed traditional evaluation metrics as described in §3.1. Table 1 shows average inter-rater or rater-to-AES performance in terms of SCC, PCC, AC2 and RMSE calculated between 1) operational scores (Op), scores assigned by an expert (Ex1–Ex5) or scores predicted by an AES system, and 2) each of the experts' scores (excluding the expert being evaluated, if any).[7] For instance:

$$\text{SCC(Ex3)} = \frac{1}{n-1}\sum_{i\neq 3}\text{SCC(Ex3, Ex}i\text{)} \tag{3}$$

For each metric (row) in Table 1, we have highlighted the best performance in bold. AC2 scores 7 of the 10 models the same (top) score of 0.94 and thence, in our experimentation, does not aid in system comparison. Apart from AC2, these traditional evaluation metrics indicate that the NN model outperforms all examiners and feature-based (TAP) models. Both TAP models perform comparatively to the individual examiners, that is, fall in the performance range achieved by examiners (Ex1–Ex5). Performance of the combined TAP and NN models (the average score) is shown in the last two columns of Table 1. Based on these traditional

[7]For interested readers, we have included pair-wise results for SCC, PCC, AC2 and RMSE metrics in the Appendix.

metrics, it is unclear whether combining models improves performance. PCC and AC2 indicate no improvement is made over the single NN model, while SCC and RMSE indicate that TAP+NN and TAP_1+NN are best, respectively.

Table 2 compares the AES systems using RMSE and $RMSE^M$ calculated using the average examiner scores (ExAvg) as the single reference score. The combined TAP_1+NN achieves the best RMSE and $RMSE^M$ performance (in line with average examiner RMSE performance in Table 1). $RMSE^M$ is the only metric that illustrates a large performance difference between TAP and TAP_1 models. In fact, TAP_1 significantly outperforms the NN model as well for this metric, indicating that this model performs better across the assessment scale than the other AES models. RMSE and $RMSE^M$, over ExAvg scores, suggest that there is some small performance gains made by combining models.

In addition to traditional evaluation methods, we employed novel multi-marked metrics, as described in §3.2. Tables 3 and 4 illustrate the accuracy (percentage of scores that fall in range) over the ALL and MID3 ranges, respectively. Tables 5 and 6 show the corresponding $RMSE^R$ performance for these ranges, respectively. For all four tables, performance is directly comparable within each column, with the highest accuracy highlighted in bold.[8] The most important evaluation relates to the first column for the ALL range in Tables 3 and 5, as these results compare the performance of the AES models evaluated against all 5 examiner scores' range. Other columns in these tables (-ExN) facilitate comparison between the AES systems and each human examiner (N).

[8]Note, the asterisk symbol in these four tables indicate that the score is part of the acceptable range.

Accuracy and $RMSE^R$ metrics are complementary, as accuracy represents the proportion of scores that are correct while $RMSE^R$ evaluates the degree to which scores fall outside the range of human examiner scores. Operationally, we consider $RMSE^R$ more important than accuracy, given AES systems should be consistent and errors, when they do occur, should be penalised to a greater degree as the scores falls further outside the range of human examiner scores.

Tables 5 and 6 suggest that NN outperforms both TAP models and all human examiners, while both TAP models perform comparatively to the individual examiners; in line with evaluation based on traditional metrics in Table 1. However, in contrast to the metrics discussed thus far, the $RMSE^R$ metric indicates combined models outperform their corresponding individual models. This improvement is more evident for TAP_1+NN, which outperforms all human examiners and AES models across both ranges.

As described in §3.3, we produced novel $RMSE_c$ graphs to compare model performance across the assessment scale. $RMSE_c$ (and $RMSE_c^R$) graphs for the single and combined AES models are shown in Figure 2. The Op and ExAvg graphs plot $RMSE_c$ calculated against the operational and average examiner scores (i.e. c on the x-axis), respectively. The bottom graph, a $RMSE_c^R$ graph, plots the $RMSE^R$ performance for the ALL range where the c score (x-axis) is the average examiner score in the ALL range (i.e. using the same distribution of test items as the ExAvg $RMSE_c$ graph).

Comparing the AES models across the assessment scale, we can see that all AES models follow a similar pattern; they perform better in the mid ranges and worse in the lower and upper score ranges. This finding is not unexpected, given we have ample training data in the mid ranges and very little training data in the upper and lower ranges of the assessment scale (see Figure 1). The TAP_1 model, trained over a more uniformly distributed training set trades smaller declines in performance in the middle of the scale for more consistent results across the scale, in line with the $RMSE^M$ evaluation metric. The NN model achieves better performance in the upper and lower scores compared to TAP, suggesting that it is more robust over skewed training datasets. However, as evident in these $RMSE_c$ graphs, the TAP and NN models tend to perform better in particular ranges of the scale and thence these models are complementary, and combined models benefit from the relative strengths of individual models across the scale.

6. CONCLUSIONS

We deployed two types of AES systems: feature-based and neural network. We found that the NN model is more robust over skewed datasets as it achieves better performance in the upper and lower scores. However, the feature-based models are more interpretable, require significantly less computational overhead to train and can be trained over much smaller datasets than neural-based models. The TAP_1 model, trained over a more uniform subset of the training data performed more consistently than NN across the assessment scale. We illustrated that feature-based TAP and NN models are complementary, and combined models benefit from the relative strengths of individual models across the scale, outperforming human examiners. In operational deploy-

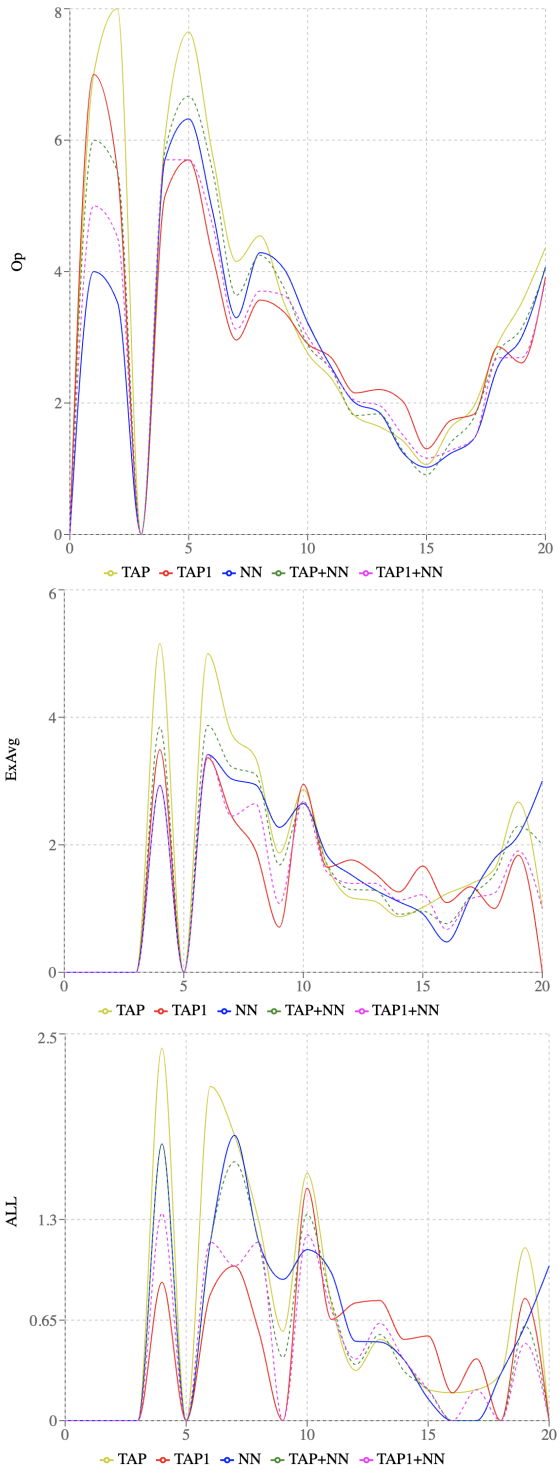

Figure 2: $RMSE_c$ graphs for operational score (Op) and average examiner score (ExAvg). $RMSE_c^R$ graph for the ALL range.

ment, the best performing TAP_1+NN model can make effective use of the constantly growing set of training data by retraining TAP_1 frequently to incorporate any new information available and only retraining the NN models over the full training set from time to time.

We presented novel approaches to evaluating AES that make use of multi-marked/annotated data. These approaches have advantages over traditional evaluation methods and also demonstrate the value of using resources to repeatedly annotate essays for the AES context. Building on the recommendations made by Yannakoudakis & Cummins [29], we make the following observations and suggestions for those working on AES:

- In addition to $RMSE^M$, we recommend calculating $RMSE_c$ and plotting $RMSE_c$ graphs to explicitly analyse how system performance varies across an assessment scale.
- We recommend that, where feasible, a proportion of texts in evaluation sets should be annotated by multiple examiners to allow different forms of evaluation that account for rating variability exhibited by human examiners.
- Where multiple human-derived scores are available, system performance should be evaluated using methods that incorporate the range of scores given for each text. We recommend using a novel RMSE variant; $RMSE^R$, that considers the size of the error as equal to the distance between the score and the upper or lower bound of the range.
- Where multiple human-derived scores are available, we also recommend that the accuracy of a system is calculated, by treating texts scored within the range of scores provided by humans as correct classifications.

Further work is needed to explore the evaluation approaches proposed here to establish how they vary in different contexts, to inform how they should be interpreted. For example, we expect these evaluation metrics to behave differently according to the granularity of the reporting scale, the distribution of evaluation sets and the inter-rater reliability observed between human examiners. Therefore, work to systematically investigate these measures in terms of their robustness to trait prevalence, robustness to marginal homogeneity and robustness to scale scores should be conducted systematically, in a similar vein to simulations reported by Yannakoudakis & Cummins [29].

We have demonstrated the value of producing multi-marked data to support evaluation. However, our proposed metrics can be refined further to allow for more sophisticated uses of multi-marked data, by incorporating methods commonly used for psychometric evaluation and quality assurance, such as Many-Facet Rasch Measurement [17, 12]. Further work should explore how these methods can account for examiner reliability issues when making use of multi-marked data.

7. ACKNOWLEDGMENTS

We would like to thank Ted Briscoe, Michael Corrigan, Helen Yannakoudakis and the anonymous reviewers for their

valuable comments and suggestions. This paper reports on research supported by Cambridge Assessment, University of Cambridge.

ABSTRACT

Students using self-directed learning platforms, such as Duolingo, cannot be adequately assessed relying solely on responses to standard learning exercises due to a lack of control over learners' choices in how to utilize the platform: for example, how learners choose to sequence their studying and how much they choose to revisit old material. To provide accurate and well-controlled measurement of learner achievement, Duolingo developed two methods for injecting test items into the platform, which combined with Educational Data Mining techniques yield insights important for product development and curriculum design. We briefly discuss the unique characteristics and advantages of these two systems - Checkpoint Quiz and Review Exercises. We then present a case study investigating how different study approaches on Duolingo relate to learning outcomes as measured by these assessments. We demonstrate some of the unique benefits of these systems and show how educational data mining approaches are central to making use of this assessment data.

Keywords

online learning; language learning; assessment; regression

1. INTRODUCTION

Online learning platforms have at their disposal large volumes of data about how students engage with learning material, how they navigate educational software, and how the learning process unfolds over time. Using a variety of methods - machine learning, statistics, psychometrics, etc. - Educational Data Mining (EDM) and Learning Analytics (LA) researchers identify students at risk of dropout from a course [e.g., 13], detect changes in study behavior [e.g., 11], predict exam performance [e.g., 1, 4, 12], and characterize the different learning strategies that learners adopt [e.g., 1, 12].

Duolingo is a learning platform that provides free language education through mobile apps and a website. With around 40 million users active on the platform each month, Duolingo may well possess the largest language learning dataset of any company or research institution. Researchers at Duolingo leverage EDM/LA methodologies to mine datasets - including internal assessment and log data - for insights that inform improvements to the learning experience, help identify opportunities for changes to curriculum design, and fuel research on second language (L2) learning more generally.

Due to the self-directed nature of the Duolingo learning platform and the desire for holistic learner assessment, we have developed two assessment systems - the Checkpoint Quiz and Review Exercises - that allow for carefully controlled measurement of learner achievement. These two assessments were designed with the challenges gamified platforms struggle with in mind, including ensuring the learning experience remains motivating and maintaining a scalable content creation process.

The utility of the Checkpoint Quiz and Review Exercises for assessing learner achievement depends, at least in part, on the high volume of data collected from Duolingo learners and the EDM methodologies that can be applied to that data. By leveraging predictive modeling and natural language processing (NLP) methods, we are able to control for the various ways that learners choose to navigate through the platform. Further, these methods allow us to uncover useful insights into how this variation in user navigation relates to learning outcomes - insights that we can leverage for product development and curriculum design. In this paper, we present two of our assessment systems and a case study highlighting the importance of applying EDM methodologies to derive insights from Duolingo assessment and log data.

2. RELATED WORK

Most EDM/LA applications at Duolingo focus on pedagogy-oriented issues [10] or computer-supported predictive analytics [2]. Most relevant to the current work are studies focused on predicting performance on upcoming course exercises [9] and predicting performance on an assessment [1, 4, 12]

Rather than relying on assessment data, some systems discussed in other studies instead model student interaction with and performance on individual course exercises. Knowledge tracing [7] is a popular approach for maintaining a model of whether students have learned specific concepts in a course. One system [9] compared the performance of a Bayesian Knowledge Tracing (BKT) model with a Deep Knowledge Tracing (DKT) model using Long Short-Term Memory (LSTM) to better capture longer-

Lucy Portnoff, Erin Gustafson, Joseph Rollinson and Klinton Bicknell "Methods for Language Learning Assessment at Scale: Duolingo Case Study". 2021. In: Proceedings of The 14th International Conference on Educational Data Mining (EDM21). International Educational Data Mining Society, 865-871. https://educationaldatamining.org/edm2021/
EDM '21 June 29 - July 02 2021, Paris, France

term learning. These models predicted future performance on exercise x_{t+1} given the previous performance record for a student (x_0, ..., x_t). This system treats every student interaction as an opportunity for assessment and the model output was used for developing student-facing modules for progress tracking and content recommendation. However, knowledge tracing approaches primarily focus on characterizing mastery of specific concepts rather than providing a holistic assessment of knowledge or achievement.

Other studies rely both on knowledge tracing and assessment data to analyze course effectiveness and provide this more holistic view. This approach is especially useful in more self-directed learning platforms. One study [4] used BKT to characterize learning using a digital game and used outputs from these models to predict post-test scores following a period of learning with the game. They found that mastery scores for two knowledge components (output from BKT models) had positive and significant association with post-test scores. Insights from the BKT model itself were also useful for identifying concepts that are difficult for students to master, which highlights opportunities for improving course effectiveness. This study also found evidence that learners have poor meta-cognition about their mastery of key concepts; when left to use the learning platform freely, many students continue to practice concepts the BKT model predicts they have mastered rather than moving on to new material.

Knowledge tracing is not the only approach used for characterizing student behavior using clickstream or log data. To make log data useful for predictive modeling, many researchers turn to methods from NLP to aggregate events [1, 12]. Simple methods include calculating n-grams for particular event types. For example, unigrams can capture the number of times a student completes a particular learning module and bigrams can capture the number of times students complete two modules in sequence [12]. Such data can be used as inputs into predictive models either relying solely on raw n-gram counts [12] or by processing the data further using unsupervised machine learning methods - such as hierarchical clustering - to identify common sequence patterns [1].

3. DUOLINGO ASSESSMENT SYSTEMS

3.1 Duolingo Course Structure

Duolingo courses are organized into a series of *units*, each of which concludes with a *Checkpoint*. Courses used by the majority of learners have the following structure: 25-30 *skills* per unit with five difficulty *levels* per skill and 5-6 *lessons* per level. Skills are designed around a particular theme (e.g., Travel). The vocabulary taught in the skill is aligned around that theme (e.g., hotel, airport, passport) and grammatical topics tend to be consistent across lessons within a skill. Lessons typically consist of 12-15 exercises designed to teach some vocabulary and/or grammatical concept. Duolingo curriculum designers incorporate aspects of spiral curriculum [5] to revisit familiar concepts in more complex contexts in future skills. See Figure 1 for an example of the typical Duolingo course structure.

The five levels for each skill provide a scaffolded learning experience, where learners review the same vocabulary or grammatical concepts in increasingly difficult contexts. All skills start with a foundational Level 0 and as learners "level up" a skill they see the same sequence of lessons teaching the same content but using different exercise types. Early levels include exercises that focus on passive recognition, such as matching a second language (L2) word/picture pair with the corresponding word in the first language (L1); see Figure 2). Exercises in later levels are more difficult, as they require recall and production in the L2 (e.g., translating an L1 sentence into L2; see Figure 2). The level achieved for a given skill is indicated in the user interface with a number inside a crown icon (see Figure 1).

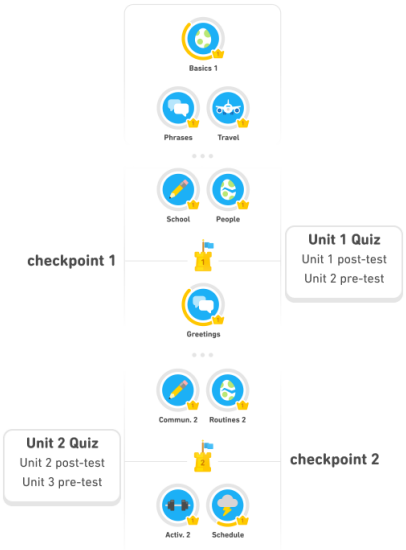

Figure 1. Duolingo course and Checkpoint Quiz design.

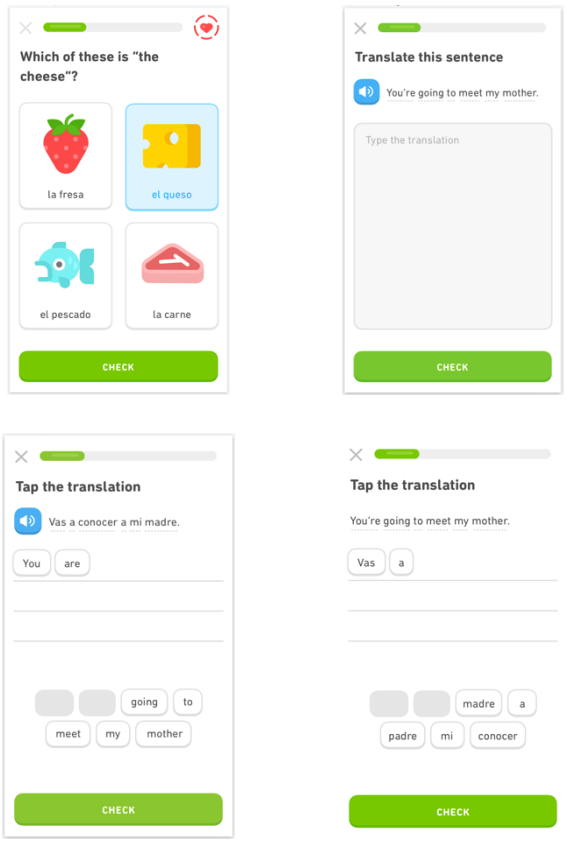

Figure 2. Example exercise types. Top left: passive recognition; top right: recall and production. Bottom left: recall L2→L1; bottom right: recall L1→L2.

When learners begin a Duolingo course, not all skills in the first unit are immediately available; a row unlocks once Level 0 is complete for all skills in the prior row. For example, only the Basics 1 skill is available at first and the next set of skills in the row below Basics 1 (e.g., Phrases and Travel; see Figure 1) will only unlock once Basics 1 reaches Level 1. Once skills are unlocked, learners are free to return to them to practice previously studied material and "level up" the skill. Duolingo learners are, therefore, given agency to choose their learning path. Some learners prefer to attempt only the foundational level in a skill (Level 0) before moving on to new material, while others prefer to level up all skills. Leveling up is entirely optional and learners are required to complete only the foundational level for each skill before they can move on to the next unit of content. This self-directed nature of the learning platform provides challenges for assessing learner achievement.

Other modes of learning are available to users outside of course skills. Learners can build reading and listening proficiency through the Stories feature, which reinforces unit content through interactive dialogues with exercises to check comprehension. Learners can also complete generalized practice sessions, which drill users on content they have already studied from throughout the course. Further, after learners have leveled a skill up all the way, they can return for skill practice to reinforce their knowledge. If learners find skill material too easy, they also have the option to "test out" of a level and jump to harder exercises at the next level.

We use a variety of methods to assess learner achievement and proficiency throughout a Duolingo course. In the sections below, we describe two of the core assessments in use today: Checkpoint Quiz and Review Exercises.

3.2 Checkpoint Quiz

For a subset of Duolingo's courses, learners must complete a custom-built assessment once they finish a unit and reach a Checkpoint. The Checkpoint Quiz is an achievement test that measures the extent to which our learners have achieved the objectives for each unit of a course. Checkpoint Quiz items are independent from the items used in course skills and users are only exposed to the quiz items during the assessment. This ensures that learners do not have the opportunity to learn the items in the assessment while studying course content and is important for test validity. Checkpoint Quiz items were designed by curriculum experts and Duolingo assessment scientists have conducted analyses to ensure their quality.

Learners do not receive corrective feedback or a final grade for the assessment and may only take the quiz once. At each Checkpoint, learners complete a randomly generated quiz consisting of 15 items (sampled from a larger pool of items). Seven items are pre-test items that test the next unit of the course that the learner is about to start and another seven are post-test items that test the unit the learner just completed (critically, the same seven items the learner saw in the previous quiz as a pre-test). This pre-test / post-test design allows us to establish a baseline level of performance so we can later assess gain in accuracy from pre-test to post-test. The final item is a self-directed writing item designed to assess the current unit (with no pre-test). See Figure 1 for an illustration of Checkpoint Quiz design.

The assessment tests knowledge of vocabulary, grammar, listening comprehension, reading comprehension, and free-form writing using separate items designed to test one of these language skills and components. Vocabulary and grammar items are a combination of multiple choice and fill-in-the-blank questions (i.e., learners type the missing word), listening and reading are exclusively multiple choice, and writing questions are free-response. Each item is accompanied by a set of curated tags for grammatical concepts and communicative components.

3.3 Review Exercises

Review Exercises prompt learners to review content from a skill earlier in their course. A single Review Exercise is inserted into randomly selected lessons in the foundational level of a skill (only for skills beyond the first five in the course). These exercises are randomly and uniformly sampled from the pool of available exercises from either three skills or five skills earlier in the course. For example, randomly selected exercises from the Animals skill are injected into Level 0 lessons seen by learners studying the Places skill (see Figure 3). These exercises are inserted into the lesson in a random position, as long as it is not among the first two or last two exercises. Therefore, lessons with Review Exercises will be one exercise longer than a standard lesson. Review Exercises come in two forms: assisted recall and translation from L1-to-L2 or vice versa (see bottom row of Figure 2).

Figure 3. Review Exercise design for testing five skills earlier in course.

Review Exercises as a form of assessment have a number of advantages over the Checkpoint Quiz: 1) Review Exercises are available in all courses; 2) they allow us to measure learning at every skill in a course, rather than just at unit-terminal Checkpoints; and 3) they provide an order of magnitude more data than Checkpoint Quizzes.

However, Review Exercises have a few disadvantages over the Checkpoint Quiz. One key disadvantage is that the items used for Review Exercises overlap with items used for lessons with skills; therefore, we sacrifice some test validity in order to be able to use the assessment at scale across all courses and all skills in a given course. Further, the sentences used as Review Challenges have not been assessed for their quality as measures of learning. Another disadvantage is that the data is not tagged for grammatical concepts or communicative components, which

limits the insights this assessment can provide for informing curriculum design.

Table 1. Key differences between the Checkpoint Quiz and Review Exercises.

Checkpoint Quiz	Review Exercises
Slow data collection (only at Checkpoints)	Fast data collection (at every skill in a course)
Tagged and calibrated by curriculum experts	Not tagged or calibrated
Items siloed from course	Items sampled from course
Only certain courses	All courses

4. CASE STUDY

Learners on Duolingo use the platform in a variety of different ways. In this case study, we investigate how learning decisions impact outcomes, so that we could "nudge" learners to use the app more effectively.

This case study demonstrates how EDM methodologies allow us to investigate the various ways that learners choose to navigate through the platform - focusing on differences in "leveling up" behavior - and how course navigation relates to learning outcomes. We show a correlation between leveling up and higher accuracy on the Checkpoint Quiz. Complementary modeling with Review Exercise data establishes a causal link between completing sessions in higher levels and accuracy on assessments.

4.1 Checkpoint Quiz

4.1.1 Data

Our work uses four months of Checkpoint Quiz data. For every learner completing at least two consecutive Checkpoint Quizzes within this timeframe, we collected the pre-test / post-test item response pairs (e.g., the pre-test responses collected at Checkpoint 1 and the corresponding post-test responses collected at Checkpoint 2) as well as summary statistics on learners' studying behavior in the unit the items assess (e.g., number of lessons completed at each level across skills in Unit 2, number of Stories completed between pre-test and post-test). Responses to free-form writing items were not included in this analysis.

4.1.2 Methods

To isolate the impact of lessons completed at each level on Checkpoint Quiz outcomes, we built a logistic regression model to predict post-test scores for items that were answered incorrectly in the pre-test (a measure of learning gain). Primary variables of interest capture the number of lessons learners completed at a given level for each skill in the unit of interest (frequency counts for Level 1 through Level 4; e.g., a learner completed 20 Level 1 lessons, 15 Level 2 lessons, etc.). Although Duolingo has five levels for all skills (starting with Level 0), we exclude counts for the foundational level because all learners must complete the same number of Level 0 lessons to finish a unit. The model controls for item and user covariates: language component of the item (e.g., vocabulary), unit (e.g., Unit 2), course (e.g., French for English Speakers), number of sessions completed for other types of study material (e.g., Stories, generalized practice, test-outs), self-reported prior proficiency (0-10), and subscriber status[1] (non-paying or paying learner).

4.1.3 Results

We found that average post-test item accuracy increases linearly with every skill-level completed (Figure 4). In other words, each additional level completed across all skills increases the odds of answering a Checkpoint Quiz item correctly by the end of the unit.

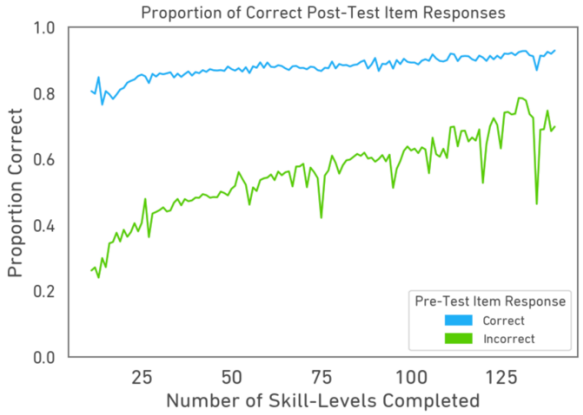

Figure 4. Average post-test accuracy by the number of skill-levels completed as a function of pre-test accuracy.

This finding was supported by the results of our logistic regression model (summarized in Figure 5). We observed that the probability of answering a post-test item correctly increases with every additional lesson in Levels 1, 2, and 4. Level 3 has a negative coefficient, but this is likely an artifact of variable suppression[2].

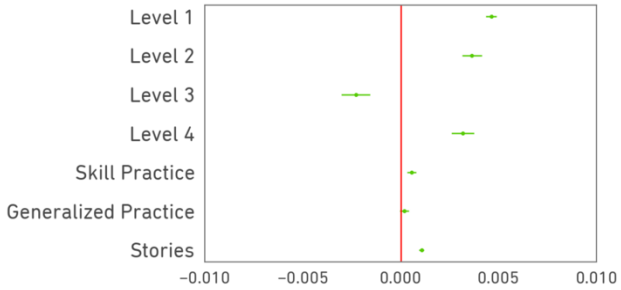

Figure 5. Checkpoint Quiz logistic regression model output. Coefficients of the number of times a user completed seven different session types in a model including other user and item covariates (see Section 4.1.2).

[1] Duolingo offers a paid subscription that removes ads, allows offline access, and includes additional features and learning modes. All learners have access to the same course content.

[2] Because learners tend to complete the same number of lessons in Levels 3 and 4, we attributed the negative coefficient to the statistical consequence of highly collinear relationships existing in the correlation matrix, which can cause variable suppression and model instability [8]. To verify that this multicollinearity did not result in model instability, we repeatedly fit the model on bootstrapped samples of the original data. We found that small changes to the data do not cause any erratic changes in the coefficients, so we concluded that our model estimates are stable.

We also compared the magnitudes of the leveling up effects with those of other types of learning modes, specifically Stories (interactive dialogues to practice reading and listening skills), skill practice, and generalized practice (see Section 2 for more details about these learning modes). Coefficients capturing leveling up behavior show dominant effects in the model; one additional skill-level has a greater impact on Checkpoint Quiz scores than one additional Story, skill practice, or generalized practice.

The Checkpoint Quiz findings show that providing learners with multiple difficulty levels to practice study material improves learning outcomes. Further, we found evidence that completing lessons at Levels 1, 2, 4 is not only positively associated with learning outcomes, but is *more* positively associated than any other activity. However, the Checkpoint Quiz analysis is not necessarily causal. The findings could also be due to self-selection biases, wherein the type of learner that is motivated to complete additional (non-required) levels is likely to perform better in general. A complementary analysis is required to establish a causal link.

4.2 Review Exercises

We utilized Review Exercise data to establish a causal link between leveling up and better learning outcomes. Review Exercises are better suited to this complementary analysis than the Checkpoint Quiz because each Review Exercise targets material from a single source lesson. This design allows us to compare learners who exhibit the same studying behavior except for the completion of one additional level for that lesson. Isolating the change in accuracy from one additional level means that we have controlled for self-selection biases and can interpret the change as causal.

4.2.1 Data

For the Review Exercise analysis, we collected all Review Exercises completed over the course of approximately two months. Data comes from all Duolingo courses. Along with Review Exercise response accuracy, we collect important control variables: whether the exercise came from 3 or 5 skills earlier in the course, exercise type, and the skill the exercise was sampled from (see Figure 3 for Review Challenge design).

4.2.2 Methods

Using logistic regression and a regression discontinuity design (RDD) [3, 6], we are able to model the impact of completing higher levels on Review Exercise accuracy while controlling for self-selection bias that may occur for learners who choose to level up vs. those who do not. An RDD is a quasi-experimental approach where a synthetic treatment condition is assigned to observations that fall above or below a certain "cut-off" point. We achieve this by first identifying learners who have completed any lessons at a given level for the skill a Review Exercise was sampled from (e.g., learners who have completed at least one Level 1 lesson). Among those learners, we define a cut-off point to compare those who have completed that level for the Review Exercise source lesson (e.g., Level 1) to those who have completed that level for the lesson that *immediately precedes* the source lesson but who have not yet completed that level for the source lesson itself (e.g., preceding lesson to Level 1, but source lesson to Level 0). This approach controls for most potential self-selection bias in deciding to level up (all comparisons include learners who have chosen to level up the skill) and can provide stronger evidence for a causal relationship between leveling up and Review Exercise accuracy.

We created a variable with eight levels for use in the regression model to capture 1) the highest level a learner has leveled up the Review Exercise source lesson to and 2) whether the learner studied the source lesson to the same level as the preceding lesson (e.g., both at Level 1) or studied the source lesson one time less than the preceding lesson (e.g., preceding lesson at Level 2 but source lesson at Level 1). For example, this scheme yields coefficients of the form `Level 1:Same Level`, indicating learners for whom both the source lesson and preceding lesson were at Level 1, or `Level 1:Lower Level`, indicating learners for whom the source lesson was at Level 1 and the preceding lesson was at Level 2. This coding scheme required excluding certain observations. Cases where the learner had completed the highest level possible for the Review Exercise source lesson (i.e., Level 4) is not included because it is impossible for the lesson preceding the source lesson to be leveled up any higher. We also exclude observations where the source lesson is the first lesson of a skill because there will be no preceding lesson to serve as a control comparison.

In addition to this main variable, we also control for other factors that influence Review Exercise accuracy: the number of skills away from the source skill (three or five), and the exercise type of the Review Exercise (L1-to-L2 translation or vice versa), and the difficulty of the source skill. We defined difficulty of source skills by computing the log-odds of answering a Review Exercise correctly in each skill in the data overall[3]. This allows us to control for the fact that, all else being equal, accuracy is likely to be lower overall for Review Exercises sampled from more difficult skills, which increases the power of the analysis.

4.2.3 Results

If leveling up causes higher Review Exercise accuracy, we expected to see that the `Level N:Same Level` (source lesson and preceding lesson to Level N) coefficients were significantly larger than the `Level N-1:Lower Level` (source lesson one level lower than preceding lesson; Levels N-1 and N, respectively) coefficients. Such an effect would indicate that - controlling for leveling up behavior overall - completing higher levels of the lesson a Review Exercise came from yields significant improvements in Review Exercise accuracy.

Figure 6 summarizes the results of our logistic regression model. We can see that `Level 1:Same Level` is significantly higher than `Level 0:Lower Level`. This effect indicates that learners who have studied a Review Exercise source lesson twice (at Level 0 and Level 1) are more likely to provide a correct response on their Review Exercise than learners who have studied a Review Exercise source lesson once (only at Level 0) but already had studied the previous lesson twice (at Level 0 and Level 1). This result provides evidence for a causal relationship between leveling up study material and assessment performance, at least for the first time learners level up. The model shows similar trends for leveling up beyond Level 1 (e.g., `Level 2:Same Level` is numerically higher than `Level 1:Lower Level`), suggesting this relationship continues to exist as users study the Review Exercise source lesson additional times (although perhaps with diminishing returns).

The regression results also show significant differences between `Level 0:Same Level` / `Level 0:Lower Level` and

[3] Empirical log odds defined as *log((correct + 1) / (incorrect + 1))*.

`Level 1:Same Level` / `Level 1:Lower Level`. Although the learners captured in the `Lower Level` coefficients had not leveled up the source lesson to Level 1, we see clear improvements in Review Exercise accuracy stemming from leveling up any lessons preceding the source lesson. These learners will not have had additional opportunity to study the exact exercise used for the Review Exercise, but the content and concepts in other lessons in the skill will have been related. Therefore, the benefit of studying in one lesson transfers to other lessons.

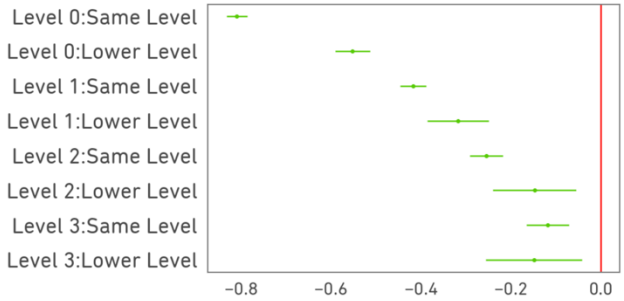

Figure 6. Review Exercises model output. Coefficients of leveling up behavior in a model including other item covariates (see Section 4.2.2).

5. CONCLUSIONS

In a case study of the levels mechanic, wherein learners study content in increasingly difficult contexts by "leveling up", complementary analyses of the Checkpoint Quiz and Review Exercises showed that completing sessions in higher levels leads to stronger performance on assessments. Analyzing accuracy rates on the Checkpoint Quiz by the number of skill-levels completed in the course unit revealed a strong positive trend. Because variation in how learners navigate the platform may introduce self-selection bias and complicate interpretation of these results, we conducted an additional analysis of Review Exercises that controlled for this bias. The Review Exercises analysis supports a causal link between leveling up and improved assessment performance, showing that completing additional levels for a skill (beyond the foundational level) has measurable learning value.

Together, these results directly motivated the implementation of a number of interventions that encourage learners to reach higher levels. For example, because learner awareness of the existence and purpose of levels was relatively low, we added design elements that give learners a visual stand-in for how the levels system works. Learners also now receive a pop-up with a redirect button upon finishing a level prompting them to start the next level in the skill. Randomized controlled experiments (i.e., A/B tests) introducing these changes showed >10% increases in the number of lessons completed in each level beyond the required foundational level and significantly more studying activity on the app overall. These interventions exemplify how insights from the Checkpoint Quiz and Review Exercises have lasting impact on the Duolingo learning experience.

This study focused on one type of variation in how learners choose to navigate the Duolingo learning platform, namely leveling up. Learners can additionally choose their own study sequence for the skills (e.g., completing all the levels in a skill before starting the next skill, completing the entire course unit one level at a time, leveling up clusters of skills within a unit), as well as which types of learning material to study (e.g., course skills, generalized practice, Stories). Future iterations of this work will aim to capture such variation, thereby improving model fit and deepening our understanding of how other types of navigational choices relate to learning outcomes. Previous EDM studies [1, 9] provide methodologies that can be used to characterize this variation.

Future work will also continue to explore the utility and limitations of the Review Exercise assessment system. For example, data from Review Exercises show promise as a method for measuring learning improvements over the course of an A/B test due to the high volume of daily data generated, highly localized measurement (i.e., testing learning of content from specific course skills), and the distributed nature of the assessment (i.e., testing learning in all course skills). Future work could also consider whether Review Exercise accuracy can be predicted based on engagement with (and accuracy on) source lessons in the past.

Self-directed learning platforms such as Duolingo require accurate and well-controlled assessments to measure learner achievement. Because learners exercise a high degree of agency in how they navigate the courses, achievement cannot be adequately assessed by analyzing exercise responses alone. Duolingo developed two forms of assessment - the Checkpoint Quiz and Review Exercises - to capture insights about how different study approaches relate to learning outcomes. Applying EDM techniques to these assessments yields useful insights that inform our understanding of how the navigation of course content relates to learning outcomes and how we can leverage these insights to improve the learning experience on the platform.

ABSTRACT

Today, there is a vast amount of online material for learners. However, due to the lack of prerequisite information needed to master them, a lot of time is spent in identifying the right learning content for mastering these concepts. A system that captures underlying prerequisites needed for learning different concepts can help improve the quality of learning and can save time for the learners as well. In this work, we propose an unsupervised approach, UPreG, for automatically inferring prerequisite relationships between different concepts using NLP techniques. Our approach involves extracting the concepts from unstructured texts in MOOC (Massively Open Online Courses) course descriptions, measuring semantic relatedness between the concepts and statistically inferring the prerequisite relationships between related concepts. We conducted both qualitative and quantitative studies to validate the effectiveness of our proposed approach. As there are no ground truth labels for these prerequisite relations, we conducted a user study for the evaluation of the prerequisite relations. We build the concept graph using prerequisite relations. We demonstrate few examples of the learning maps generated from the graph. The learning maps provide prerequisite information and learning paths for different concepts.

Prerequisite relation, Text mining, Learning path

1. INTRODUCTION

In today's fast-paced world, skill development and a strong foundation in fundamental concepts are becoming very crucial for career growth. MOOCs, offering a wide variety of courses online are becoming ubiquitous among many learners interested in acquiring knowledge and becoming competent in their field of interest. In this journey, learners need to know the order in which they must learn different concepts to attain a good level of mastery in a specific topic. Knowing the prerequisites when learning a topic improves the learning experience of learners and is influential to the learner's achievements [20]. Prerequisite concepts define the concepts one must know or understand first before attempting to learn or understand something new.

With the increasing amount of educational data available, automatic discovery of concept prerequisite relations has become both an emerging research opportunity and an open challenge. There is a growing interest today in researching different techniques for automatically inferring the prerequisite relations between concepts [17][20]. Various solutions like curriculum planning [23], learning assistant [10], automated reading list generation [9] etc, have been developed based on such techniques.

Prerequisites at the course-level have been manually curated by experts and this helps find prerequisite relations between the concepts covered within the courses. For example, concepts in a course on Optimization are prerequisites to concepts in a course on Deep Learning. An example in this scenario would be the Gradient Descent algorithm being a prerequisite for understanding the Backpropagation algorithm used in Deep Neural Networks. Such relations created manually will not scale in real-world online applications. Modern applications today support learning content from a wide variety of domains and cater to learners from multiple educational backgrounds. Manual processes for creating prerequisite relations in such applications are expensive and time-consuming. Hence, it is necessary to develop solutions that can infer prerequisite relations using automated approaches.

In this work, we propose an unsupervised approach, UPreG, for automatically inferring prerequisite relationships between different concepts using NLP techniques. We built a concepts graph capturing the concepts and the prerequisite relation between them. Concepts here refer to technologies, programming languages, tools, and topics in the Software and Computer Science domain. The concepts graph can be

leveraged to find the right content for the learner, including the prerequisite content. We conducted both qualitative and quantitative studies to validate the effectiveness of our proposed approach. As there are no ground truth labels for these prerequisite relations, we conducted a user study for the evaluation of the prerequisite relations. We observed that our approach is effectively able to infer the prerequisite relations between concepts. The approach can be extended to other domains as well.

This paper is structured as follows. We present the related work in Section 2. In Section 3, we describe our approach for concept graph generation followed by the evaluation methodology and results in Section 4. In section 5, we discuss the challenges we encountered while building the concepts graph. Finally, Section 6 concludes with future work.

2. RELATED WORK

Pan et al. [17] propose a learning-based method for latent representations of course concepts. They defined various features and trained a classifier that can identify prerequisite relations among concepts. Roy et al. [20] proposed PREREQ, a supervised learning method for inferring concept prerequisite relations. The approach uses latent representations of concepts obtained from the Pairwise Latent Dirichlet Allocation model, and a neural network based architecture. They assumed that concept prerequisites are available to train supervised model. Yu et al. [24] present an improved version PREREQ-S by introducing students' video watch order to enhance the video dependency network. They sorted the watched videos of each student by time and utilize these sequences for replacing the video sequences. They apply two simple DNN models, which first encode the embeddings of the concept pairs and then train an MLP to classify the prerequisite ones. Alzetta et al. [3] applied a deep learning-based approach for prerequisite relation extraction between educational concepts of a textbook. Lu et al. [13] proposed an iterative prerequisite relation learning framework, iPRL, which combines a learning based model and recovery based model to leverage both concept pair features and dependencies among learning materials. Liang et al. [12] addressed the problem of recovering concept prerequisite relations from university course dependencies. They [11] further applied active learning to the concept of prerequisite learning problem. Pal et al. [16] proposed an approach to find the order of concepts from textbooks using the rule-based method. Prior work assumes the prerequisite relationship pairs available as ground truth and apply supervised learning approach. However, acquiring labeled prerequisite pairs is time-consuming and expensive. Currently, the major drawback of supervised learning is that it doesn't perform well over cross-domains [16]. To the best of our knowledge, we are the first to apply unsupervised approach to extract the prerequisite relationship for software domain.

3. APPROACH

In this section, we discuss our approach to build the concepts graph. It is a directional graph where nodes represent the concepts and the edges between nodes represent the prerequisite relationship between them. Our approach in building the concepts graph involves concept representation, measuring semantic similarity between the concepts and identification of the prerequisite relationship between them.

3.1 Concept Representation

The descriptions of the courses in MOOCs contain rich information about the concepts that will be taught to the learners. Many courses do not have annotated course tags to represent the concepts taught in the course. It is very expensive and time-consuming to manually create course tags from the course content [13]. Hence, the concepts must be extracted from the course content using text mining approaches. We collected course metadata from different MOOCs (Udemy and edX) and our internal Learning Management System. We apply Latent Dirichlet Allocation (LDA) [4], a topic modeling algorithm on each course description to extract the concepts. The algorithm generates a topical distribution for each course description. To determine the most relevant topic that represents the concepts a course covers, the topic with highest probability from the distribution is selected. After performing several iterations, we found that setting k=5 (number of topics to be extracted) gave the best results. We extract a total of 9750 unique concepts.

3.2 Semantic similarity between concepts

The Semantic similarity measure between concepts gives a measure of the semantic relatedness between them. Concepts that appear in the same context or appear together very often have higher semantic similarity scores. Semantic Similarity computation eliminates noise present in the results of the topic modeling algorithm and reduces the possibilities of weak relations in the concepts graph. It is also useful in prerequisite relation identification as it is likely that concepts appearing in similar contexts will have better chances of being identified with prerequisite relation. This improves the selection of candidates in the concepts graph.

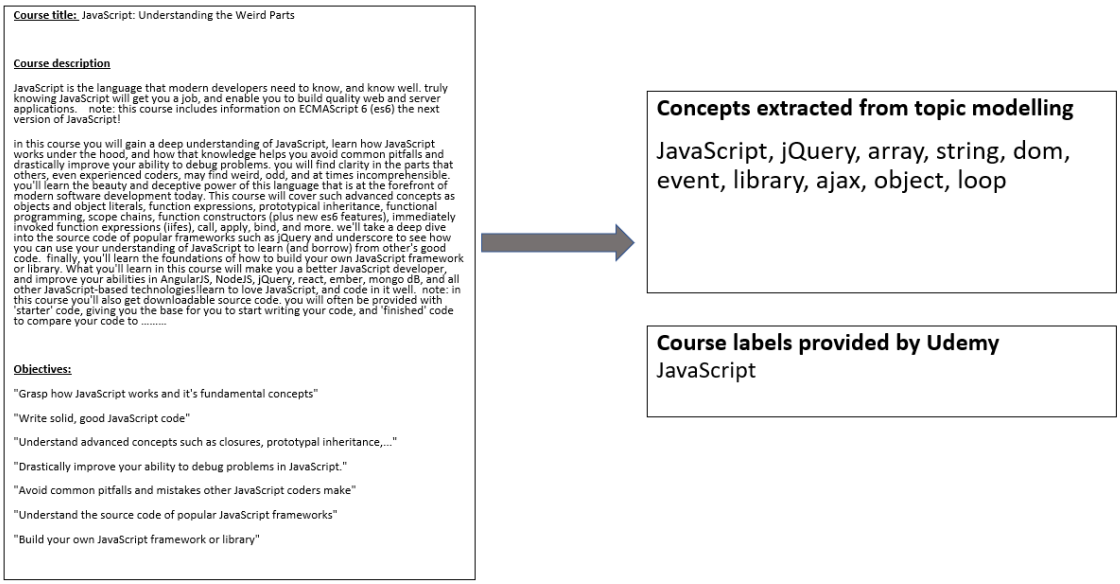

Figure 2: Concepts generated for a JavaScript course

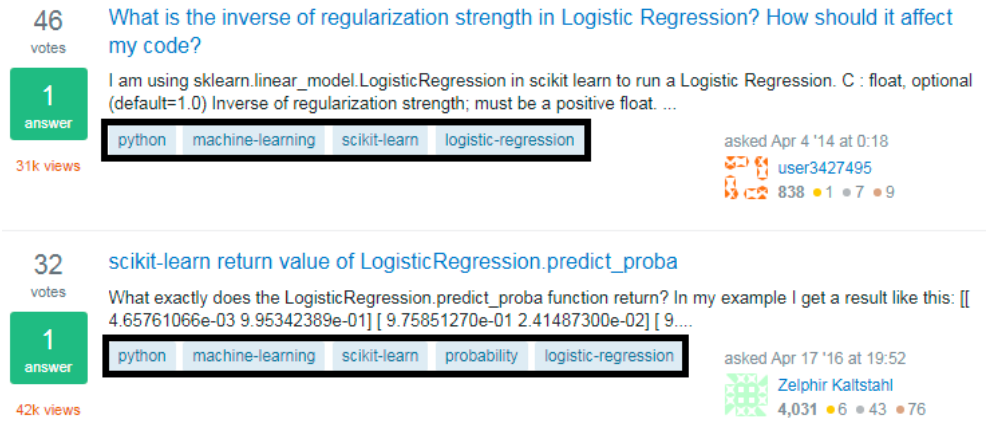

Figure 3: Stack Overflow questions and tags

To measure semantic similarity between the concepts we compute Pointwise Mutual Information (PMI) and Word2Vec cosine similarity scores. The Semantic similarity scores between the concepts are computed as the weighted average of the two scores.

3.2.1 *Pointwise Mutual Information*

PMI gives a measure of concept association used in information theory [6]. It gives a measure of how likely two concepts would occur together when compared to their independent occurrences in the data. For computing the PMI of concept pairs, tags of Stack Overflow questions obtained from Stack Overflow data dumps were used. The author posting a question on Stack Overflow is asked to provide tags associated with the posted question (as shown in Figure 3). Tags that appear often together across all the questions are likely to be strongly related. Higher the score between the two concepts, the more similar they are. We assume that the concepts occurring together have some correlation over a large set of pairs. To compute the PMI scores, we leverage the Stack Overflow dump consisting of 1,000,000 Stack Overflow questions along with their tags [21]. PMI score between any two concepts c_1 and c_2 is defined as:

$$PMI(c_1, c_2) = max\left(0, \frac{\log\left[p(c_1) \cdot p(c_2)\right]}{\log p(c_1, c_2)} - 1\right) \quad (1)$$

Here $p(c_1, c_2)$ is the probability of co-occurrence of concepts c_1 and c_2. It is fraction of Stack Overflow questions in which concepts c_1 and c_2 co-occur as tags. $p(c_1)$ and $p(c_2)$ is the probability of the independent occurrence of concepts c_1 and c_2 as tags across all Stack Overflow questions. The score obtained is a normalized score that takes values between 0 and 1. This ensures PMI and Word2Vec similarity scores have the same scale when taking their weighted average.

3.2.2 *Word2Vec Embeddings*

Raw word frequency is not a great measure of association between words. One problem is that raw frequency is very skewed and not very discriminative. It also does not capture

the kinds of contexts shared between the words, which word embedding techniques capture [2]. We apply Word2Vec approach to learn semantic relatedness between concepts. The Word2Vec model is based on the intuition that words which are similar in context appear closer in the word embedding space. Word2Vec algorithm uses a neural network model to learn word associations from a large corpus of text. We use skip-gram model [15] to learn word embeddings which are low dimensional vector representations of the extracted concepts. The neural network is trained using a text corpus of course descriptions. We train the skip-gram model for generating 300-dimensional word embeddings. Word2Vec neural network is trained using the text corpus of the course description and objectives. We train Word2Vec model on a corpus of 64,150 courses using the Python library gensim [18] with default parameters. Some of the Word2Vec similarity scores between concepts are captured in Table 2. Word2Vec(W2V) similarity score between the concepts is computed as the cosine similarity between these word embeddings.

$$W2V(\mathbf{c_1}, \mathbf{c_2}) = \frac{\mathbf{c_1} \cdot \mathbf{c_2}}{\|\mathbf{c_1}\|\|\mathbf{c_2}\|} \quad (2)$$

Here $\mathbf{c_1}$ and $\mathbf{c_2}$ represent 300 dimensional embedding vectors of concept c_1 and c_2.

Finally, we compute the similarity score as a weighted average of the above two scores. For simplicity, we set the weights to 0.5.

$$Sim(c_1, c_2) = w_1 \cdot W2V(\mathbf{c_1}, \mathbf{c_2}) + w_2 \cdot PMI(c_1, c_2) \quad (3)$$

We observed that extracted concepts can appear with different representations in the Stack Overflow question tags. Examples include synonymous pairs such as node.js and nodejs, javascript and js, mvc and model view controller, etc. To identify such instances, we use the Stack Overflow synonym tag api [22] and identify the matching or synonymous concepts in the Stack Overflow tags. We also filter out irrelevant concepts having no occurrence or synonyms in the Stack Overflow tags. After this process, we end up with 5200 concepts. During the computation of probabilities for PMI scores, we also consider the occurrence count of the synonyms. For example, when computing PMI between javascript and any other concept, we compute the independent and co-occurrence probabilities by counting occurrences of both javascript and js tags in the Stack Overflow questions.

3.3 Identifying Concept Relation

In this section, we explain the process of identifying the prerequisite relationship between different concepts. We only consider the concept pairs with high semantic similarity scores. It is very likely that concept pairs that have very low semantic similarity scores are not related at all and we can ignore such pairs. For example, it is not useful to learn the relationship between Neural Network and PHP which are not related and occur in different domains (deep learning and web development respectively). However, it would be interesting to study the concept pairs Gradient Descent and Backpropagation which are algorithms used in machine learning and share high semantic similarity scores. Inferring the relation that Gradient Descent is a prerequisite of Backpropagation and not vice-versa would be useful. To infer such relations, we make use of Wikipedia articles. For each pair of concepts with high semantic similarity (threshold of 0.5), we compute the concept relevancy scores. For concepts c_1 and c_2, we measure how often the concept c_1 is referred in the Wikipedia article of concept c_2 and vice-versa. Based on the concept relevancy scores, we can infer the prerequisite relation. For example, we know that Java is a prerequisite of Spring Boot. So, it is quite possible that in an explanation for Spring Boot (a Java Web framework), the concept Java would be mentioned more often when compared to the concept Spring Boot being mentioned in an explanation about Java. Algorithm 1 captures the steps to identify the prerequisite relation between concepts.

Algorithm 1 Prerequisite relation inference between concepts

Input: Pair of concepts c_i and c_j which are strongly related, and Wikipedia Knowledge articles.

Output: Relationship between concept pairs (prerequisite relationship) i.e. c_1 is prerequisite of c_2 or vice-versa

1: Tokenize the knowledge articles for all the concepts (C_n), where C_n is set of concepts
2: **for** ordered pair concepts (c_i, c_j) **do**
3: Compute Concept Relevancy scores (CRS) for ordered pairs (c_i, c_j) as

$$CRS(c_i, c_j) = \frac{TF(c_i \in D_j)}{V(D_i, D_j)}$$

$$CRS(c_j, c_i) = \frac{TF(c_j \in D_i)}{V(D_i, D_j)}$$

where c_i and c_j are the concepts for which CRS is computed, D_i and D_j are the wikipedia articles for concepts c_i and c_j respectively, $TF(c_i \in D_j)$ captures the term frequency for concept c_i in wikipedia article D_j, $TF(c_j \in D_i$ captures the term frequency for concept c_j in wikipedia article D_i, and $V(D_i, D_j)$ is the normalization term that captures the total vocabulary in articles D_i and D_j.
4: If $CRS(c_i, c_j) > CRS(c_j, c_i)$, then c_i is prerequisite of c_j and vice-versa
5: **end for**

3.4 Learning Maps

The identified prerequisite relation pairs were used to build the concept graph. The concept graph has 1325 concepts and 1868 edges. We use networkx [8] python library to build the concept graph. We pass the adjacency list created from the identified concept-prerequisite pairs as an input to the library. The edges in the graph have directions from the concept node to the prerequisite node. The learning maps are built for each concept in the graph using the Depth-first search (DFS) algorithm. They are represented as DFS trees generated by the algorithm. To visualize the learning maps

Table 2: Semantic similarity scores from Word2Vec Embeddings and PMI

c_1	c_2	PMI Scores	W2V Scores

4. EVALUATION AND RESULTS

4.1 Datasets

We collected metadata about various courses from MOOC platforms and our internal Learning Management System (LMS) using REST APIs. We fetched data from categories relevant to Software Development and Design. The distribution of the number of courses fetched from different platforms is shown in Table 1. There are 13,600 courses from Udemy, 1,050 courses from edX, and 49,500 courses from our LMS in the Software Development and Design category. The output from the REST APIs was in JSON format and each had a different schema. Hence, we selected MongoDB, a NoSQL database to store the retrieved data.

We apply text pre-processing on course metadata. Specifically, the course descriptions from Udemy contain HTML tags. We parse the HTML tags in course descriptions using Beautiful Soup [19]. We remove stopwords and apply Lemmatization and Stemming to reduce words to their base forms. We also create custom stopwords manually by analyzing the topic modeling output. We stored pre-processed data in MongoDB for further processing and evaluation.

4.2 Evaluating extracted concepts

We apply Latent Dirichlet Allocation (LDA), a topic modeling algorithm to infer topics from the course descriptions. We extract five topics from each course description. Each topic is a vector representation that not only indicates the words belonging to the topic but also the probability of the words belonging to the topic. From the topical distribution for the course description, the words from the topic with maximum probability were considered and stored against each course metadata as tags in the database. Figure 2 shows the description and the tags obtained for a Javascript course in Udemy.

To evaluate the concepts extracted from the course description, we apply the Overlap Coefficient to measure the similarity between the concepts extracted from the course description and concepts tagged by Udemy. The overlap coefficient, or Szymkiewicz–Simpson coefficient, is a similarity measure that measures the overlap between two finite sets [1]. It is related to the Jaccard index and is defined as the size of the intersection divided by the smaller of the size of the two sets. Mathematically, we define the Concept overlap coefficient as

$$concept\_overlap(X, Y) = \frac{|X \cap Y|}{min(|X|, |Y|)} \quad (4)$$

where concept_overlap(X, Y) captures the average concept overlap between two sets X and Y, X is the concepts extracted from topic modeling, Y is the concepts tagged in course descriptions of Udemy dataset, and N is the number of course descriptions in the dataset. We observed the average concept overlap coefficient to be 0.97. This shows that the concepts extracted from the topic modeling algorithm quite well capture the relevant concepts covered in the course. Udemy's course description contains a maximum of two concepts tagged. We further analyzed how well our approach is able to identify the other concepts from course descriptions, not captured in Udemy's concepts tag. We performed a quantitative analysis with 20 Subject Matter

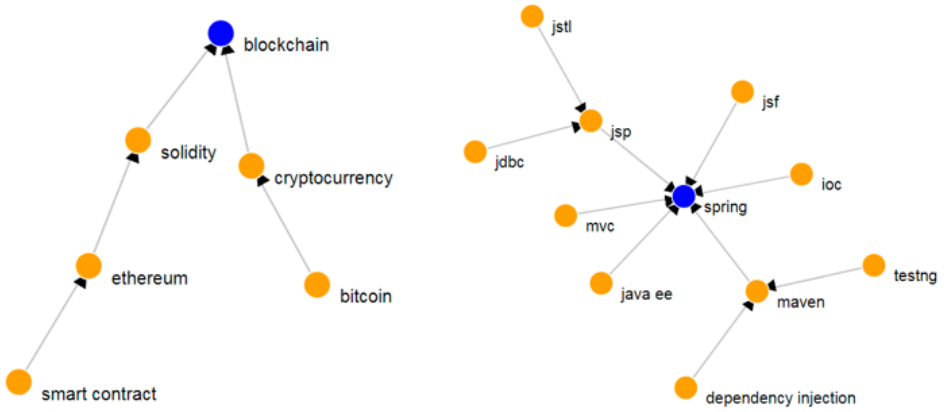

Figure 4: Learning maps for Blockchain and Java Spring framework

Experts (SMEs). The SMEs are having experience ranging from 5-10 years and have worked on different technologies in IT companies. We randomly sampled 100 courses offered on Udemy and provided five courses to each SME along with inferred concepts for each course. The SMEs were asked to provide their response on whether these inferred concepts are relevant for the course or not. We computed the accuracy considering SME's responses as true labels. We observed the accuracy of inferred concepts to be 0.73.

4.3 Evaluating concept Prerequisite Relations

There are no ground truth labels available for inferred prerequisite relationships. To assess the effectiveness of prerequisite pairs generated by our approach, we conducted a quantitative analysis with 25 SMEs to identify if a concept c_1 is a prerequisite for another concept c_2. We created five groups with 5 SMEs in each group. We randomly sampled 250 concept prerequisite pairs. Each group is provided with 50 concept prerequisite pairs. We used the Majority voting approach to aggregate their responses. We computed the accuracy of these pairs considering the SME's response as ground truth labels. We observed the accuracy of concept prerequisite pairs to be 0.82. We also measure inter-rater agreement amongst experts using Fleiss' Kappa [14]. Fleiss' Kappa is a statistical measure for assessing the reliability of agreement between a fixed number of raters when assigning categorical ratings to a number of items or classifying items. If the raters are in complete agreement then $\kappa = 1$. If there is no agreement among the raters (other than what would be expected by chance) then $\kappa \leq 0$. We observed κ coefficient to be 0.74 which indicates a level of strong agreement among the raters. We believe some level of disagreement may be due to the fact that prerequisites can be subjective [12] i.e. it is difficult to get consensus for some pairs of concepts. Different individuals may have different experiences of acquiring knowledge on specific topics, and this may lead to different opinions of the prerequisite requirement for a topic. Some of the extracted prerequisite relationships are shown in Table 3.

5. CHALLENGES

Some of the challenges that we faced while building the concepts graph.

1. For some concepts extracted from the course description we had disambiguation issues when checked in Wikipedia. For example, Java can refer to a programming language or an island in Indonesia. To deal with this issue, we pass the extracted concepts to google search API [7] and fetch the Wikipedia article that is ranked higher in the search results. Due to the popularity of these software concepts, we observe that relevant results were returned by picking the higher ranked Wikipedia article from the search queries.
2. Our inference of prerequisite relationships is based on reference scores computed from Wikipedia articles of the concepts. These scores may not always provide accurate results. It is possible that articles for some of the concepts may have high reference scores for concepts that are derived from it and not vice-versa.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we proposed our approach to infer prerequisite relations between concepts and build the concept graph. The proposed method does not require manually annotated data which was the major drawback of supervised learning approaches. We use relevant data sources in different steps to incorporate relevant and rich semantic information to infer prerequisite relations accurately. To validate our results, we performed both quantitative and qualitative evaluations. The identified concept prerequisite pairs were evaluated by subject matter experts. We observed an accuracy of 0.82 for the inferred prerequisite relations. We built the concept graph from the prerequisite relation pairs and demonstrated few examples of the learning maps generated from the concept graph. Learning maps can be used in many applications ranging from content-based recommendation systems to more sophisticated online tutoring systems etc. As future work, we plan to extend our research by creating a personalized curriculum planner system that captures the concepts learners currently know and what they want to learn. By leveraging this information, the system will create a personalized learning plan for them using their input information and prerequisite relations. Although, our approaches are not limited to the software domain, we plan to carry out further studies and experimentation to measure the system's generalization to other domains.

Online Estimation of Student Ability and Item Difficulty with Glicko-2 Rating System on Stratified Data

Jaesuk Park
Knowre Korea Inc.
epark@knowre.com

ABSTRACT

We propose an adaptation of the Glicko-2 rating system in a K-12 math learning software setting, where variable time intervals between solution attempts and the stratification of student-item pairings by grade levels necessitate modification of the original model. The discrete-time stochastic process underlying the original system has been modified into a continuous-time process to account for the irregularity of intervals between solution attempts. Also, conceptual prerequisite relationships between items were used to provide initial rating estimates that allow for rating values to be meaningfully compared across grade levels. Fitting the model using real student learning data results in rating value distributions successfully exhibiting a gradation with the increase of grade level. A potential area of application in a personalized education setting is also briefly discussed.

Keywords

Item response theory, dynamic paired comparison model, stratified data, educational assessment, stochastic variance model

1. INTRODUCTION

We consider the problem of assigning appropriate curriculum levels in a large-scale K-12 math learning software to students who are substantially ahead or behind their peers. Previous studies have suggested the importance of matching learning content difficulty to a student's ability for positive student learning outcomes [3, 10, 16]. In light of this, students who are much farther ahead (e.g., gifted students) or behind their peers (e.g., students with learning disabilities) can benefit much from receiving a more tailored educational feedback, based on learner and skill models that can model their differences more effectively.

With the recent advances in computing devices, various approaches have been sought to harness the power of computing to model learners more accurately in educational contexts, as comprehensively overviewed in [2]. In one particular line of approach [11, 13, 12, 15], dynamic paired comparison models were used to quickly estimate student abilities and item difficulties in a scalable manner. In these adaptations, the players consist of students ("users") and units of learning task (e.g., problem items, assignments), and each solution attempt is conceptualized as a match between a student and a learning task, in which the winner earns 1 point and the loser earns 0 points (with no draw). The primary advantage of such models over traditional IRT methodologies is in their ability to compute ability estimates "on the fly" [11] while retaining a similar mathematical structure to IRT.

The problem occurs, however, when the dataset is *stratified*—i.e. when student-problem pairings can be grouped into distinct (or largely nonoverlapping) groups such that a problem's rating cannot be adequately adjusted by a student outside the group to which it belongs. In a K-12 math learning software, because students are only exposed to problems appropriate for their grade level, grade levels serve as strata. Consequently, we cannot adequately tell how a student would perform outside of their regular grade level just by looking at the student's rating value. See Fig. 1 for an illustration.

Ideally, we would not have this problem by gathering enough learning data from a large number of students for 12+ years, during which they would work through all curricula offered by the product in sequence. However, in a commercial educational software context where a user is not bound to use products from just one vendor, this is highly impractical.

Hence we raise a question: is there a way to enforce rating values to reflect the relative positions of the strata, despite the absence of sufficient overlaps in students/items among them? One possible strategy is to initialize the ratings differently for each stratum according to their relative positions, e.g., to initialize first-grade rating values to 100, second-grade rating values to 200, etc., and then let the dynamic paired comparison algorithm do the calibration within each grade level. But then how could we justify that the initial estimation done for all curricula is properly reflective of their actual difficulties relative to one another?

Here, the key insight is that the partial ordering of mathematical concepts due to prerequisite relationships provides a basis for the division of concepts into grade-level curric-

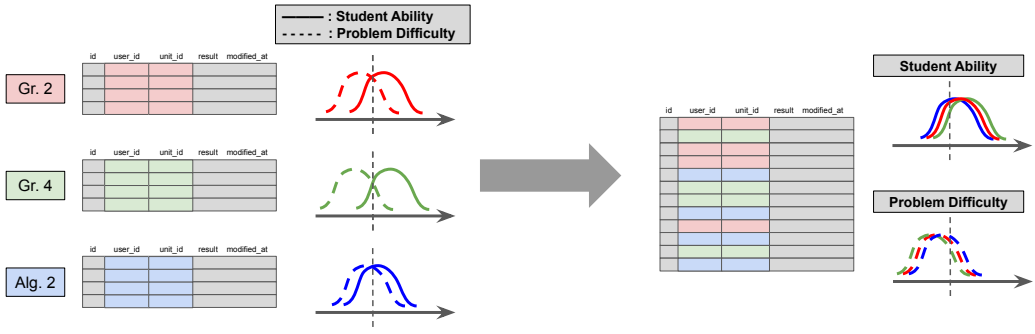

Figure 1: An illustration of the impact of data stratification on the rating interpretability. As a result of stratification, the distributions of rating values can overlap unreasonably much with each other, and the corresponding mean rating values may not align with the actual order of grade levels.

ula, which then in turn stratifies the learning data. In the K-12 math learning software used in our study, each problem item is conceptualized as a particular instantiation of a mathematical concept ("knowledge unit," or just "unit") with specific values. These mathematical concepts have prerequisite relationships defined among them, the collection of which can be represented as a directed graph. We attempt to employ these relationships to obtain statistically interpretable and contextually appropriate estimations.

Specifically, our contribution is twofold: 1) modification of a dynamic paired comparison rating system model to account for imbalance in rating update frequencies between students and items, and 2) use of prerequisite relationships between concepts for rating initialization to achieve rating comparability between curriculum levels. We aim to yield, from a stratified dataset, a set of ratings that can be meaningfully compared across grade levels: where students and items in a lower grade level would generally have lower ratings than those in a higher grade level.

The remainder of this paper is organized as follows. Section 2 presents our particular adaption of a dynamic paired comparison model, including the details for incorporating the conceptual prerequisite information into rating initialization. Section 3 describes the dataset used for evaluating our model and presents our results. Section 4 discusses the potential for applying our model to assign grade levels for students far ahead or behind their peers, lists some of the limitations of our work, and suggests a few possible directions for further research.

2. MODEL

The Glicko-2 rating system [7] falls under the family of dynamic paired comparison models, along with the Glicko rating system [6] (its predecessor) and the Elo rating system [4] (of which the two Glicko systems are extensions). Improving upon its predecessor, the Glicko-2 rating system models the change in variance of player strength as another stochastic process, thereby accounting for the possibility of sudden changes in strength. More specifically, the algorithm models the change in player strength per unit time with a normal distribution with variance equal to the square of the rating *volatility*, whose logarithmic change per unit time is itself normally distributed.

2.1 Continuous-time Glicko-2 Model

The original Glicko-2 system presented in [7] assumes the underlying stochastic processes to be discrete-time, where the overall measurement period is discretized into time increments called "rating periods." Within each rating period, the matches are assumed to occur simultaneously. However, because there is too much imbalance in the average number of matches between users and items, [7]'s recommendation of having 5-10 matches per rating period for every player is not feasible to implement in our application context. [15] has successfully worked around this limitation by constraining each rating period to contain only one match, but the workaround did not account for an increase in rating uncertainty due to the passage of time, which is a key feature of the Glicko rating system family. Here, we take the approach of modifying the Glicko-2 model under a continuous-time stochastic process framework, so that the model can account for rating uncertainty increase due to the passage of time without discretizing the measurement period.

Let $\theta_s(t)$ denote the ability estimate of user s at time t, and let $\beta_i(t)$ denote the difficulty estimate of unit i at time t. Then as a result of using continuous-time stochastic process framework, the model equations for latent trait parameters become

$$\theta_s(t) \sim \mathcal{N}(\mu_s(t),\ \phi_s^2(t)). \tag{1}$$

$$\theta_s(t+\Delta t) \mid \theta_s(t),\ \sigma_s^2(t+\Delta t) \sim \mathcal{N}(\theta_s(t),\ \Delta t\, \sigma_s^2(t+\Delta t)) \tag{2}$$

$$\log \sigma_s^2(t+\Delta t) \mid \log \sigma_s^2(t),\ \tau^2 \sim \mathcal{N}(\log \sigma_s^2(t),\ \tau^2) \tag{3}$$

for user ability estimates, and

$$\beta_i(t) \sim \mathcal{N}(\mu_i(t),\ \phi_i^2(t)) \tag{4}$$

for unit difficulty estimates. Here, as in [8], μ denotes rating, ϕ denotes rating deviation (RD), and σ denotes rating volatility. Note that the difficulty of a mathematical concept is expected to remain constant over time, so we do not impose any stochastic volatility assumption on $\beta_i(t)$.

As for the correctness probability (i.e., the probability of user s correctly answering an instantiation of unit i at time

t), the Glicko rating system family differs from the Elo rating system in its incorporation of rating uncertainty to calculate this quantity. We are generally interested in the correctness probability *before* the user s actually attempts unit i. However, the time elapsed between the user's last attempt and the current attempt can vary throughout the user's activity history, which also varies the amount of inflation to apply each time on the user's rating uncertainty, ϕ_s. Hence we apply equation (2) prior to calculating the correctness probability. Let t_s and t_i denote the last time user and unit latent trait estimates, respectively, were updated. Let $Y_{s,i}(t)$ be a Bernoulli random variable denoting user response correctness. Then the correctness probability is given by:

$$\Pr(Y_{s,i}(t) = 1) = E(\hat{\mu_s}(t),\ \hat{\mu_i}(t),\ \hat{\phi_s^2}(t) + \hat{\phi_i^2}(t)) \quad (5)$$

where $E(\mu_1,\ \mu_2,\ \phi^2) = \left[1 + e^{-g(\phi^2)(\mu_1 - \mu_2)}\right]^{-1}$ is the expected score function that accounts for rating uncertainty [7], and

- $g(\phi^2) = \left[1 + \frac{3\phi^2}{\pi^2}\right]^{-1/2}$,
- $\hat{\phi_s^2}(t) = \phi_s^2(t_s) + (t - t_s)\sigma_s^2(t_s)$,
- $\hat{\phi_i^2}(t) = \phi_i^2(t_i)$,
- $\hat{\mu_s}(t) = \mu_s(t_s)$, and
- $\hat{\mu_i}(t) = \mu_i(t_i)$.

Here, we use $\sigma_s^2(t_s)$ in place of $\sigma_s^2(t)$ to estimate $\hat{\phi_s^2}(t)$, although their equivalence only holds in expectation.

After user s finishes solution attempt for unit i with result $y_{s,i} \in \{0, 1\}$, the update equations for latent trait estimates are given as below, following [7]'s derivation of corresponding equations under the continuous-time framework:

$$\sigma_s^2(t) = \exp\left(\arg\max_{a(t)} p(a(t)|y_{s,i})\right) \quad (6)$$

$$\phi_s^2(t) = \min\left\{\phi_s^2(0), \left[\frac{1}{\phi_s^2(t_s) + \sigma_s^2(t)} + \frac{1}{v_s^2(t)}\right]^{-1}\right\} \quad (7)$$

$$\phi_i^2(t) = \min\left\{\phi_i^2(0), \left[\frac{1}{\phi_i^2(t_i)} + \frac{1}{v_i^2(t)}\right]^{-1}\right\} \quad (8)$$

$$\mu_s(t) = \mu_s(t_s) + \phi_s^2(t) \cdot g(\hat{\phi_i^2}(t)) \cdot (y_{s,i}(t) - E_s(t)) \quad (9)$$

$$\mu_i(t) = \mu_i(t_i) + \phi_i^2(t) \cdot g(\hat{\phi_s^2}(t)) \cdot ((1 - y_{s,i}(t)) - E_i(t)) \quad (10)$$

In these equations, we have

- $E_s(t) = E(\hat{\mu_s}(t), \hat{\mu_i}(t), \hat{\phi_i^2}(t))$,
- $E_i(t) = E(\hat{\mu_i}(t), \hat{\mu_s}(t), \hat{\phi_s^2}(t))$,
- $v_s^2(t) = \left[g(\hat{\phi_i^2}(t))^2 E_s(t)(1 - E_s(t))\right]^{-1}$, and
- $v_i^2(t) = \left[g(\hat{\phi_s^2}(t))^2 E_i(t)(1 - E_i(t))\right]^{-1}$.

Also, in equation (6), $p(a(t)|y_{s,i})$ is the marginal posterior density function for $a(t) = \log \sigma_s^2(t)$, approximated using the product of the following two normal density functions (here, $\varphi(z; m, \varsigma^2)$ denotes the normal density function with mean m and variance ς^2):

1. $\varphi(a(t); a(t_s), \tau^2)$, which comes from equation (3), and
2. $\varphi(\theta_s^*(t); \mu_s(t_s), \phi_s^2(t_s) + (t - t_s)e^{a(t)} + v_s^2(t))$, which is the normal approximation of the marginal likelihood distribution of $\theta_s(t)$, whose mode is denoted with $\theta_s^*(t)$.

The latter normal density function features the quantity $(\theta_s^*(t) - \mu_s(t_s))$, which is approximated in [6] using first-order Taylor expansion.

Finally, note that to prevent a rating deviation from becoming arbitrarily large, the quantity is constrained in equations (7) and (8) to never exceed the value for a brand new user/unit, just like how it was done in [5].

2.2 Initial Parameter Estimation

To address the stratification issue mentioned in the introduction, the user and unit ratings are differentially initialized based on their respective curricula. Instead of setting each curriculum's initial rating value arbitrarily, we want the values to reflect more closely our prior knowledge of the distributions of concepts within each curriculum.

We find this prior knowledge in our proprietary conceptual precedence graph, where units are represented as nodes (vertices) in a directed graph. Each edge (u, v) in the graph is interpreted as: "An instance of unit u is being used as a step in solving an instance of unit v." Hence unit u corresponds to a prerequisite concept that a user must have mastered before being able to successfully master unit v.

The key idea in our usage of the graph is that a question item (corresponding to a specific knowledge unit) that involves one or more steps to solve must in general be harder than any of the steps themselves. Hence we assign each unit with a non-negative integer value, which we call "depth," in such a way that for every edge, the tail node is assigned with a lower depth value than the head node. This way, a concept appearing in a higher grade level would in general correspond to a higher depth value (since they would generally incorporate lower-level curriculum concepts as prerequisites), making the depth values roughly signify how "in-depth" the corresponding concepts are. See Fig. 2 for an illustration.

We also seek to differentiate among units with no parents (i.e., concepts with no prerequisites) by imposing that the depth difference between a unit and its successor be as small in magnitude as possible, while still ensuring that every unit has a strictly greater depth value than any of its parents.

From a graph theory perspective, the problem of assigning depth values can be formulated as a variant of layer assignment problem on a directed acyclic graph $G = (V(G), E(G))$ with minimal dummy vertices, formally stated as the follow-

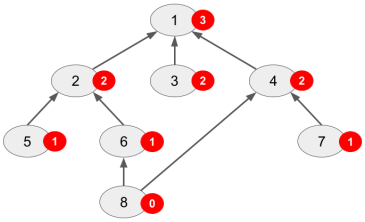

Figure 2: Illustration of assigning depth values to knowledge units in a simple conceptual precedence graph. Knowledge units are represented as nodes (gray ovals). On the right of each oval, a red circle shows the corresponding depth values assigned.

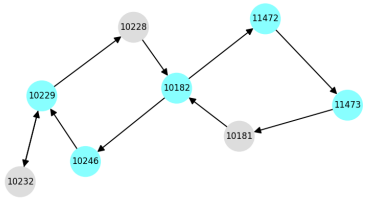

Figure 3: Three instances of simple cycles in the conceptual precedence graph used in our study, which all belong to one strongly connected component. We found that cycles exist mostly due to the presence of "gateway units" (shown in cyan ovals), whose main role is to select which concept to apply from multiple related concepts.

ing integer linear program (ILP):

$$\begin{aligned} \min \quad & \sum_{(u,v)\in E(G)} d(v) - d(u) & \\ \text{s.t.} \quad & d(v) - d(u) \geq 1 & \forall (u,v) \in E(G) \\ & d(v) \in \mathbb{Z}_{\geq 0} & \forall v \in V(G) \end{aligned} \tag{11}$$

(here, $d(v)$ denotes the depth value assigned to node v). For a general overview of the layer assignment problem and its variations, readers are referred to Section 13.3 of [9].

Two challenges arise in initializing rating values through solving the depth assignment problem. The first challenge is that our conceptual precedence graph could contain cycles, such as ones shown in Fig. 3. To address this challenge, we assign the same depth value to all units in the same strongly connected component (SCC), noting that any directed cycle is strongly connected. Implementationally, this corresponds to solving the ILP given in (11) on the conceptual precedence graph's *condensation*, which is a directed acyclic graph formed by contracting each SCC into one node.

The second challenge in assigning depths to nodes on the conceptual precedence graph is that the graph (and thus also its condensation) may consist of multiple weakly connected components (WCCs), which are subgraphs whose underlying undirected graphs are connected. The above ILP assigns depth values relative only to other SCCs in the same WCC, so additional steps must be taken to equate the depth value distributions for each curriculum across all WCCs. In particular, we label each SCC with the lowest-level curriculum that features at least one of its constituent units. Next, we take the smallest number of WCCs that together contain all curriculum labels. We call this collection of WCCs *reference WCCs*. Afterward, we offset the depth value for each SCC in every non-reference WCC to be at least the minimum depth value of all SCCs in the reference WCCs that are labeled with the same curriculum.

Once the adjusted depth values for all SCCs (and thereby all units) are thus computed, each curriculum's depth value is set to be the average depth value of all units in the curriculum.

Below is the summary of procedure for assigning depth $d(k)$ for each curriculum $k \in X = \{1, \ldots, K\}$:

1. Let $G = (V(G), E(G))$ be our conceptual precedence graph, which is a directed graph such that each node $v \in V(G)$ is associated with a curriculum $\chi(v) \in X$.
2. Condense G to yield a directed acyclic graph $C = (V(C), E(C))$.
3. Let $W_1, \ldots, W_n$ be WCCs of C, from largest to smallest.
4. For each $W_i = (V(W_i), E(W_i))$, solve the ILP given in (11) to yield pre-adjustment depth values $d_{init}(S)$ for each SCC S.
5. Label each SCC S with a curriculum
$$\chi_{min}(S) = \min_{v \in V(S)} \chi(v).$$
6. Let $A = \{W_1, \ldots, W_r\}$ be the reference WCCs (defined above), such that r is minimized; i.e., choose no more WCCs than necessary.
7. For each curriculum $k \in X$, let
$$d_{min}(k) = \min\{d(S) \mid \chi_{min}(S) = k, S \in \bigcup_{i=1}^{r} V(W_i)\}.$$
8. For each $W_j = W_{r+1}, \ldots, W_n$, adjust depth value $d(S)$ for each SCC $S \in W_j$ to be at least $d_{min}(\chi_{min}(S))$. However, do so in a way that the adjusted depth values still satisfy the constraints of the ILP given in (11).
9. We now have the adjusted depth values for every SCC $S \in V(C)$. For each SCC S, let $d(v) = d(S)$ for all $v \in S$.
10. For each $k \in X$, let
$$d(k) = \text{mean}\{d(v) \mid v \in V(G),\ \chi(v) = k\}.$$

We now give each user s or unit i associated with curriculum k as follows:

$$\mu_s(0) = \mu_{min} + \alpha \cdot d(k) \tag{12}$$

$$\mu_i(0) = \mu_{min} + \alpha \cdot d(k) \tag{13}$$

where quantities μ_{min} and α are hyperparameters to be optimized.

3. EVALUATION

We evaluate our model using a dataset consisting of student practice records from January 2016 to December 2019 through our adaptive software used in math learning centers located throughout the United States. Students are given problems to practice based on their current grade level and the content areas where they struggle. The data consists of 5,179,493 records of 10,194 users' combined attempts for problems associated with 7,513 knowledge units, ranging from Grade 2 concepts to Algebra 2 concepts. When a student gets a problem wrong in the first attempt, the student gets to make a second attempt for the same problem after being walked through the steps; in our analysis, however, only the first attempt's result was considered.

For the Glicko-2 model hyperparameters, we used the values suggested in [8]: 350.0 for the initial RD (in Glicko-1 scale; [8] shows how to convert between the two scales) and 0.06 for the initial user volatility. In the case of τ, for which a range of values is suggested, we used 0.5. The time elapsed from one attempt to the next, used in rating uncertainty inflation, is measured in days. Finally, through extensive simulations, we chose $\alpha \approx 0.2303$ and $\mu_{min} \approx -2.8782$, which, in Glicko-1 scale (on which the values were originally set), are exactly 40.0 and 1000.0, respectively.

Each unit's associated curriculum was based on the information provided in our content management system. For units appearing in multiple curricula, the earliest curriculum in the sequence was used. For users, due to the lack of availability of exact registration dates for all users at the time of the study, each user's curriculum was set as the curriculum associated with the first unit attempted by the user. The initial parameters for both users and units were then set following the procedure described previously.

3.1 Predictive Performance

To assess the predictive performance of our adaptation of the Glicko-2 rating system, we plotted the change in RMSE values for every 1,000 records over time (for the rationale behind the metric choice, see [14]). As the latent trait estimates are calibrated based on student practice records, we expect the RMSE across the entire system to decay over time. We see that this is exactly the case in Fig. 4, where the calibration curve for our model is also reported along with the reliability and resolution values.

We also report a convergent pattern in unit rating values and dynamically adjusting user rating values, analogous to the results obtained in [15], in Fig. 5.

3.2 Gradation of Unit Rating Distributions

We also plot the distributions of the final unit rating values for each curriculum. We expect that using a conceptual precedence graph to initialize rating values would cause the central tendencies of the rating distributions would show an upward trend as the curriculum level increases. As shown in Fig. 6, the final ratings computed without the graph-based rating initialization fail to show an upward trend in the mean rating values, whereas they do with the graph-based rating initialization. Also noteworthy is the complete disappearance of overlap in IQR between two curricula far

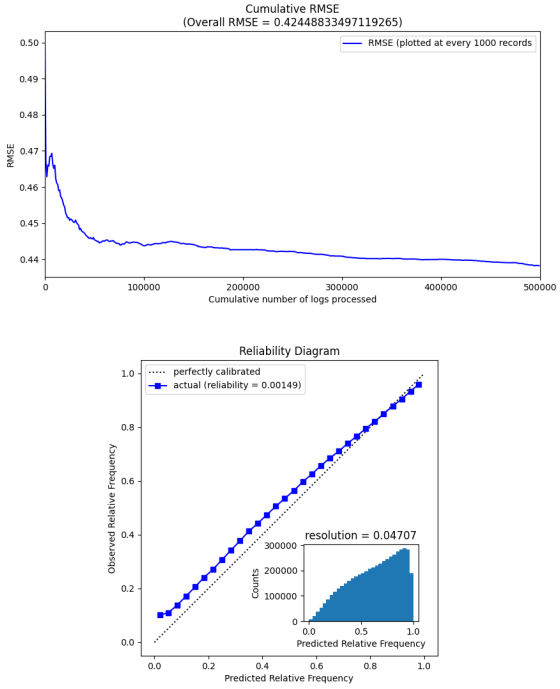

Figure 4: Top: Cumulative RMSE values calculated at every 1,000 records. For effective visualization, only results from the first 500,000 records were plotted. Bottom: Reliability diagram with sharpness graph inserted in the lower right.

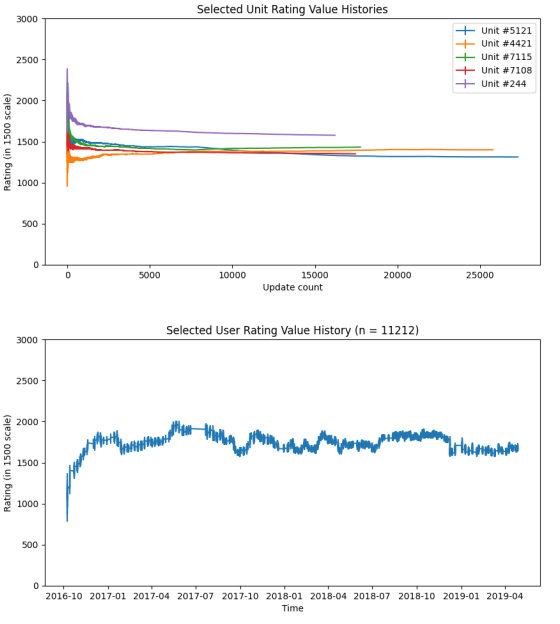

Figure 5: Rating values as a function of time for 5 most frequently attempted units (top) and for the user with the most number of attempts (bottom).

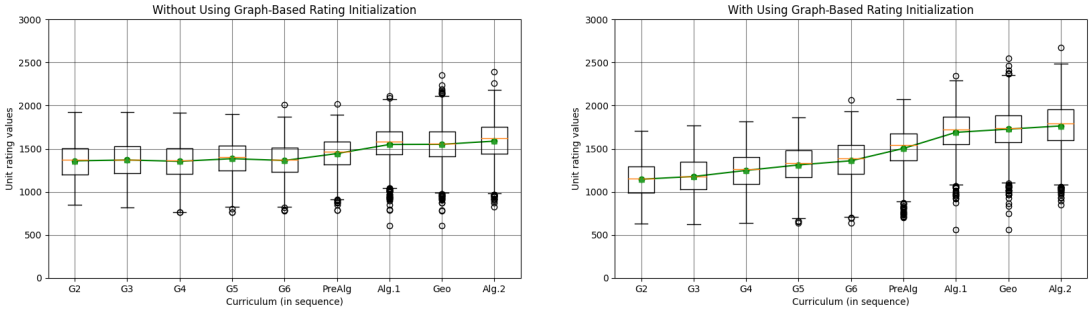

Figure 6: Final distributions of knowledge unit ratings. Orange bars indicate medians, green dots indicate means. Note that the rating values on the vertical axis are on the Glicko-1 scale.

apart from each other, such as Grade 2 and Algebra 2, upon using a conceptual precedence graph to initialize ratings.

4. DISCUSSION

We have used conceptual prerequisite relationships to give our model a better prior distribution— one that better reflects the stratified nature of student practice data. The depth values used to calculate the initial rating values, however, are still quite coarse estimates; for example, the difference in difficulty between a unit and one of its prerequisite units may not be even across the conceptual precedence graph. Nevertheless, we see that the distribution of the lowest-level curriculum (Grade 2 in our study) and that of the highest-level one (Algebra 2 in our study) show a substantially little overlap compared to when we used the initialization method of the original Glicko-2 system, which suggests that there was still a nontrivial improvement. Note that the separation of unit rating distributions between two adjacent curricula (for example, Grade 2 and Grade 3) are not well separated. This is expected, as we would not expect a huge jump in terms of curriculum difficulty from one school year to the next.

One interesting area of application of this framework is determining the appropriate grade level for students whose mathematical achievement levels are substantially ahead or behind their grade levels. With estimates of item difficulties that account for grade-level hierarchy, we can have a data-based justification that would allow gifted students to be placed at a higher-level curriculum that is neither too hard nor too easy for them. Likewise, we could allow for students lagging behind their peers to be placed at a lower-level curriculum, where they could ensure that their foundational understanding of lower-level mathematical concepts is firm before moving onto the next grade level. For this application, a separate round of validation with external measurements, e.g., standardized test scores, must first take place.

A well-known limitation of using the Glicko rating system family for educational applications is its inability to model multiple-choice item correctness probabilities. This is because the correctness probability of such an item has an infimum strictly greater than 0, making the corresponding probability distribution improper. Hence a natural future direction would be to address this limitation, e.g., by incorporating the particle-based method presented in [12].

Another potential threat to the validity of using the Glicko-2 model for student ability measurement is in its unidimensionality assumption. Part of the challenge of verifying whether the student response data can be modeled with a one-dimensional construct in a learning setting is that unlike in IRT settings, a student's ability is expected to change throughout the data collection period. An interesting future direction would be to investigate whether there is sufficient evidence to suggest that students' mathematical ability is multidimensional, and if so, how a model like the Glicko-2 rating system can be extended to reflect the multidimensionality; the degree to which the extension presented in [1] can be applied also remains to be seen.

Also, when assigning each curriculum with a depth value, the average depth values for all constituent units were calculated. In practice, however, as learning software product continues to expand, units can be added or removed, or their edge connections may change. Our current choice of taking an average makes the algorithm sensitive to changes in the conceptual precedence graph's internal connectivity structure. Median may be a more robust, and thus more practical, choice, though this may come at the risk of decreased differentiability across consecutive curricula.

5. CONCLUSION

We have presented an adaptation of the Glicko-2 rating system in a K-12 math learning software context. The stratified nature of student-item pairings has made effective discrimination of students and problems across grade levels challenging. We have shown evidence that by using the prerequisite relationships between concepts to initialize rating values, we can allow for the gradation of rating distributions from lower-level curriculum to the higher-level curriculum while ensuring that the prediction error for student response correctness still decreases over time. A potential area of application is for determining the grade level appropriate for students substantially ahead or behind their peers.

6. ACKNOWLEDGEMENT

I thank my boss Kurt Cho, who gave nudges in productive directions whenever I was stuck, and my colleagues Sunghwan Cho and Seunghun Lee, who worked on developing data pipeline infrastructure on which the proposed model can be deployed. Also, I thank everyone in my company, who patiently waited in support while the project was in the works.
