35 ABSTRACT

36	The worm-like snakes (Scolecophidia, ~400 nominal extant species) have a conservative
37	morphology and are among the most poorly-known terrestrial vertebrates. Although
38	molecular evidence has helped elucidate their higher-level relationships, such data have rarely
39	been used to discriminate among species. We generated a molecular data set for the
40	continental Australian blindsnakes (genus Ramphotyphlops) to determine the concordance of
41	molecular and morphological information in the taxonomic recognition of species. Our dataset
42	included 741 specimens morphologically attributed to 27 nominal Ramphotyphlops species.
43	We proposed species hypotheses (SHs) after analysis of sequences from a variable
44	mitochondrial gene (cytochrome b) and examined these SHs with additional evidence from a
45	nuclear gene (prolactin receptor) and geographic data. Although the nuclear marker was not
46	as fast-evolving and discriminating as the mitochondrial marker, there was congruence among
47	the mitochondrial, nuclear, and geographic data, suggesting that the actual number of species
48	is at least two times the current number of recognized, nominal species. Several biogeographic
49	barriers and complex phytogeographic and geologic patterns appeared to be involved in the
50	division of some burrowing snake populations, and by consequence in their diversification
51	and speciation through isolation.

69 INTRODUCTION

Species inventory and delineation are essential for assessing biodiversity, conservation or biological control projects and more generally understanding the natural world (Wheeler et al., 2004). However, it is well known that the number of described species on earth is far less than the total (Trontelj & Fišer 2009). Most of the species yet to be described are thought to be fungi and 'invertebrate' animals, and particularly those living in tropical environments (Pfenninger & Schwenk 2007) Over the last 12 years, the total number of nominal extant species of squamates increased by 1.7 % each year (Pincheira-Donoso et al., 2013) and this value is much lower for mammals and birds (0.1-0.2%) (Uetz, Goll & Hallerman 2013; Lepage 2012; Wilson & Reeder 2005). Cryptic species, two or more distinct species that were classified as a single species due to their morphological similarity, are almost evenly distributed among major metazoan taxa and biogeographical regions (Pfenninger & Schwenk 2007). Therefore, the diversity of many vertebrate groups has yet to be explored (Oliver et al., 2009).

Here we focus on Australian blindsnakes of the genus *Ramphotyphlops* (Scolecophidia, Typhlopidae), whose systematics was little studied until recently (Aplin & Donnellan 1993; Rabosky et al., 2004; Vidal et al., 2010). Blindsnakes typically are small (~10–30 cm), burrowing species, and feed on social insects (Vidal & Hedges 2009). They comprise 402 named species segregated in five families: Anomalepididae, Leptotyphlopidae, Typhlopidae, Xenotyphlopidae, and Gerrhopilidae (Vidal et al., 2010; Uetz et al., 2013). The 42 currently recognized Australian scolecophidian species all belong to *Ramphotyphlops*, a genus of 66 species distributed across South and Southeast Asia, Australasia and Melanesia (as far east as Fiji, and across the Caroline Islands from Palau to Pohnpei), and comprise one of the least-known elements of the Australian herpetofauna (Rabosky et al., 2004; Wynn et al., 2012). Previous molecular genetic studies on scolecophidian snakes, including members of the familiesTyphlopidae and Leptotyphlopidae, have suggested a high level of hidden diversity, as indicated by several recognized species being paraphyletic and polyphyletic, and harbouring deep divergences (Hedges & Thomas 1991; Aplin & Donnellan 1993; Rabosky et al., 2004; Hedges 2008; Adalsteinsson et al., 2009; Marin et al., 2012; Kornilios et al., 2013). Strong selection associated with a fossorial lifestyle has led to miniaturisation, cranial consolidation, and body elongation, all common features in burrowing reptile (Gauthier et al., 2012). Moreover, there are limited characters for which inter-versus intraspecific variations are adequately understood, partly due to the lack of interest in scolecophidians (Adalsteinsson *et al.*, 2009).. Here, we focus on testing and refining species boundaries within the Australian
radiation of *Ramphotyphlops* in light of new molecular genetic data.

Although many theoretical species concepts have been discussed over the years, there is general agreement, supported by genetic data, that species are reproductively isolated from one another (Coyne & Orr 2004). It is then a practical matter how to identify and delimit species. If two species occur together in sympatry and are not exchanging genes, then identifying concordance of two or more characters (coded by unlinked genes) will usually suffice in demonstrating reproductive isolation and delimitation of species. However, whether or not to recognize allopatric populations as full species is a more subjective decision, often requiring additional case-specific information. Padial et al., (2010) discuss two different approaches to distinguish species: (1) "cumulation", where only one character set (e.g., mitochondrial DNA sequences) is used, and (2) "congruence", where multiple data sets (e.g., DNA sequences and morphology) are used. Rather than alternative approaches, they could also be viewed as a continuum concerning level of evidence (stringency), especially because a single study might diagnose some species using one character set and other species using multiple sets, depending on availability.

In our study, we have explored species limits in Australian *Ramphotyphlops* using data from only one character set (mitochondrial DNA) and multiple sets (mitochondrial DNA, nuclear DNA, and geography). We took the general approach of defining preliminary species hypotheses (SHs) using the low stringency approach (mitochondrial DNA data set) and then comparing the SHs with additional character sets (Padial et al., 2010; Goldstein & DeSalle 2011; Yeates et al., 2011; Puillandre et al., 2012b). By adding more specimens (634) to our previous molecular genetic dataset (Marin et al., 2012) we built a new dataset. The ABGD (Automatic Barcode Gap Discovery) method (Puillandre et al., 2012a) was used with mitochondrial gene (cytochrome b) sequences, and resulting SHs were then compared with variation from a nuclear gene (*prolactin receptor*), and geography. Genetic divergent population in sympatry or divided by recognized barriers was used as additional evidence. The goal was to test the following hypothesis: is the number of nominal species a reasonably accurate reflexion of true species diversity?. This represents an initial step that could assist a morphology-based taxonomic revision, providing a better delimitation of some Australian Ramphotyphlops species.

- 134 MATERIALS AND METHODS

136	Taxon sampling
137	Ingroup sampling included 741 individuals belonging to 27 nominal Australian
138	Ramphotyphlops species (as identified using morphology). Appendix 1 lists the taxa,
139	localities, and GenBank accession numbers of specimens used in the study. Three typhlopid
140	snakes were used as outgroups: Acutotyphlops subocularis (Vuovo Camp, West New Britain,
141	Papua New Guinea, cyt b: JQ910524, PRLR: JQ910414), Ramphotyphlops acuticaudus
142	(Palau, cyt b: JQ910543, PRLR: JQ910412), and R. braminus (Florida, United States, cyt b:
143	JQ910548, PRLR: JQ910434).
144	
145	Molecular genetic markers
146	A mitochondrial protein coding gene and one nuclear protein coding gene were used.
147	The mitochondrial marker, <i>cytochrome b</i> (<i>cyt b</i>), is highly variable (intraspecific variation)
148	and thus potentially useful to identify recent speciation events (Burbrink, Lawson &
149	Slowinski 2000; Adalsteinsson et al., 2009). Among the nuclear genes available for squamate
150	phylogenies (Townsend et al., 2008) we selected one of the most variable, the prolactin
151	receptor (PRLR). For this work, 83.9 % of the sequences were newly determined; 943
152	sequences were deposited in GenBank under accession numbers KC489799–KC490909 and
153	KC493653.
154	
155	DNA extraction, amplification, and sequencing.
156	DNA extraction was performed with the DNeasy Tissue Kit from Qiagen.
157	Amplification and sequencing was performed using primers listed in Table 1.
158	For the two markers, DNA amplification was performed by PCR in a final 21 μ L
159	volume containing 1 µL DMSO, 0.8 µL of dNTP 6.6 mM, 0.12 µL of Taq DNA polymerase
160	(MP Biomedicals or Qiagen), using 2.5 μ L of the buffer provided by the manufacturer, 100
161	uml ⁻¹ and 0.32 μ L of each of the two primers at 10 pM; 1 μ L of DNA extract was added.
162	The PCR reactions were performed with the following conditions: an initial denaturation
163	at 94°C for 3 min followed by 40 cycles (3 min at 94°C, 40 s at 50°C, 1 min at 72°C) and a
164	final elongation at 72°C for 10 min, using a PCR System 2700 thermocycler (Applied
165	Biosystems). Amplification products were visualised on ethidium-bromide stained agarose
166	gels. Sequencing was performed by the National Centre for Sequencing (Genoscope, Evry,
167	France) using the same primers.
168	The two strands obtained for each sequence were combined using the Sequencher 4.9
169	software (GeneCodes, Ann Arbor, Michigan). Sequence alignment was performed with

ClustalW2 (default parameters) (Larkin *et al.*, 2007) implemented in BioEdit (Hall, 1999) and
then manually refined with MEGA 5 (Tamura *et al.*, 2011), using amino acid translations. The
absence of stop codons was checked.

Phylogenetic analysis

Cyt b analyses were performed on all the obtained sequences; *PRLR* analyses were performed on haplotypes only to reduce computation time. We built phylogenies using Bayesian and Maximum Likelihood (ML) methods of inference. Bayesian analyses were performed with MrBayes 3.1.2 (Ronquist & Huelsenbeck 2003) and ML analyses were performed with RAxML 7.2.8 (Stamatakis, 2006; Stamatakis, Hoover & Rougemont 2008). For both *cyt b* and LRPR, the three-partition strategy (by codon position) was preferred to the one partition strategy (by gene) using standard Bayes factors (Nylander et al., 2004). Bayesian analyses were performed by running 50,000,000 generations in four chains, saving the current tree every 1000 generations (until convergence), with GTR+I+G model, applied to each partition (best-fit model inferred by Modeltest (Posada & Carndall 1998)). Convergence of ESS values were checked with Tracer 1.4.1 (Rambaut & Drummond 2009) using the default burning (10%). The last 45,000 trees were used to construct a 50% majority rule consensus tree. For the ML analysis, we defined the same partitions and performed 1000 bootstrap replicates to obtain a bootstrap majority rule consensus tree. Trees were visualised with FigTree 1.3.1 (http://tree.bio.ed.ac.uk/software/figtree/).

191 Species delimitation

The ABGD method (Puillandre *et al.*, 2012a) was employed to statistically detect a barcode gap (i.e. a gap in the pairwise genetic distance distribution, presumably between intraspecific and interspecific distances) from the *cyt b* data set, which is then used to partition the data set (initial partition) into species hypotheses. The resulting inferences are then recursively applied to yield finer partitions (recursive partitions) until no further partitioning is possible. We used the online version

- 198 (http://wwwabi.snv.jussieu.fr/public/abgd/abgdweb.html) to analyse the pairwise distance
- 199 matrix calculated for each dataset with PAUP (Swofford, 2003) under a GTR+I+G model, as
- 200 inferred by Modeltest (Posada & Carndall 1998) using the AIC criterion as the best-fitting
- 201 model of nucleotide substitution for the entire data set. ABGD default parameters were used,
- 202 with the exception that the relative gap width (X) was set to 1 (except for *Ramphotyphlops*

Biological Journal of the Linnean Society

2		
3	203	nigrescens (Gray): 0.9), and Pmin (minimal prior intraspecific divergence) was set to 0.01 to
4 5	204	avoid the capture of intraspecific gaps due to weak sampling.
6 7	205	The number of putative species (species hypotheses, SHs) was first determined using
8	206	cyt b. Then, those cyt b SHs were compared with the nuclear gene data to assess concordance
9 10	207	or discordance. Major geographic features which can be barriers to gene flow (rivers,
11	208	mountains, climatic zones) for well-sampled groups were identified and used in further
12 13	209	comparisons of the SHs.
14 15	210	
16	211	LRPR haplotypes
17 18	212	The software DnaSP v5 (Librado & Rozas 2009) was used to determine the haplotypes.
19 20	213	For generating the haplotypes data files, invariables sites were included and sites with gaps or
21	214	missing data were not considered.
22 23	215	
24 25	216	RESULTS
26 26	217	For the <i>cyt b</i> gene, the alignment comprised 678 sites, with 386 variable sites among the
27 28	218	741 specimens successfully sequenced (4.6% of missing data). For the <i>PRLR</i> gene, the
29	219	alignment comprised 483 sites, of which 197 were variable among the 583 specimens (0.38%
30 31	220	of missing data), 158 specimens were unsuccessfully amplified. The alignments were
32 33	221	straightforward for both genes.
34	222	
36 36	223	Phylogenetic analyses
37 38	224	Based on the <i>cvt b</i> analysis, 17 of the 27 nominal species are monophyletic in the <i>cvt b</i>
39 40	225	tree with moderate support using both methods (ML bootstrap $> 75\%$ / PP > 95) except
40 41	226	Ramphotyphlops diversus (Waite) (ML bootstrap = $71 / PP = 1$) (see Appendix 1), and five
42 43	227	species <i>R</i> affinis (Boulenger) <i>R</i> howi (Storr) <i>R</i> longissimus (Aplin) <i>R</i> silvia (Ingram &
44	228	Covacevich) and <i>R</i> troglodytes (Storr) have one representative only <i>Ramphotypholops</i>
45 46	229	ligatus (Peters) is polyphyletic in the $cvt b$ phylogram (Fig. 1) and <i>R</i> kimberlevensis (Storr)
47 48	230	<i>R</i> leptosoma Robb <i>R</i> grypus (Waite) and <i>R</i> guentheri (Peters) are polyphyletic in both the
49	231	mtDNA and nDNA phylograms (Figs 1, 2)
50 51	231	
52	232	Species delineation
53 54	233	Molecular ganatic data
55 56	224	The ABGD method was applied independently to 21 monophylatic groups defined from
57	233 224	the art h phylogeny (Fig. 1) because groups including a limited number of lineages allowed
50 59	230	the cyt o phylogeny (11g. 1), because groups meruding a minited number of inteages allowed
60		

 us to avoid problems linked to the heterogeneity of evolution times between lineages. This phenomenon may lead to inter- and intraspecific pairwise distributions overlapping and by consequence may prevent the barcode gap detection. These groups corresponded to 17 nominal species that are represented by at least two specimens (16 nominal species and *Ramphotyphlops guentheri* lineage 1) plus three *cvt b* clades with non-monophyletic nominal species (clade 1: R. grypus lineage 1, R. leptosoma and R. longissimus; clade 2: R. kimberleyensis and R. troglodytes; clade 3: R. ganei (Aplin) and R. ligatus) and R. grypus lineage 2. Three nominal species and the *R. guentheri* lineage 2 were represented each by only one specimen and were not analysed with ABGD. Based on the distribution of pairwise genetic distances, ABGD proposed several partitions that varied according to the different a *priori* thresholds. Apart from the two extreme a priori threshold values (p = 0.009 and p =(0.013), for which aberrant number of species hypotheses were obtained for some groups (almost every haplotype was considered as a different species hypothesis for p = 0.009 and, conversely, all the haplotypes were combined in a single species hypothesis for p = 0.013, as described in Puillandre et al. 2011), all the tested *a priori* thresholds lead to the same splitting. The only exception is for five groups (R. ammodytes, R. bituberculatus, R. ganei, R. hamatus and *R. ligatus*), for which ABGD proposed two different partitions. We only used initial partitions because they were stable on a wide range of values contrary to the recursive partitions (results not shown); the initial partitions are also supposed to more closely match the groups described by taxonomists (Puillandre et al., 2012a). Considering all possible initial partitions allowed the delineation of 92 partitions or *cvt* b SHs (Table 2). SHs containing more than one specimens are monophyletic and highly supported with three exceptions: SH 55 (ML bootstrap = 70 / PP = 0.93), SH 90 (ML bootstrap = 43 / PP = 0.79) and SH 91 (ML bootstrap = 61 / PP = 0.53) (Appendix 2). SH 15 and SH 11 are polyphyletic (Figure 1). In a few cases, when ABGD splits one nominal species into several *cyt* b SHs, the divergence between these SHs is similar to the divergence between pairs of nominal species. For example, the genetic distance (p-distance) between Ramphotyphlops guentheri lineage 2 (SH 54) and *R. howi* (SH 62) is 0.10, whereas it is 0.12 among SHs 86–89 within the group of specimens identified morphologically as R. unguirostris (Peters). The 92 cyt b SHs displayed 121 different PRLR haplotypes. Among them, 55 SHs are defined by their own haplotypes, i.e. their haplotypes are not shared with any other *cvt b* SHs (Table 2, Fig. 2): Ramphotyphlops affinis (SH 1), R. ammodytes (SH 3, 7), R. australis (Gray) (SH 12–13), R. bicolor (Peters) (SH 14–15), R. bituberculatus (SH 16–18), R. diversus (SH

 24-26, 30-31), R. grypus (SH 40-48), R. guentheri (SH 49-54), R. hamatus (SH 61), R. howi (SH 62), R. kimberlevensis (SH 65–66), R. leptosoma (SH 67–68), R. ligatus (SH 71–72), R. longissimus (SH 73), R. nigrescens (SH 74–78), R. pilbarensis (Aplin & Donnellan) (SH 79), R. pinguis (Waite) (SH 80), R. polygrammicus (Schlegel) (SH 81-82), R. proximus (Waite) (SH 83), R. silvia (SH 84), R. troglodytes (SH 85), R. unguirostris (SH 86-89) and R. wiedii (Peters) (SH 92). Among them, SH 15 (R. bicolor) was the only non-monophyletic SH in the *cyt b* ABGD analysis; however, it is represented by unique *PRLR* haplotypes. Five species include only one sample. The 33 remaining cyt b SHs share PRLR haplotypes, the SHs within a nominal species that are sharing haplotypes are phylogenetically closely related.

281 Geographic data

Geographic distributions of mtDNA clades for several well sampled species are congruent with landscape features (Fig. 3). Three main climatic zones are recognized across the Australian continent (Fig. 4). The monsoon tropic zone in northern Australia receives heavy rainfall during the summer and dates from the Late Eocene/Early Oligocene (Greenwood 1996; Pole & Bowman 1996; Alexandre et al., 2004). The mesic zone, which includes the Wet Tropics rainforest in the far northeast, extends south along the Great Dividing Range of the eastern coast, with an isolated region in the southwest. It is the oldest Australian biome, originating from the forests of the Mesozoic that were widespread until the Early Miocene (Hill, 1994; Schodde, 2006). The arid zone in central and western Australia is much younger, with origins from the Early Pliocene (Fujioka et al., 2005; Byrne et al., 2008; Fujioka et al., 2009).

In the monsoon tropic zone of northern Australia four major phylogeographic barriers have been identified: the Daly River Drainage Barrier (Ford 1978), the Victoria River Drainage Barrier (Joseph & Omland 2009), the Ord Arid Intrusion (Ford & Blair 2005; Bowman et al., 2010) and the East-West Kimberley Divide (Potter et al., 2012). These barriers are congruent with the distributions of *Ramphotyphlops guentheri*, *R. kimberleyensis* and *R. unguirostris* (Fig. 3), with SHs restricted to each side of the barriers. The geographical repartition of mitochondrial lineages of *R. diversus* can be partly explained by these geographic barriers, and by the boundary between the arid and monsoon regions (Fig. 3). For *R. waitii* (Boulenger), the boundary between the south-west mesic zone and the arid zone is congruent with distributions of SHs 90 and 91 respectively (Fig. 3). Further south, two rivers (Darling River, River Murray) and the Flinders Ranges are congruent with the three major mtDNA lineages of *R. bituberculatus* (SHs 16, 19 and 20; Fig. 3) and to a lesser degree with

those of R. bicolor (not shown). SH 14 and SH 15 (R. bicolor) are distributed on each side of the Flinders Ranges except three specimens of the SH 15 located within the eastern SH 14 geographic zone. The separation by recognized barriers of allopatric SHs is additional evidence for SHs 19 and 20 (R. bituberculatus; separated by Darling River and River Murray), SHs 63–64 (*R. kimberlevensis*; separated by four major phylogeographic barriers: the Daly River Drainage Barrier, the Victoria River Drainage Barrier, the Ord Arid Intrusion and the East-West Kimberley Divide) and SHs 69–70 (R. ligatus; separated by the Victoria River Drainage Barrier and also a huge distance (~2600 kilometers)) (Fig. 3). Other species display different distribution patterns. Instead of observing geographically restricted mtDNA lineages, some species harbour deep genetic divergences (0.73 between SHs 7 and 8 (R. ammodytes) and 0.137 between SHs 40 and 45 (R. grypus)) among geographically close and/or sympatric clades. This pattern is clearly observable for Ramphotyphlops ammodytes and R. grypus, each with many SHs in the rocky Pilbara region, and to a lesser degree for *R. australis* and *R. leptosoma* that are restricted to the west central coast and for R. nigrescens on the east coast. Divergent genetic lineages (a SH with distinct nuclear haplotype) found in sympatry reinforce SHs, because despite geographical proximity there is no evidence of gene flow. But as many PRLR haplotypes are shared among the SHs of *R. ammodytes*, is it more parsimonious to consider these SHs (2,4-6 and 8-11) as a single species than a complex of several species with incomplete lineage sorting or hybridization. Conversely, the four *R. endoterus* (Waite) SHs occur across the arid zone in four allopatric mtDNA lineages but without recognized barriers between them. In this case, as with the seven *R. hamatus* SHs (distributed across the rocky Pilbara zone and the eastern part of the arid zone), geographic data do not suggest consolidation of SHs. In several cases, there is strong congruence among mitochondrial, nuclear, and geographic data, leading us to recognize 55 robust putative species using *cyt* b and *PRLR* haplotypes and 61 putative species when adding geographic (sympatry or allopatry with barriers) data only (Table 2). In the least conservative scheme (*cyt b* only), there are 92 putative species (Table 2).

DISCUSSION

The concordance of independent genes (nuclear and mitochondrial) is generally considered valuable evidence for species delimitation (Knowlton, 2000; Barberousse & Samadi 2010). In our data set, 55 of the 92 *cyt b* SHs are robustly defined by an independent nuclear gene. The other *cyt b* SHs shared nuclear haplotypes, but the fact that these SHs

Biological Journal of the Linnean Society

 remain closely related in the *cvt b* phylogram suggests a lack of variability of the *PRLR* gene at this scale, or a nuclear gene flow. To clarify this situation the use of other more variable nuclear markers is needed in the future. Analyzing more specimens per nominal species should be useful as well. Indeed the probability to find rare and shared haplotypes is higher for species that are densely sampled (several localities and several specimens per localities) even if some nominal species appear to be genetically uniform. For example, the 9 SHs of the nominal species *Ramphotyphlops grypus* are defined by specific haplotypes over the 59 species analyses with the nuclear marker. Concerning R. pilbarensis, even when the number of nuclear sequences was relatively high (29), only 2 different haplotypes were found. If we analyse the cyt b SHs on an individual basis, the number supported by different independent sources of information increases to 61 when geographical data are considered. Therefore, from the 27 nominal species of Australian blindsnakes studied here, our results support at least 55 (most conservative) and up to 92 (least conservative) species. Nine nominal species were not subdivided. The identification of new morphological characters should also help to discriminate among the different hypotheses proposed here. The visceral anatomy traits may be useful as they allowed the discrimination of some leptotyphlopid species (Adalsteinsson et al., 2009).

The early diversification of Australian *Ramphotyphlops* was probably driven by the development of the arid zone ~ 20 Ma (Marin *et al.*, 2012). As the arid zone expanded in central Australia, mesic-adapted lineages were confined to the east coast and southwest, to the northern monsoonal tropics, and also to Pilbara in the arid zone which likely served as refugia (Martin 2006; Byrne et al., 2008, 2011). Occupation of areas like the Pilbara and Kimberley (northern monsoonal tropics), that have humid refugia but are seasonally very arid may have allowed time for this lineage of snakes that has a wet-tropical origin to acquire adaptations to resist seasonally dry conditions which then pre-adapted them for the truly arid conditions further inland (Fujita et al., 2010).

Several biogeographic barriers within these refugia seem to be involved in a later, younger than eight Ma (Marin *et al.*, 2012), allopatric diversification of species (*R. bicolor*, *R.* bituberculatus, R. diversus, R. guentheri, R. kimberlevensis R. ligatus and R. unguirostris) (Fig. 3). They are more subject to isolation due to their fossorial lifestyle (Vidal *et al.*, 2010). Similar patterns of diversification were recently found for rock wallables in the monsoon tropic zone (Potter et al., 2012) and for beaked geckos in the eastern arid zone and southeast mesic zone (Pepper et al., 2011). Some other SHs of our Ramphotyphlops dataset display close and/or sympatric geographic distributions in the rocky Pilbara region. This region is

 characterized by geological heterogeneity, complex phytogeography and long-term geological stability (Pepper, Doughty & Keogh 2006) leading to a mosaic of habitat types (Doughty et al., 2011). This may explain the sympatric distribution observed for R. ammodytes, R. grypus and *R. hamatus*. Assuming that each SH may be restricted to a particular habitat, they should have evolved independently through ecological diversification. But contrary to the results for *R. grypus* and *R. hamatus*, nuclear haplotypes of *R. ammodytes* are shared between SHs. This could reflect a more recent speciation event or more probably could be linked to the fact that *R. ammodytes* is one species. One other interesting geographic pattern concerns *R. endoterus*, which is consistent with a sandy desert expansion out of the west. Several different genetic groups (SHs 33–35) have differentiated in the west, but only a single lineage (SH 32) has expanded eastward into the younger central and eastern desert areas, a pattern seen in other arid zone non-snake taxa (Moritz & Heideman 1993; Kearney et al., 2006). Ramphotyphlops hamatus shows a similar though less expansive pattern. SHs of R. endoturus share a common nuclear haplotype, reflecting a recent speciation event or a single species with a polymorphic mitochondrial marker.

Overall, our results suggest that the current complement of nominal Australian *Ramphotyphlops* species is less than the total, with the true species diversity ranging between 210–340% of the currently described species. However, even though our dataset is large (~740 specimens), the sampling is limited for some taxa, and adding more specimens— especially for species with a single sequenced specimen— may help to more accurately delimitate the current species. On a larger taxonomic scale, these new species (55–96) represent an increase of 7–16% of the entire scolecophidian species diversity. Currently 402 scolecophidian species are described, while acknowledging that extrapolations of hidden biodiversity from limited surveys are subject to sampling errors (Gray, 2002), taken at face value our results suggest that up to 1200 scolecophidian species may exist, mostly hidden from current taxonomy. If true, that would be an exceptional increase in the number of reptile or vertebrate species.

400 The morphological conservativeness of blindsnakes may be responsible for this hidden 401 diversity, as potentially informative characters have been reduced or eliminated as an outcome 402 of their burrowing lifestyle (Hedges & Thomas 1991; Thomas & Hedges 2007). The limited 403 knowledge on the morphological characters useful for the discrimination of blindsnakes is 404 also likely responsible. Fortunately, in other cases where genetic analysis has revealed hidden 405 species of scolecophidians, non-traditional morphological characters always have been found 406 and used to diagnose the species (Hedges & Thomas 1991; Aplin & Donnellan 1993; Rabosky

 et al., 2004; Thomas & Hedges 2007). For this reason, we suspect that most of all of the putative new species revealed here will be diagnosed morphologically and named. These results also have implications for conservation, because accurate taxonomic data are critical for determining basic parameters of protection such as distributions and threat levels (Rondinini et al., 2006). Also, nominal species already considered endangered or threatened may be composed of several species, each of which are often rarer than their "parent species," making them more susceptible to extinction (Hedges & Conn, 2012). For these species, taxonomic revisions are urgent. Without published descriptions, these species are essentially "off the conservation radar" and therefore cannot be considered in conservation plans (Hedges & Conn, 2012).

CONCLUSION

Morphological conservativeness and the limited knowledge of useful morphological discriminant characters seem to have prevented the recognition of numerous Australian blindsnake species (*Ramphotyphlops*). Using several lines of independent evidence, including mtDNA, nuclear DNA, and geography, we found that as least 55 species exist, which is twice the currently recognized number of species. This is consistent with the results of previous smaller-scale studies of scolecophidians elsewhere in the world, suggesting that the proportion of species of these burrowing snakes yet to be described is greater than is typical in terrestrial vertebrates.

428 ACKNOWLEDGEMENTS

We thank three anonymous reviewers for their helpful comments. This work was supported by the 'Consortium National de Recherche en Génomique', and the 'Service de Systématique Moléculaire' of the Muséum National d'Histoire Naturelle (UMS 2700; OMSI). It is part of the agreement number 2005/67 between the Genoscope and the Muséum National d'Histoire Naturelle on the project 'Macrophylogeny of life' directed by Guillaume Lecointre. We thank Kyle Armstrong, Chris Austin, Patrick Couper, Karim Daoues, Paul Horner, Yuki Konishi, Robert Palmer, Olivier Pauwels, Luke Price, Steve Richards, Ross Sadlier and Miguel Vences for specimen collection or access to tissue samples in their care. The project was supported by the Australian Department for the Environment, Water, Heritage and the Arts' CERF programme to K.P.A. and S.C.D., and by the U.S. National Science Foundation to S.B.H.

Figure1. Bayesian inference phylogenetic tree of Australian *Ramphotyphlops* based on analysis of sequences of a mitochondrial protein-coding gene, *cytochrome b*, showing species hypotheses (SHs) obtained with the ABGD method, with bootstraps (>70) and posterior probabilities (>0.9) indicated next to each node

Figure 2. Maximum Likelihood phylogenetic tree of Australian *Ramphotyphlops* based on the analysis of a nuclear protein-coding gene, *prolactin receptor (PRLR)*. Species hypotheses (SHs) reported here were obtained with the ABGD method using *cytochrome b*. Bootstraps (>70) and posterior probabilities (>0.9) are indicated next to each node.
