Abstract—Patch-based image denoising can be interpreted under the Bayesian framework which incorporates the image formation model and a prior image distribution. In the sparsity approach, the prior is often assumed to obey an arbitrarily chosen distribution. Our motivation is to estimate the probability directly from the distribution of image patches extracted from good quality images, thanks to a given dictionary and the redundancy of information between different images. In this paper, we provide a scheme to estimate the probability distribution and also an optimized algorithm for denoising. We demonstrate that using the estimated probability distribution as the image prior is more efficient than the state-of-the-art sparsity models for noise removal.

Index Terms—Patch-based, denoising, sparse representation, probability distribution estimation.

I. INTRODUCTION

Image denoising is a well-known technique in low level computer vision that aims to recover a clean image X from its noise-corrupted observation Y. We assume that the noisy image is generated by $Y = X + V$, where $V$ is zero-mean additive Gaussian noise with standard deviation $\sigma$. Many denoising approaches in the state-of-the-art have been developed, including filtering based [1], total variation based [2], transform based [3], learning based [4], sparse representation based [5, 6], or deep-learning based methods [7, 8], etc. Among various contributions, the class of patch-based representation methods [6, 9–12] have achieved success and attracted intensive research interests in the past decade. In these algorithms, a noisy image $Y$ is divided into a set of overlapping image patches $\{ y \}$ ($y \in \mathbb{R}^m$), and the denoising process is considered on each patch. The noisy patch is modeled as $y = x + v$, where $x \in \mathbb{R}^m$ is the corresponding clean version of $y$ and $v$ is the additive Gaussian noise in each patch.

The idea of patch-based denoising is based on an interesting observation in which a clean image patch $x$ can be represented as a linear combination of atoms in a given dictionary $D$, $x = D \alpha$, with $D \in \mathbb{R}^{m \times K}$, $m \leq K$, and $\alpha \in \mathbb{R}^K$ is a coefficient vector. The denoising task is equivalent to solving for the coefficient vector $\alpha$ such that $y = D \alpha + v$. More precisely, our objective is to find the value of $\alpha$ under a given dictionary $D$ and a noisy observation $y$, which maximizes the posterior probability distribution $p(\alpha|D, y)$. Using Bayes’s theorem, we can formulate our problem as:

$$\alpha = \arg \max_{\alpha} p(\alpha|D, y) = \arg \max_{\alpha} p(y|D, \alpha)p(\alpha)$$

(1)

By assuming that $y$ is disturbed by additive Gaussian noise $\nu \sim \mathcal{N}(0, \sigma^2)$, the likelihood term in (1) is determined as:

$$p(y|D, \alpha) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2\sigma^2} \| y - D \alpha \|^2 \right)$$

(2)

Putting (2) into (1) and using the minus logarithm, we have:

$$\alpha = \arg \min_{\alpha} \{\| y - D \alpha \|^2 - \lambda \log p(\alpha)\}$$

(3)

Where $\lambda = 2\sigma^2$. The problem in (3) cannot be solved without any prior knowledge of $p(\alpha)$. In the literature, many authors supposed that $p(\alpha)$ follows an i.i.d. (independent and identically distributed) distribution law (e.g. Laplacian [4, 13], etc). Mathematically, this leads to model the log-likelihood probability ($\log p(\alpha)$) by the $\ell_p$-norm: $\log p(\alpha) = \gamma \| \alpha \|_p = \gamma (\sum_i |\alpha_i|)^{1/p}$, where $\gamma > 0$ is a regularization parameter and $p \geq 0$. Typically, the sparsity of a vector $\alpha$ is related to the so-called $\ell_0$-norm, which counts the number of the nonzero entries of $\alpha$. By that way, an image patch can be represented as a linear combination of few atoms in the dictionary [5]. In practice, denoising problems can be resolved in taking into account $\ell_p$-norms with $0 \leq p \leq 2$. Fig. 1 shows the distribution of coefficients $\alpha$ in $\mathbb{R}^2$ with different type of sparsity priors. Many algorithms have been developed to solve the sparse problem with different hypotheses of sparsity such that $\ell_0$-norm [14], $\ell_p$-norm ($0 \leq p \leq 1$) [15], $\ell_1$-norm [16], $\ell_2$-norm [17].

In the sparse denoising approach, the reconstruction of a noisy patch under a given dictionary is forced to an arbitrary distribution (e.g. Laplacian [4, 13], etc). But in reality, there are no guarantees that $p(\alpha)$ obeys this distribution. Our motivation is to develop a patch-based denoising method where $p(\alpha)$ is estimated from the distribution of coefficient vectors $\alpha$ in a $\mathbb{R}^K$ space; this distribution is calculated with the help of standard (clean, good quality) images and a pre-trained dictionary. This idea exploits the redundancy between standard images and the denoised image, where visual contents tend to repeat in different images. Therefore, the patches in the noiseless image follow a similar distribution as the database constructed from standard images. Hence, we can use $p(\alpha)$ learned from the database to denoise an image patch. The idea of probability distribution estimation is described as follows. From the standard images, we randomly extract a set of $N$ clean image patches to form a database of patches, where each patch is denoted as $x = [x_1, \ldots, x_m]^T \in \mathbb{R}^m$. Let $D = [d_1, \ldots, d_K] \in \mathbb{R}^{m \times K}$ denote a given dictionary. A good quality patch $x$ in the database can be represented in dictionary space $\Omega_x \in \mathbb{R}^K$ by its orthogonal projection:

$$\alpha = (D^T D)^{-1} D^T x = P_D \alpha$$

(4)

where $P_D = (D^T D)^{-1} D^T$ is the projection matrix. Hence, with a database of patches in the image domain, we can obtain a distribution of decomposition coefficients $\Omega_x$. Fig. 2 shows the distribution of $\alpha$ in 3D and 2D visualization, respectively, whose forms are different from sparse distribution in Fig. 1.

There are two main contributions in this paper. First, we propose using the probability distribution function $p(\alpha)$, which is estimated from image patches in the database, as an image prior to replace the sparsity models in the denoising problem. Second, we propose a denoising strategy to take into account the obtained $p(\alpha)$ in solving the optimization problem in (3). The remainder of this paper is organized as follows: Section II tackles the estimation of the probability distribution $p(\alpha)$ in which $p(\alpha)$ is a piece-wise constant function. Then, a scheme for solving the optimization problem indicated in (3) is proposed to find $\alpha$. Experimental results presented in section III.
prove the out-performance of proposed method over the sparsity ones. Section IV discusses the limitations, future developments and concluding remarks.

II. DENOISING BY PROBABILITY DISTRIBUTION ESTIMATION

A. Estimation of probability distribution \( p(\alpha) \) from the database

As estimation is a difficult problem in high dimensional spaces, we consider the \( \alpha \)-space with dimensions up to three (\( \Omega_\alpha \subseteq R^3 \)). This is equivalent to choosing a dictionary with only three atoms. (a) The given dictionary with 3 atoms. (b) 3D view of \( \Omega_\alpha \). (c) 2D view of \( \Omega_\alpha \).

In the scope of this work, rather than forcing the probability distribution \( p(\alpha) \) to a specific i.i.d. distribution law according to a sparsity model \( \log(p(\alpha)) \sim ||\alpha||_2 \), we prefer to estimate it directly from the distribution of patches in \( \Omega_\alpha \). A simple and efficient approach is to discretize \( \Omega_\alpha \) into a set of disjoint subvolumes, \( \Omega_\alpha = \{ \Omega^n_\alpha \} \), and count the density of occurrence of points in each subvolume \( \Omega^n_\alpha \). As a result, \( p(\alpha) \) becomes a piece-wise constant value function. Precisely, we divide \( \Omega_\alpha \) into grid cells (each cell corresponds to a subvolume \( \Omega^n_\alpha \)), in which each dimension is split into a set of intervals along the range limited by the minimum and maximum values of \( \alpha \) in this dimension. The probability distribution \( p(\alpha) \) is a cell-wise constant function whose values are calculated by the density of number of points falling in each cell as indicated in (5).

\[
p(\alpha) = \begin{cases} 
\frac{1}{V_\alpha} \sum \text{point } \in \Omega^n_\alpha, \frac{N_\alpha}{V_\alpha} \text{ if } \alpha \in \Omega^n_\alpha, \\
0, \text{ otherwise} 
\end{cases}
\]

where \( N_\alpha \) is the number of points inside cell \( \Omega^n_\alpha \) which contains \( \alpha \), \( V_\alpha \) is the volume of \( \Omega^n_\alpha \) (as \( D \in R^{m \times 3} \), \( N \) is the total number of points in \( \Omega_\alpha \) that is equal to the number of image patches in the database.

An important notification in the estimation of \( p(\alpha) \) is how to divide each dimension of \( \Omega_\alpha \) into the set of intervals to restrict the number of empty subvolumes, in which the solution of \( \alpha \) in (3) is undetermined. Our strategy is to split each axis of \( \Omega_\alpha \) such that the same number of points falls into each interval. By that way, the length of each interval can adapt to the density of points. In the experiments, each axis of \( \Omega_\alpha \) is separated into \( 2^n \) intervals by \( 2^n - 1 \) median points using a recursive division (n times), so that each interval contains \( N/2^n \) points. As a result, we obtain a grid of \( (2^n - 1)^K \) quantiles \( \mathcal{G}_\alpha = \{ \alpha^i \mid i = 1, \ldots, (2^n - 1)^K \} \) in the \( R^K \) space \( \Omega_\alpha \). In Fig. 3, we demonstrate an example of distribution of points in \( \Omega_\alpha \), which is partitioned in \( 4 \times 4 \times 4 \) \( ((2^n)^K \) with \( n = 2, K = 3 \) rectangular cells.

B. Solving the optimization problem

In this section, we will present how to employ the estimated \( p(\alpha) \) in image denoising task. Given the dictionary \( D \) in section II-A and the prior knowledge of probability distribution \( p(\alpha) \) estimated from the database of patches, our aim is to recover a clean image patch \( x \) from its noisy version \( y \). The denoised patch can be generated as a linear combination of atoms in the dictionary, \( \hat{x} = D\alpha^* \). Our objective is equivalent to find the value of \( \alpha^* \) which satisfies the optimization problem in (3):

\[
\alpha^* = \arg \min_{\alpha \in \Omega_\alpha} \left\{ ||y - D\alpha||_2^2 - \lambda \log p(\alpha) \right\} = \arg \min_{\alpha \in \Omega_\alpha} J(\alpha) \tag{6}
\]

As indicated in previous section, we have divided the \( \alpha \)-space \( \Omega_\alpha \) into disjoint rectangular cells \( \Omega^n_\alpha \), and the value of \( p(\alpha) \) is constant in each cell \( \Omega^n_\alpha \). Consequently, the cost function \( J(\alpha) \) in (6) becomes a cell-wise quadratic function. A simple way for finding the solution of \( \alpha \) is to minimize \( J(\alpha) \) on each rectangular cell \( \Omega^n_\alpha \) and then select the best value \( \alpha^* \) from which we achieve the smallest cost. Therefore, we can rewrite (6) as:

\[
\alpha^* = \arg \min_{\alpha \in \Omega^n_\alpha} \left\{ \arg \min_{\alpha \in \Omega^n_\alpha} J(\alpha) \right\} = \arg \min_{\Omega^n_\alpha} J_u(\alpha) \tag{7}
\]

With \( p(\alpha) \) is calculated from (5), the minimum cost function on \( \Omega^n_\alpha \), denoted as \( J_u(\alpha) \), becomes:

\[
J_u(\alpha) = \arg \min_{\alpha \in \Omega^n_\alpha} \arg \min_{\alpha \in \Omega^n_\alpha} ||y - D\alpha||_2^2 - \lambda \log \left( \frac{N_\alpha}{V_\alpha N} \right) \tag{8}
\]

\( J_u(\alpha) \) turns into the minimization of a convex quadratic function \( J(\alpha) \) on a subvolume \( \Omega^n_\alpha \). Because there exists only one cell \( \Omega^n_\alpha \in \Omega_\alpha \) such that the derivative \( \frac{\partial J(\alpha)}{\partial \alpha} = 0 \) at \( \alpha^d = (D^T D)^{-1} D^T y \), and \( \alpha^d \in \Omega^n_\alpha \), it is easy to prove that for all other cells \( \Omega^n_\alpha \neq \Omega^n_\alpha \), the optimized value of \( J_u(\alpha) \) occurs at one of four corners of \( \Omega^n_\alpha \). Moreover, we have partitioned the \( \alpha \)-space \( \Omega_\alpha \) into \( 2^K \) rectangular cells by grid of \( (2^n - 1)^K \) quantiles \( \mathcal{G}_\alpha \). Therefore, these points becomes the corners of rectangular cells \( \Omega^n_\alpha \), and the optimal value of \( J(\alpha) \) in (6) will take place either at \( \alpha^d \) or at one point in \( \mathcal{G}_\alpha \). Let \( L_\alpha = \{ \alpha^d, \mathcal{G}_\alpha \} \) denote the set of anchor points. For a noisy image \( y \), to minimize (8), we can easily compute the value of cost function \( J(\alpha) \) at anchor points and choose the optimized point \( \alpha^* \) among \( L_\alpha \), where \( J(\alpha^*) \) is minimum. The value of \( p(\alpha) \) (second term in (8)) and the production \( D\alpha^* \) at each anchor point \( \alpha \in L_\alpha \) can be computed offline to accelerate the speed of the optimization (8). The complexity of solving (8) is \( O(m^22^{2nK}) \) which depends on the patch size \( (y \in R^n) \) and the number of anchor points \( (2^n - 1)^K \). To sum up, the denoising work flow involving the optimization process is described in algorithm (1).

As it can be seen in (6), the estimation of probability distribution \( p(\alpha) \) has a direct influence on solving \( \alpha \). The two important parameters that affect the determination of \( p(\alpha) \) are the number of dimensions \( K \) of \( \alpha \)-space \( \Omega_\alpha \), as well as the number of intervals along each dimension. The former, \( K \) is related to the number of
atoms in the dictionary \( (K) \), and the latter depends on the number of grid points we choose on each dimension. In our experiments, each coordinate axis of \( \Omega_a \) is split by 32 intervals \((2^n\) intervals with \( n = 5 \)). Moreover, in high dimensional space \( \Omega_a \) \((K > 3)\), for a given distribution of patches (points) in \( \Omega_a \), the number of rectangular cells will increase exponentially, resulting in a large portion of empty cells, and thus invalid estimates. For the visualization purpose, we choose a dictionary composed of only three elements \((K = 3)\) so that \( p(\alpha) \) can be visually drawn in a three dimensional coordinates.

**Algorithm 1: Denoising**

**Input**: Set of standard images \( \{X\} \), Noisy image \( Y \).

**Dictionary** \( D \), noise level \( \sigma \), regularized parameter \( \lambda \), patch size, overlap between two patches.

1. Estimate the probability distribution \( p(\alpha) \) using (5) by first determining the grid of \((2^n - 1)^K\) median points \( \mathcal{G}_o = \{\alpha^i|i = 1, \ldots, (2^n - 1)^K\} \) (divide each dimension into \( 2^n\) intervals, each one contains \( N/2^n \) points) from standard images \( \{X\} \) and dictionary \( D \) as described in section (II-A).
2. Partition noisy image \( Y \) into overlapping patches \( y \).

3. For each image patch \( y \in Y \) do
   4. Subtract its mean value: \( y = y - \mu_y \).
   5. Calculate \( \alpha^d = (D^T D)^{-1} D^T y \) and find its rectangular cell \( \Omega_a^d \) such that \( \alpha^d \in \Omega_a^d \subset \Omega_a \).
   6. Define a set of anchor points: \( L_o = \{\alpha^d, \mathcal{G}_o\} \).
   7. Calculate values of the cost function \( J(\alpha) \) in (6) at all anchor points \( \alpha \in L_o \).
   8. Choose the optimized value \( \alpha^* = \arg \min_{\alpha \in L_o} J(\alpha) \).
   9. Estimate the denoised image patch: \( \hat{x} = D\alpha^* + \mu_y \).
10. Average the overlapped regions of denoised patches \( \hat{x} \) to obtain the entire denoised image \( \hat{X} \).

**Output**: The denoised image \( \hat{X} \).

### III. Denoising Performance and Evaluation

In this section, our aim is to demonstrate that for a given dictionary, using the estimated probability distribution as the image prior is more efficient than the sparsity models for noise removal. Given a dictionary, our method differs from the existing sparsity models in the way we determine the probability distribution function \( p(\alpha) \). While the sparsity models assume that the probability \( p(\alpha) \) in \( \Omega_o \) obeys a specific model, we propose to estimate \( p(\alpha) \) directly from the distribution of \( \alpha \) in \( \Omega_a \). In the remaining of this section, we compare the denoising performance of our proposed method with two famous sparse models \( \ell_0\)-norm (9) and \( \ell_1\)-norm (10), which known as least absolute shrinkage and selection operator (LASSO). The comparison evaluates the influence of the chosen probability models of \( p(\alpha) \) (sparsity or estimation) on the reconstruction of noisy image via solving the optimization problem (6). Therefore, we fix the dictionary \( D \), as well as the size of image patch \( y \) for the proposed and sparse methods to have a nondiscriminatory assessment. Comparison with other denoising methods such as BM3D [3], NLM [9], deep-learning [8] is out of the scope of the current manuscript.

\[
\alpha = \arg \min_{\alpha} \left\{ \|y - D\alpha\|^2_2 - \lambda ||\alpha||_0 \right\} \tag{9}
\]

\[
\alpha = \arg \min_{\alpha} \left\{ \|y - D\alpha\|^2_2 - \lambda ||\alpha||_1 \right\} \tag{10}
\]

The problem in (9) can be efficiently solved by the orthogonal matching pursuit (OMP) algorithm [14]. In our implementation, we use the LARS algorithm [13] to find the solution of (10). We refer to our proposed method as ProbaEst, and the others in (9) and (10) as OMP and LARS, respectively.

Our proposed estimation method is limited to a dictionary with three atoms \((K = 3)\). For this reason, the method is a priori best suited for low complexity images. To explore its performance, we have constructed a test benchmark on synthetic images in section III-B. We also discuss the results obtained on binary and natural images in sections III-C and III-D.

#### A. Parameter Setting

In all tests, the size of an image patch is set to \( 3 \times 3 \) and the overlap between two adjacent patches is 2 pixels. In cases of binary and natural images, the Kodak PhotoCD Dataset (shown in Fig. 4) is used as standard images. For the stage of estimation of \( p(\alpha) \) as described in section II-A, we use \( N = 500000 \) patches randomly extracted from standard images to form the database of patches.

In our empirical work, each axis in the \( \alpha \)-space is divided into \( 2^5 = 32 \) intervals. Moreover, the noisy images are generated from the corresponding noise-free versions by adding Gaussian noise with different levels \( \sigma = 10, 20, 30 \). In regard to binary tests, all images are converted into binary ones using a threshold method. To evaluate the objective quality of denoising of vertical structure and natural images, two widely used metrics peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM) are employed. For binary images, we adopt two metrics: the Dice ratio and the Distance-Reciprocal Distortion Measure (DRDM [18]) which exploits mutual relations of pixels within image to measure the distortion between two images. An essential notice is that the small value of DRDM indicates that two binary images are close.

Fig. 4: Some of standard images in Kodak PhotoCD Dataset (http://r0k.us/graphics/kodak/)

#### B. Denoising of vertical structure images

We first evaluate the denoising performance of our proposed method ProbaEst with two sparse models OPM and LARS on simple vertical structure images. We generate 4 vertical structure test images made of constant-gray-value stripes placed on a dark background as show in Fig. 5(b)-(e), where both the width and values of stripes are chosen randomly. We also need an adaptive standard image with similar vertical structures to exploit the redundancy of informations between images. Therefore, we create an image with stripes of gray levels gradually increasing from 1 to 255 as shown on Fig. 5(a) and use it as standard image for all comparing methods.

Fig. 5: (a) Vertical structure standard images with gradually increasing values of stripes. (b)-(e) Vertical structure test images with random width and values of stripes. (f)-(h) The patch-form of the three elements (atoms) of the dictionary \( D \)

In our experiments, we observe that the results of denoising are highly dependent on the choice of dictionary \( D \). In regard to our task, where all images are composed of vertical stripes, a dictionary with vertical structural atoms can be more adapted to the image structure. Therefore, we select a dictionary with the vertical structure
as exposed in Fig. 5(f)-(h). Tables I provides the results of denoising, where the best values of PSNR and SSIM are in bold red numbers. We can observe that for small noise corruption ($\sigma = 10$), the LARS algorithm (10) yields better values of PSNR, but with heavier noise levels, the proposed method produces higher performance, with the improvements are $0.4 \sim 1.5$ dB of PSNR and $0.03 \sim 0.12$ of SSIM. For visual assessment, Fig. 6 demonstrates the subjective results of image test4 with noise levels $\sigma = 30$. It is evident that the OMP and LARS are likely to generate much more artifacts in the denoised images than the proposed method. More precisely, referring to the results from Fig. 6(c)-(e), with the chosen adaptive vertical dictionary, the sparsity methods tend to strengthen the vertical artifacts, while the proposed method ProbaEst is more robust against that kind of reconstruction distortion.

D. Denoising of natural images

In the rest of our work, we compare the performance of the proposed method with two sparsity-based algorithms OMP and LARS for natural images. As in section III-C, we use all 24 images in the Kodak dataset (Fig. 4) as standard images. Moreover, we carry out the experiments by adopting the same dictionary for all methods, which is directly trained from each noisy image, using the K-SVD method [10]. In reality, with a simple dictionary of three atoms, the denoising results will not be good enough for visual quality requirement. But we have to emphasize again that the objective of our research is to demonstrate that using the estimated probability distribution as the image prior is more efficient than a sparsity model for noise removal. As illustrated in table III, the proposed method yields better values of PSNR and SSIM than the others in most cases of high noise levels ($\sigma = 20, 30$). In particular, Fig. 9 shows the denoising results in which the proposed method ProbaEst and the LARS are more efficient in noise reduction than the OMP. The results of LARS and ProbaEst are very similar. But if we carefully observe the background and some homogeneous regions (R.O.I) in the images, the ProbaEst produces less artifacts than the LARS.

IV. DISCUSSION

In this paper, we proposed a novel idea for patch-based denoising where the prior of patches distribution is learned from the external database. More precisely, we proposed a method for the estimation of probability distribution function by spatial division and demonstrated how to employ it in an optimization-based denoising process. The experimental results indicate that the approach improves considerably the results of denoising for some simple models of image when compared to the classical sparsity methods. The objective of our work is to make in evidence that the idea of embedding the probability distribution learned from external database is efficient and is a promising approach for image denoising.

However, a drawback of the proposed method is the implementation for high dimensional ($K > 3$) $\alpha$-space due to the curse of dimensionality. In that case, using the same framework of spatial

TABLE III: Denoising performance on natural images with respect to PSNR and SSIM.

discretization is not efficient and inapplicable. Nevertheless, to improve the quality of denoising for real natural images, we have to select a dictionary with higher number of atoms ($K \gg 3$). To deal with this problem, we can use the Gaussian mixture model (GMM) to learn the probability distribution function $p(\alpha)$ as a mixture of a finite number of Gaussian distributions. We will expand proposed method with GMM in future work.
