12	Abstract
13	Biocrust sustainability relies on dew and rain availability. A study of dew and rain resources
14	in amplitude and frequency and their evolution is presented from year 2001 to 2020 in
15	southern Africa (Namibia, Botswana, South Africa) where many biocrust sites have been
16	identified. The evaluation of dew is made from a classical energy balance model using
17	meteorological data collected in 18 stations, where are also collected rain data. One observes
18	a strong correlation between the frequency of dew and rain and the corresponding amplitudes.
19	There is a general tendency to see a decrease in dew yield and dew frequency with increasing
20	distance from the oceans, located west, east and south, due to decreasing RH, with a relative

21 minimum in the desert of Kalahari (Namibia). Rain amplitude and frequency decreases when

going to west and north. Short-term dew/rain correlation shows that largest dew yields clearly
occur during about three days after rainfall, particularly in the sites where humidity is less.

The evolution in the period corresponds to a decrease of rain precipitations and frequency, 24 25 chiefly after 2010, an effect which has been cyclic since now. The effect is more noticeable 26 towards north. An increase of dew yield and frequency is observed, mainly in north and south-east. It results in an increase of the dew contribution with respect to rain, especially 27 after 2010. As no drastic changes in the distribution of biomass of biocrusts have been 28 29 reported in this period, it is likely that dew should compensate for the decrease in rain precipitation. Since the growth of biocrust is related to dew and rain amplitude and frequency, 30 future evolution should be characterized by either the rain cycle or, due to global change, an 31 acceleration of the present tendency, with more dew and less rainfalls. 32

38 **1. Introduction**

Biocrust are typically found in drylands with arid or semi-arid ecosystems. In great interaction with the soil, biocrust concern cyanobacteria, lichens, algae and mosses. These organisms contribute strongly in the ecosystem's functioning and plant organization and are present all around the world.

Numerous works detail their physical, chemical and biological characteristics in semi-arid or
arid climates. Negev (Jacobs et al., 2002; Kidron and Tal, 2012), Europe (Raggio et al., 2021),

Spain (Cano-Díaz et al., 2018), China (Yao et al., 2019), USA (Aguirre-Gutiérrez et al., 2019) 45 are a few examples. According to Chen et al. (2020), biocrust correspond to 30% of global 46 drylands. It is in China, Australia, North America and Spain in Europe that are found the more 47 studied biocrust sites. In the present study, a representative area for biocrust studies was 48 chosen in a less investigated area, the southern part of Africa. Namibia, South Africa and 49 Bostwana are the main countries involved in this study, representing 18 sites of measurement 50 (7 in Namibia, 7 in South Africa and 4 in Bostwana, respectively). One should note that, these 51 locations are based on previous works of a few scholars within certain research sites and 52 cannot obviously replace an objective map. A map of soil can help to locate biocrust, it is 53 54 given in Fig. 1 together with the above studied sites.

Moisture from atmosphere (rainfall, fog, dew, vapor absorption) plays an important role in 55 sustaining life in arid or semi-arid climates. Pan et al. (2010) concluded on the mutual 56 enhanced effect between dew and artificially revegetation ecosystems in the arid desert 57 ecosystem in Shapotou (China). Li et al. (2021a,b), in a recent paper, determine that biocrust 58 59 benefits from non-rainfall water deposition and modify their distribution in drylands soils. 60 Dewfall can be presented as a critical source of water in deserts environments allowing to determine the sustainability of sand to stabilize planted vegetation (Zhuang and Zhao, 2017). 61 62 Dew, fog and rain can play an important role for the development of biocrust in semi-arid regions. Kidron (2020) suspects dew to be a necessary water source for cyanobacteria. 63 Biocrust alter non-rainfall distribution by depth, concentrating it in the surface (Li et al., 64 2021a, b). Biocrust can boost the use of non-rainfall water according to Ouyang et al. (2017). 65 Büdel et al. (2009) conclude their study by noting that the time frequency of rain 66 67 precipitations is more important than their amount.

68 The amount and frequency of rain and dew are then the main factors which influence the 69 growth of biocrust. This paper aims to evaluate the evolution of these contributions to over a

long period of time (20 years, from 2001 to 2020) in order to put in evidence the long term 70 71 trend and extrapolate to the near future. Because certain data are lacking before 2011, a few analyses are restricted to 10 years (2011-2020). The paper is organized as follows. After 72 having reported on measurements and methods in Section 2, mainly concerning the physical 73 model used to determine the dew yields, Section 3 is devoted to the main results with maps i) 74 for dew and rain atmospheric deposition, ii) cumulative rainfall and dew yields comparisons 75 and iii) short time and longtime evolution of dew and rainfalls yield and frequency. A Section 76 4 is devoted to discussions and relation of the rain and dew studies with biocrust. 77

78

79 2. Meteorological data and methods

80

81 2.1. Dew yield estimation from meteorological data

In order to estimate the dew potential, Beysens (2016) developed an energy balance model 82 83 which, thanks to some approximation, uses only a few classical meteorological data without adjustable parameters: cloud cover (N, oktas), wind speed (V, m.s⁻¹), air temperature (T_a , °C), 84 air relative humidity (RH, %) and dew point temperature (T_d , °C). Near the ground level 85 where dew forms, in the atmospheric boundary layer, the contribution from water vapor 86 (about 0.2–2% by volume) and, to a lower extent, carbon dioxide (about 0.03% in volume) is 87 88 of great importance for the radiative balance, with radiation from water vapor being by far the more important of the two. The results are concerned with dew yields h [mm. $(\Delta t)^{-1}$] where 89 90 Δt corresponds to the period (in h.) of the analyzed data. It is assumed that the substrate emissivity is unity (which is close to the emissivity ≈ 0.98 of a wet substrate, see Trosseille et 91 92 al., 2021) and is thermally insulated from below. The data can be obtained from the airport meteo stations by using the following formulation: 93

95
$$h = \left(\frac{\Delta t}{12}\right)(HL + RE) \tag{1}$$

96

97 The factor Δt is the measurement period of the data (here 6, 3 or 1 h. depending on the 98 stations). The data for h > 0 correspond to condensation and h < 0 to evaporation, which have 99 to be discarded. The quantity *HL* represents the convective heat losses between air and 100 condenser, with a cut-off for windspeed $V > V_0 = 4.4 \text{ m.s}^{-1}$ where condensation vanishes:

101

102
$$h = \begin{cases} \left(\frac{\Delta t}{12}\right) \left[0.06(T_d - T_a) + RE\right] & \text{if } V < V_0 \\ 0 & \text{if } V > V_0 \end{cases}$$
(2)

103

104 The quantity RE is the available radiative energy, which depends on air water content 105 (measured by the dew point temperature T_d , in °C), site elevation H (in km) and cloud cover N106 (in oktas):

107

$$108 \quad RE = 0.37 \times (1 + 0.204323H - 0.0238893H^2 - (18.0132 - 1.04963H + 0.0238893H^2) - (18.0132 - 0.04963H + 0.0238893H^2) - (18.0132 - 0.04963H + 0.04963H + 0.04963H + 0.04963H)$$

109
$$0.21891H^2$$
) × 10⁻³ T_d) $\left(\frac{T_d + 273.15}{285}\right)^4 \left(1 - \frac{N}{8}\right)$ (3)

110

By filtering the rain and fog events and integrating the time series on a daily time-step corresponding to h > 0, calculated daily yields and their cumulated values are obtained. We give an example of calculation in Appendix 1.

115 2.2. Studied area

The study area (Fig. 1) is characterized by a spatial extent of about $3\ 000\ 000\ \text{km}^2$ between 15° to 35° south latitude and 13° to 30° for east longitude. In the following are detailed the different climate characteristics of the countries.

Namibia (824 292 km² surface area). The country shows three different climates, the most 119 prevalent being semi-arid (Köppen-Geiger classification BSh) and hot desert (BWh). The less 120 frequent is cold desert climates (BWk). The climate is characterized by great differences in 121 day and nighttime temperatures, low rainfall and overall low humidity. Along the coast, the 122 average annual precipitation does not exceed 15 mm. Inside the country, the continental 123 plateau has a more contrasted situation with abundant precipitations (> 500 mm). The dry 124 season, between May to October, correspond to little or no rainfall during July and August. 125 Wildlife uses mainly waterholes and rivers when the water sources dry up. In desert areas, the 126 average minimum temperature is cold and can fall below freezing at night. The wet season, 127 128 between November to April, present daytime temperatures of about 30°C with the first rains observed in November (mean rainfall 26 mm to a maximum in January with 91 mm). 129 Sometimes, torrential downpours are observed in the afternoon up to March and April, where 130 rainfall decrease and stops before the dry season. 131

Botswana (581 730 km² surface area). The climate is characterized as hot semi-arid, the dominant climate (Köppen-Geiger classification BSh), and hot desert (BWh). During summer months (November-March), a rainy season is observed with high temperatures. The mean annual rainfall varies from over 650 mm in the extreme northeast area (Chobe District) to a minimum of 250 mm in the extreme southwest part (Kgalagadi District). The winter season during May to August corresponds to the dry season with less than 10% of the annual rainfall. The variability of rainfall increases while the quantity decreases toward the south and west.

South Africa (1,22 million km² surface area). The country corresponds to a subtropical 139 140 area, influenced by the vicinity of the oceans along the coastlines and the altitude of interior plateau (1 500 m in the dolerite-capped Roggeveld scarp in the south-west, to a height of 3 141 142 482 m in the KwaZulu-Natal Drakensberg). The country has several climatic zones depending on its geography: in the northwest, near the Atlantic coast stretching to the center of the 143 country, the climate is mainly characterized by arid lime (BWh) or cold (BWk) deserts. In the 144 south-east, the country offers a temperate climate with dry and hot (Csa) or warm (Csb) 145 summers. Finally, along the southern coast of the country, we find a hot (BSh) or cold (BSk) 146 arid climate with steppes but also a temperate zone, along the ocean between the towns of 147 148 George and Port Elisabeth with dry winters and hot summers (Cwa). The eastern part of the country, which is more mountainous, is characterized by a predominantly temperate climate, 149 without a dry season, with hot to temperate (Cfb) or cold (Cfc) summers. Mean rainfall is 150 151 about 460 mm with a large dispersion according to the location. Usually, the western Cape presents major rainfalls in winter whereas the rest of the country exhibits summer rainfalls. 152

153

154

Figure 1

The spatial distribution of rainfall between Namibia, Bostwana and South Africa presents 155 some differences in space and time (New et al., 2000). In Namibia, for the locations of Dante 156 Cave at the north of the country, summer rainfall is observed from October to April, with 157 mean annual rainfall between 500 and 600 mm.yr⁻¹, a value much less than the potential 158 evapotranspiration estimated to 2900 mm.yr⁻¹ (Railsback and al., 2019). A similar behavior is 159 observed at the frontier between Bostwana and South Africa (27°S, 21°E), with summer 160 rainfall. The situation is more complex in South Africa. According to the location, one 161 observes winter rainfall as in Cape Town with precipitations mainly during April to 162

163 September, weak precipitations but year-round in George and summer rainfall with a dry164 winter in Pretoria (Railsback and al., 2019).

165

166 2.3. Extraction data

All ground stations are installed on international or national airports where standard 167 meteorological parameters are measured. The meteorological stations meet the data 168 169 measurement standards of the World Meteorological Organization. Air T_a (°C) and dew T_d (°C) temperatures, relative humidity (RH, %), atmospheric pressure (P, Pa) are measured in a 170 meteorological shelter, 1.5 m from the ground. The windspeed (V, km.h⁻¹) and direction 171 (sectors or degrees) are measured at 10 m from the ground. Note that wind speed can be 172 extrapolated at any height z above the ground by the classical logarithmic variation (see e.g. 173 Pal Arya, 1988) $V(z) = V_{10} \ln \left(\frac{z}{z_c}\right) / \ln \left(\frac{10}{z_c}\right)$ where V_{10} is windspeed at 10 m and z_c is the 174 roughness length (generally ≈ 0.1 m in flat areas) where V = 0. Available data were extracted 175 from the online data base "Weather Underground" (Weather Underground, 2021) during a 176 period of maximum 20 years (2001-2020) with a minimum of 10 years (2011-2020) 177 depending on data availability (Table 1). 178

179

180

Table 1

181

182 Dew yields have been computed from Eq. 2 using standard meteorological databases 183 extracting air and dew point temperatures (T_a and T_d , °C), relative humidity (RH, %), wind 184 speed (km.h⁻¹ to be transformed in m.s⁻¹), wind direction (sectors), absolute pressure (hPa) 185 and sky cover. An hourly time-step for measured data is accessible except for Oranjemund and Luderitz (Namibia) where two time-steps are available (Oranjemund: 6 h. on 2005-2014
and 3 h. on 2014-2020); Luderitz (6 h. on 2006-2012 and 3 h. on 2012-2020).

Wind direction values in degrees have been computed from wind direction sectors (N, NNE,
NE, E, ESE, SE, S, etc.) using a standard law of proportionality: 0° for north, 180° for south
and calculation of all intermediate values with respect to these references.

The sky cover was considered variable if it varies by one or more of the reported values 191 192 (CLR, FEW, SCT, BKN, or OVC) during the period of observation (NOAA's national weather service glossary, 2021). Cloud cover in oktas was computed from the nightly 193 observation of sky cover using the correspondence listed in Table SM1 in Supplementary 194 Materials, which was used in a previous work (Muselli et al., 2020). However, cloud cover is 195 sometimes not available at night on some sites (the missing percentage of total values is noted 196 for each site in Table 1). When the sky conditions data are unavailable, we imposed to these 197 sites three possible values, corresponding to the most probable: N = 0, 1 and 3. 198

199

Measured rainfall data, available on a daily time step, are extracted from the meteorological data base (Infoclimat database, 2021). All data are obtained for the same stations as used for dew calculation except for Swakopmund where the rainfall data of Walvis Bay are used (both sites are only 25 km apart).

204

205 2.4. Kriging maps

Kriging methodologies are mainly used for mapping spatial distribution of a given variable.
The classical algorithm is presented in Appendix 2. Belkiri et al. (2020) use Kriging to study
ground water composition. Tomaszkiewicz et al. (2016) propose ordinary Kriging to develop

dew maps integrating projected climate changes in the Mediterranean basin. Martinez et al. 209 (2017) present median polish Kriging (MPK) for space-time analysis of monthly precipitation 210 in Colombia. Pue et al. (2021) introduce a Kriging-based Gaussian process for the evaluation 211 for the prediction of soil water retention in tropical and temperate climates. Other studies 212 combine Kriging models for the estimation of rainfall with Lagrangian (Amani et Lebel, 213 1997) or Bayesian (Lima et al., 2021) approaches. 214 215 3. Results 216 217 3.1. Evolution 218 For each site, dew (subscript i = d) and rain (subscript i = r) monthly yields h_i (mean, min, 219 max in mm) are computed. Annual dew yield (mm) is deduced by adding the monthly h_i : 220 221 $H_i = \sum_{t=1}^{12} h_i(t)$ 222 (4) 223 In order to estimate the evolution, monthly dew yields can be fitted by a linear regression on 224 225 the measured period: 226 $h_i(t) = \alpha_i t + h_{i,0}$ (5) 227 228 With t in month, the coefficient $\alpha_i = dh_i/dt$ represents the monthly evolution rate. 229

10

233 3.2.1. Data description

Mean, minimum and maximum dew yields are calculated on monthly and yearly time bases and reported in Table SM2 in Supplementary Materials. The calculated annual dew yields show significant variations depending on the sites studied even within the same country (Fig. 2 and Table SM2).

In Namibia, the sites on the west coast (Walvis Bay, Luderitz, Swakopmund and 238 Oranjemund) benefit from high dew yields (> 10 mm.yr⁻¹) mainly explained by the high 239 humidity due to the vicinity of the Atlantic Ocean. For example, mean dew yields in the range 240 12.6 to 38.2 mm.yr⁻¹ (for $N_{\text{missing}} = 0, 1, 3$) have been obtained in Swakopmund and Walvis 241 Bay, located near the Namib national Park, corresponding to mean monthly dew yields 242 243 between 2.8 and 6.9 mm. For both stations, dewy days represent between 79.1 (Swakopmund, 244 N = 3) and 85.8% (Walvis Bay, N = 0) of the year. On the other hand, the stations established in the interior of the country suffer from very low annual dew yield ($< 5 \text{ mm.yr}^{-1}$). For 245 example, Eros, Keetmanshoop and Ondangwa, respectively located at about 250 and 350 km 246 247 from the ocean, exhibit annual dew yields less than 4.9 mm. In Keetmanshoop, monthly dew yields are very weak with a mean of 0.1-0.3 mm and a monthly maximum of up to 1.8 mm. 248 249 For Eros and Keetmanshoop, only 10-20% of the days are dewy (min = 8.7% and max = 18.4%), while for Ondangwa it is 25% or even 15% (N = 0 for missing data) or even one day 250 a week in the most unfavorable case (N = 3 for missing data). 251

The situation is more homogeneous in Botswana. The mean annual yields are between 6.9 and 16.2 mm depending on the sites (min = 1.8-6.6 mm and max = 16.5-26 mm), with monthly

yields averaging between 0.6 and 1.4 mm (min = 0 mm and max = 4.2-5.9 mm).

Except in Upington (mean < 5.5 mm), located in the northern Cape Province of South Africa 255 256 on the banks of the Orange River, and Mahikeng, near to the Bostwana frontier (mean < 9.8mm), all the country exhibit mean annual dew yields more than 15 mm. For example, Cape 257 Town, Port Elizabeth and George cities, on the south coast, or Wonderboom and Bram 258 Fischer (near respectively Pretoria and Johannesburg), present averaged annual dew yields of 259 more than 18.3 mm, and up to 27 mm. Whereas the maximum monthly dew yields do not 260 261 exceed 4.7 mm in Upington and Mahikeng, the other cities present monthly dew yields larger than 4.5 mm, and up to 7.7 mm. 262

263

The spatial distribution of dew yields was determined by Kriging (Fig. 2, for N = 0, 1, 3 for 264 missing data). Maps of mean annual dew yields are presented in (Figs 2abc). As expected and 265 described in the literature (Henschel et al., 2007; Soderberg, 2010), dew exhibits the highest 266 yields along the west coast of Namibia corresponding to the Namib desert. This desert 267 268 represents about 81 000 km² and stretches over 1,500 km along a 80 to 160 km wide north-269 south coastal strip along the Atlantic Ocean. One also clearly observes the decrease in yields inland, especially from the central plateau towards the desert of Kalahari representing a 270 surface of 900 000 km² with 600 000 km² in Namibia. However, one notes that in this critical 271 272 areas, monthly dew yields can reach - mean and maximal values up to 2-3 mm and 6-8 mm, respectively. Note that the biocrust sites are located in regions of moderate dew yield. 273

More generally, there is a tendency to see a decrease in dew yield with increasing distance from the oceans, located W, E and S. A clear decrease in nocturnal RH from west to east is obvious (Fig. 2d), with the largest dew yields (Fig. 2c) corresponding to the regions of highest RH.

278

Figure 2

280

281 3.2.2. Evolution map 2001 - 2020

In Fig. SM1 (Supplementary Materials) are plotted the evolution of the summed value of dew yield, sum $(h_d) = \int_{t_0}^t h_d dt$ on a monthly basis, with t_0 the starting year (see Table 1). The dew rate is either nearly constant during the period (Swakopmund, Walvis Bay, Eros, Keetmanshoop, Cape Town, Port Elizabeth, Gaborone, Bram Fischer) or increases (Luderitz, Oranjemund, Upington, Shakawe, George, Maun, Mahikeng, Wonderboom) after year 2010. One will see in Section 3.3 that the year 2010 is also the year where rainfalls significantly decrease.

289

By considering the period where meteorological data are available on all sites (2011-2020), 290 one can determine the evolution of the average yield at any point in the study area by 291 subtracting annual dew yields between years 2020 and 2011. Figure 3 shows the difference 292 $\Delta h_d = h_d (2020) - h_d (2011)$. One sees that the evolution is different according to the locations. 293 Although dew decreases in two places where it was the most abundant (SW and NE to a lesser 294 extent), it increases in the NW (Ondangwa, Eros) where dew was the lowest. A noticeable 295 296 increase is seen in N (Maun, Shakawe) and SE regions (Bram Fischer). One notes that the biocrust sites are mostly located in regions of null or moderate dew decrease. 297

298

299

Figure 3

303 3.3.1. Data description

Table 2 and Fig. 4 present annual and monthly mean, min and max rainfall extracted from 304 Infoclimat database (2021) for the studied period (sites: See Table 1). From a general point of 305 306 view, rain decreases towards W and N. As described below, cities located at the Namib desert 307 exhibit lower rain precipitations: 13.4 mm in Swakopmund and Walvis Bay (i.e. 1% of 308 rainfall events by year) and in a lesser extent, Oranjemund with a mean annual rainfall of 309 about 42 mm (i.e. 5% of rainfall events by year). In these areas, precipitations are very erratic, with no rain for several months and few intense precipitations events. In the inland, rainfall is 310 slightly more abundant with annual averages of 115, 189 and 306 mm for Keetmanshoop, 311 Ondangwa and Eros, respectively. Although these areas can exhibit months without any rain, 312 the monthly averages are greater than 10 mm. However, one notes that less than 11% of the 313 days of the year are rainy days (10.9%, 5.3% and 3.7% in Eros, Ondangwa and 314 Keetmanshoop, respectively). 315

For Botswana, the situation is more homogenous, with a mean rainfall of 463.2 mm observed in the four cities of Gaborone, Maun, Francistown and Shakawe. With one or two months during the year without rain, this region present mean regular monthly rainfall of about 39 mm, with 13.4 % of the days being rainy.

South Africa exhibits a contrasted behavior. The regions located along the ocean in the south
and south east of the country have heavy rainfall with annual amounts greater than 500 mm
(Mahikeng, Cape Town, George, Port Elizabeth, Bram Fischer, Wonderboom), with up to 715
mm in George (18 - 31% of the year are rainy days). Monthly averages are important with a
mean of about 49.6 mm (23.5% rainy days in the year). Upington is an exception, located

further west of the country, but with lower rainfall (285 mm.year⁻¹ with a mean of 23.8 mm.month⁻¹).

One notes a marked decrease in precipitation during the 20 years period, all sites show ($\alpha(h_r)$

<br

The rainfall repartition presented in Table 2 is confirmed by the Kriging map obtained for the annual mean rainfall (Fig. 4a). Rainfall increases markedly from west to east (0-200 mm at the Atlantic coast to 600 to 700 measured at the south-east of South Africa). The same trend is observed with the monthly mean and maximum rainfall volumes (Figs. 4bc). The monthly average varies from 0 to 20 mm (W) to 50 to 60 mm (SE).

Table 2

- 340
- 341

Figure 4

342

343 3.3.2 Evolution map

By subtracting the precipitation values between years 2020 and 2011 one can map (Fig. 5) the difference $\Delta h_r = h_r$ (2020) $-h_r$ (2011). Although the mean precipitation decreases, the evolution is different depending on the locations. Rain mainly decreases in the north regions (Maun, Shakawe, Eros), where dew was seen to increase during the same time period (Fig. 3).

348	A small zone in south west (Cape Town, Oranjemund) exhibits a precipitation increase. It is
349	worthy to note that the biocrust zones are mostly in the regions that experienced a decrease in
350	rain.

- 353
- 354 3.4 Correlation between dew and rain yields

The occurrence of dew is related to the presence of atmospheric high humidity. Some correlations therefore exist between the frequency and amplitude of rain and the amplitude of dew yields. Two kinds of correlation can occur, a temporal correlation, where dew forms after rain events, which have increased the atmosphere RH, and an amplitude correlation. Both correlations are studied in the following.

360

361 3.4.1. Temporal correlation

The temporal correlation between rainfall and dew yield is evaluated by a correlation coefficient *r* between the daily rainfall, $h_r(t)$, and the time-shifted daily dew yield, $h_d(t+\tau)$, estimated at the same location. The delay time τ corresponds to the previous and next days of time *t* and is counted in days in the interval [-31, +31]. The covariance between $h_d(t+\tau)$ and $h_r(t)$ is calculated as:

367

368
$$C[h_r(t), h_d(t+\tau)] = \frac{1}{n} \sum_{j=1}^n (h_{r,j}(t) - \overline{h_r}) (h_{d,j}(t+\tau) - \overline{h_d})$$
 (6)

With $\sigma_{h_r}, \sigma_{h_d}$ the rain and dew standard deviation, respectively, one infers the correlation coefficient:

372

373
$$r[h_r(t), h_d(t+\tau)] = \frac{C\{h_r(t), h_d(t+\tau)\}}{\sigma_{h_r}\sigma_{h_d}}$$
 (7)

Considering that -1 < r < 1, a negative correlation leads to an opposite evolution of h_r and h_d , a positive correlation corresponds to the two variables moving in the same trend and $r \rightarrow 0$ means that both variables are not correlated.

The *r* correlation plots for each meteorological site according to the three *N* scenarii are reported in Fig. 6. One observes the following:

(i) For $\tau < 0$, no correlations between dew and rain amplitudes are observed (mostly r < 0.05).

380 It means that a rain event at a given day does not explain of dew events a few days earlier.

(ii) For $\tau = 0$, all curves present negative values for *r*, with amplitude in the range [-0.3 – 0.1]. This is due to the fact that, in the calculation of the dew yields in Section 2.1, one had to discard the days with rain.

(iii) For $\tau > 0$, some correlation can be observed for $\tau \le 3$ days. For the Eros and Keetmanshop sites, r = 0.29 (N = 3) and r = 0.18 (N = 1). For Mahikeng and Upington, r = 0.12 (N = 1) and r = 0.13 (N = 0). To a lesser extent, for Bram Fischer r = 0.097 for N = 1. These values thus indicate a weak but real positive correlation between rain and dew events. It means that, due to the increase of atmosphere humidity after rain events, dew events are more likely to be observed one to three days after rainfalls.

The correlation dew-rain is most noticeable (Ondangwa, Eros, Keetmanshop; Upington,Mahikeng, Bram Fisher) when the distance from the ocean increases, the atmosphere RH then

decreases (see Fig. 2d). In contrast, for stations close to the coast in arid climate (distance < 15 km) and with low annual rainfall ($H_r < 50$ mm) but large RH, such as Luderitz, Oranjemund, Swakopmund and Walvis Bay, the correlation is very low regardless of the τ value. For the cities of Cape Town, Port Elizabeth and George, presenting a more temperate climate, the correlation shows at most a weak increase for $\tau < 4$ to 5 days (with r < 0.1). All these sites have an altitude below 200 m.

Whatever is the *N* scenario, for altitudes between 800 m and 1700 m asl and > 200 km away from the ocean, the correlation is clearer with values of *r* showing a steady increase at Eros (1700 m asl, 266 km from the ocean), Keetmanshoop (1069 m asl, 285 km from the ocean). Ondangwa (1099 m asl, 385 km from the ocean) and Bram Fischer (1349 m asl, 418 km from the ocean) show a correlation with r > 0.1, respectively for $\tau = 2$ and 3. For the other mountainous stations, the correlation coefficients exhibit values that does not exceed 0.1, with $\tau = 5$ for Gaborone (r = 0.0532) or $\tau = 3$ for Maun (r = 0.0665).

405

406

Figure 6

407

408 3.4.2. Summed dew and rain yields

One now investigates the correlation between the cumulative dew and rain monthly yields, sum $(h_d) = \int_{t_0}^t h_d dt$ and sum $(h_r) = \int_{t_0}^t h_r dt$, respectively, with t_0 in Table 1. Each data point will thus correspond to a monthly mean value. For each month, a ratio a(t) is calculated:

414
$$a(t) = \frac{[\operatorname{sum}(h_d)]_t}{[\operatorname{sum}(h_r)]_t}$$

In Fig. 7a the sum (h_d) , the sum (h_r) and their ratio a(t) for two sites (Upington and Cape Town sites) are reported (at small times the dispersion is large because the smoothing effect of the summation is still weak). In Cape Town, both rain and dew amounts are nearly linear during the research period, with a decrease in rainfall rate after 2010 while the dew rate remains constant. In Upington, one observes a decrease in the rain amount and an increase in the dew amount after 2010. For sake of comparison in the whole time period, the data (Fig. 7b) can be fitted to a mean constant value

(8)

423

424
$$a(t) = a_0$$
 (9)

- 425
- 426

Figure 7

427

The values of a_0 according to the three *N* scenarios are summarized in Table 3. Taking into account all stations, the parameter a_0 shows a large variability: $\overline{a_0} = 0.4 \pm 0.8$ (N = 0), $\overline{a_0} =$ 0.3 ± 0.6 (N = 1) and $\overline{a_0} = 0.15 \pm 0.27$ (N = 3). This variability is due to the small number and erratic character of the precipitations in arid areas. When the very small quantities of rain at these sites (Namib Desert: Oranjemund, Luderitz, Swakopmund and Walvis Bay) are removed, the variability of values becomes much smaller ($\overline{a_0} = 0.022 \pm 0.008$ (N = 0), $\overline{a_0} =$ 0.020 ± 0.009 (N = 1) and $\overline{a_0} = 0.017 \pm 0.011$ (N = 3)).

The parameter $\overline{a_0}$ is mapped by the Kriging method in Fig. 8. One can clearly observe the 437 increasing importance of dew in the total precipitations along the Namibian coast and more 438 439 generally the dependence of *a* on longitude. It corroborates the fact that the distance from the ocean, which controls the atmosphere RH (see Fig. 2), is the important parameter for the 440 formation of dew. Toward the west, dew increases (Fig. 2) and rain decreases (Fig. 4), leading 441 to an increase in *a*. 442 443 Figure 8 444 445 The variation of the ratio a between 2020 and 2011 is reported in Fig. 9. One verifies the 446 general increase of the contribution of dew with respect to rain, especially towards west. 447 448 Figure 9 449 450 3.5 Time period of events 451 452 Because the frequency or time period between rain events is also an important parameter, which in itself can control the biocrust growth, we investigate below this parameter for rain 453 only, dew only and dew plus rain. For that purpose, one considers the histogram of rain, dew 454 455 and rain plus dew events (Fig. 10) where two important parameters can be extracted, the mean time period between events, θ_0 (in days) and the maximum time period, θ_M (in days). 456

457

458	Figure 10
459	
460	
461	The evolution of θ_0 and θ_M can be then considered (Fig. SM2) and maps of mean values can
462	be drawn for the considered period (Fig. 11), with the difference between 2011 and 2020
463	values (Fig. 12). Some curves are interrupted due to the lack of data.
464	
465	
466	One first notes from Figs. 10 and SM2 (in Supplementary Materials) that the number of
467	events is larger for dew than for rain. In addition, the timescale for mean and maximum time
468	period between events is much larger for rain than for dew, a difference which can reach two
469	orders of magnitudes. It results from the above observations that the dew events will
470	determine the behavior of the dew + rain time period (see Fig. SM2, Figs 11–12).
471	
472	Figure 11
473	
474	When comparing the maps of dew and rain mean annual times (Fig. 11) and dew and rain
475	amplitudes (Figs. 2 and 4), one observes a strong correlation between the zones of large times
476	and low yield, and short times and high yield. This simply means that large water yields
477	correspond to frequent dew or rain events.

The evolution of the mean and maximum time period between 2001 and 2020 (Fig. SM2) show that mean and maximum time periods evolve about the same way. The times keep 480 nearly constant over the whole period for dew, noting a slight decrease after 2010. Dew times 481 are well correlated with the dew yield amplitude, which remains constant or weakly increases 482 in the same period (Fig. SM1 in Supplementary Materials). In contrast, for rain, while the 483 times keep constant between 2001 and 2010, the times increase after 2010. This evolution 484 corresponds well with the decrease of rain amplitude (Fig. SM1).

The maps of evolution for the period 2011 – 2020 concerning the differences in rain, dew and rain + dew times are reported in Fig. 12. The evolution mean and maximum times are qualitatively similar to the evolution of the rain and dew amplitudes (Figs. 3 and 5). The evolution of rain + dew times rather follows the dew evolution, as expected from the fact noted above that the dew events mostly determine the behavior of the dew + rain times.

- 490
- 491

Figure 12

492

493

494

495 4.1. Dew height dependence

4. Discussion and relation with biocrust

Biocrust forms at the ground level while the calculation of Section 2.1 deals with a 30° tilted condenser at 1 m off the ground. Dew condensation can vary for three reasons. (i) RH can be height dependent. This is the case if wind speed is near zero and soil is wet, for instance after a rain event. (ii) Air flow depends on height, and then, the heat and mass exchange with the surrounding air. The variation of air flow velocity is known to follow a log dependence above a roughness length z_c (see Section 2.3) where air flow velocity is zero. In addition to the forced air flow induced by wind, there exists a natural convection induced by the substrate temperature colder than ambient air, with typical velocity 0.6 m.s⁻¹ (Beysens et al., 2005; Clus et al., 2009). The log dependence of the windspeed and the presence of natural convection make the heat exchange coefficient and then the mass diffusion coefficient, which determines the condensation yield, depend weakly of windspeed for values below $\sim 1 \text{ m.s}^{-1}$ (measured at the standard height of 10 m). It results a weak dependence of condensation with height for such windspeeds, making the calculation of Section 2.1 valid at the ground level.

For larger windspeeds, the heat exchange coefficients will be larger, decreasing the dew yield.
The latter will be then larger at the ground level and the calculation of Section 2.1 will be a
conservative value.

512

513 4.2. Comparison with direct dew yield measurements

The calculated dew yields can be compared with previous works available in the literature. 514 Baier (1966) reported dew and rainfall measurements from a weather station set at 515 Potchefstroom (inclined cross in Fig. 2), located in the vast interior plateau of South Africa 516 (26°44' S, 27°05' E, 1352 m asl), about 160 km from the Wonderboom site. During the 517 period 1957-1958, the annual percentage of dew days was 45.7% (Wonderboom: 65.5%) with 518 a mean annual dew amount of 12.6 mm (Wonderboom: 19.9 mm). The values in 519 520 Wonderboom are slightly larger, but the time is earlier and we will see in the next Section that the general tendency is a positive dew yield evolution. 521

522 Dew collection were also carried out in 2006 by Henschel et al. (2007) at Gobabeb (Namib 523 desert, 23°33.704 S, 15°02.466 E, right cross in Fig. 2) in Namibia's Central Namib desert, 524 situated about 84 km from Walvis Bay and 110 km from Shakopmund. The site elevation is 525 406 m. Only a few data were collected on a specially-designed 1 m² passive dew collector. In 526 July 2006, 3.3 mm of dew water was collected (12 dew days), 1.2 mm in August (10 dew days), and 1.5 mm in September (10 dew days). Meteo data at Walvis Bay and Shakopmund are, however, available only between 2010 and 2020. In these cities, the calculated annual mean in July, August and September are nearly the same: 2.6 mm (July), 2.2 mm (August) and 2.2 mm (September) (N = 0), 1.2 mm, 1.8 mm and 1.7 mm (N = 1) and 0.7 mm, 0.9 mm and 0.9 mm (N = 3). Although not determined at the same dates, these values compare relatively well with the above measured values of 3.3 mm (July), 1.2 (August) and 1.5 mm (September).

Between July 2008 and June 2009, Soderberg (2010) measured a greater amount of dew at Gobabeb, with 143 yearly dew events. The corresponding volume was 12.3 mm, which compares relatively well with the Walvis Bay and Shakopmund data for the same year: 21 mm (N = 0), 15.8 mm (N = 1), 7 mm (N = 3).

538

539 4.3 Variation in rain precipitation

540 As mentioned in Section 3.3, we observed a decrease of precipitation from west to east. All sites present a negative variation in rain precipitation during 2001 to 2020. In particular, the 541 decrease in precipitation is quite noticeable from 2010. In Namibia Lu et al. (2016) also 542 543 observed a tendency to a diminution of rainfall precipitations. On the Ghaap plateau in west center of South Africa, oscillations of rain precipitations have been already noted by Tfwala et 544 545 al. (2018) by analyzing interannual rainfall variability on the Ghaap plateau. The cycles last about 18 -22 years years in Postmarburg and between 12 and 16 years in Douglas. Another 546 analysis of rainfall in South Africa by Zvarevashe at al. (2018) also concluded to quasi-547 decadal oscillations. The question whether the decrease we observed since 2010 is related to 548 these oscillations or to the global climate change remains thus open. 549

551 4.4 Water availability and biocrust distribution

As outlined in the Introduction, the amount of rain and dew are considered as the main factors which influence the growth of biocrust (see e.g. Pan et al., 2010; Zhuang and Zhao, 2017; Ouyang et al.; 2017; Kidron, 2020; Li et al., 2021a, b). However, the frequency of rain events (longest period of drought) is the main factor according to Büdel et al. (2009). Although there are no studies concerning the effect of frequency of dew events, one can reasonably assume that this parameter also matters.

558 Frequency of events and their amplitude are strongly correlated (see Section 3.5), the regions 559 of large dew or rain amplitudes corresponding to the regions of small dew or rain time 560 periods. Both criteria (amplitude, time frequency) should thus correspond in the studied 561 regions to the same characteristics favoring biocrust growth.

The evolution between 2001 and 2020 is seen to exhibit two regimes, one from 2001 to 2010, 562 where all parameters (dew and rain amplitude, dew and rain frequency) keep nearly constant. 563 564 The second regime, from 2010 to 2020, corresponds to a neat decrease of rain amplitude and frequency of events, while dew amplitude and frequency either keeps constant or slightly 565 increase. As far as rain is concerned, it should result in a decrease of biocrust growth. 566 However, dew yield is nearly constant or increases after 2010. We are not aware of drastic 567 changes in the distribution of biomass of biocrusts during the 2001-2020 period. This may be 568 attributed to the increase of dew amplitude and frequency, which should act to compensate for 569 the decrease in rain precipitation. 570

571

572 **5.** Conclusion and trends for the future

573 The determination of dew yield using a physical model and rainfall data from 18 574 meteorological stations in Namibia, Botswana and South Africa in the period 2001-2020 allow clear tendencies to be evaluated. Dew decreases from the East, South, West coasts following the decrease in RH decrease, and rainfalls diminish toward the West and North. A noticeable decrease in rain precipitations after 2010 and a corresponding rise in dew yield are noted. It results in a steady increase of dew contribution with respect to rain after 2010. In addition, a clear increase in dew for three days in average after rainfall is observed in the arid regions where the humidity is low. These results are corroborated with the frequency of dew and rain events, which are closely correlated with dew and rain yields.

The effect on biocrust is to show zones with less rain but with increasing dew water. As far as rain is concerned, one therefore should expect a decrease of biocrust growth. However, dew yield is nearly constant or even increases slightly after 2010, which could possibly compensate the rain decrease as we are not aware of drastic changes in the distribution of biomass of biocrusts during the 2001-2020 period.

The observed evolution, studied from 2001, exhibits a change after 2010. The question whether this decrease is related to oscillations or to a general tendency due to the global climate change remains open. A more precise scenario will need the use of climate change models as was done by Tomaszkiewicz et al. (2016). We plan such a study in a near future.

761 Appendix 1 – Dew yield calculation

We give below an example of determination of dew yield from Section 2.1. The model (Eq. 2) is applied to one night (March 21-22, 2010) in Cape Town (South Africa). Considering the sky nebulosity (*N*, oktas), the air (T_a , °C) and dew (T_d , °C) temperatures, the relative humidity (*RH*, %) and the windspeed (*V*, m.s⁻¹) at 10 meters of the ground, recorded every $\Delta t = 1$ h., we compute an hourly yield h_i (mm) corresponding to evaporation ($h_i < 0$) or condensation ($h_i >$ 0) events. By discarding evaporation ($h_i < 0$) and rain events, the cumulative dew yield h for each night is computed. For the studied night, h = 0.185 mm.

Date	Hour	N	V	Ta	RH	T _d	T _d -T _a	h _i	<i>h</i> _i > 0	sum(<i>h_i</i>)

772 Appendix 2 – Kriging method

Kriging is a stochastic spatial interpolation method that predicts the value of a natural phenomenon at non-sampled sites by an unbiased, minimal variance linear combination of observations of the phenomenon at nearby sites. The Kriging tool assumes that the distance or direction between the sample points reflects a spatial correlation that can explain the surface variations. The Kriging tool applies a mathematical function to all points, or certain determined points, located within a specific radius. It determines the output value of each location.

The Kriging tool is particularly suitable for cases where it is known that there is a spatial correlation of distance or a directional deviation in the data. Kriging deduces, by weighting existing readings, the probable values of unmeasured locations. To calculate the interpolated data $\hat{Z}(s_0)$ at a specific location s_0 , the general formula of ordinary Kriging (OK) method consists of a weighted sum of the data (Goovaerts, 1997):

785

$$\hat{Z}(s_0) = \sum_{i=1}^{P} \lambda_i Z(s_i)$$

786

Here $Z(s_i)$ corresponds to the measured value at the *i*th location, λ_i the ponderation coefficient to determine and relate to the ith location, s_0 the predicted location and *p* the number of measured data.

With the Kriging method, the λ_i weighted coefficients are not only based on the distance between the surveyed points and the forecast location, but also on the general spatial organization of the surveyed points. To use the spatial arrangement in the weighing, the spatial autocorrelation is quantified. Thus, in ordinary Kriging, the weighting λ_i depends on the distance from the forecast location and the spatial relationships between the values recorded around it.

796 The experimental semi-variogram can be estimated from point pairs:

$$\hat{\gamma}(h) = \frac{1}{2n(h)} \sum_{i=1}^{n(h)} [Z(s_i) - Z(s_i + h)]^2$$

797 Where

$$n(h) = Card\{(s_i, s_j) / |s_i - s_j| \approx h\}$$

with "card" represents the number of elements for the given condition.

Classically, estimated semi-variogram are fitted by a spherical variogram model as proposed
in previous studies on rainfall spatial estimation (Bargaoui et Chebbi, 2009 ; Lepioufle et al.,
2012 ; Van de Beek et al., 2012 ; Rahmawati, 2020).

802

803 Supplementary materials

804 We present below supplementary materials for additional calculated data.

Figure SM1 reports the evolution of the dew summed values $sum(h_d)$ (dew, mm, full blue

line) and the rain summed values $sum(h_r)$ (rain, mm, interrupted red line) for the studied sites.

- Figure SM2 is concerned with the evolution of the mean time θ_0 (day) and the maximum time
- 808 θ_M (day) between (a) rain (orange line), dew (blue short interrupted line) and rain plus dew
- 809 events (green long interrupted line).

810	Table SM1 gives the correlation between the sky conditions and the cloud cover in oktas									
811	according to NOAA.									
812	Table SM2 reports the yearly (H_d) and monthly (h_d) mean, minimum and maximum dew									
813	yields calculated from meteorological data.									
814	Figure SM1

Fig. 1. Map of soils in the studied area (from Jones et al., 2013). Black rectangle and black
letters are airport stations. The interrupted blue rectangle corresponds to the biocrust sites
(green circles, see Chen et al., 2020).

Fig. 2. (a, b, c): Map of annual dew yield H_d (in mm) in the period 2001 - 2020corresponding to three scenarios for missing N data (see text and Table 1). (d): Mean nocturnal RH (%) during dew events. Red letters: Meteo sites (see Table 1); circles: Biocrust sites according to Chen et al., 2020; right cross: Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site studied by Baier (1966).

Fig. 3. Difference between 2020 and 2011 annual dew yields (mm) for three scenarios
corresponding to the missing *N* data (see text and Table 1). Red letters: Measurement sites
(see Table 1); circles: biocrust sites according to Chen et al., 2020; right cross: Gobabeb site
studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site
studied by Baier (1966).

Fig. 4. Mean rainfalls (mm) during the period 2001 - 2020. (a) Mean annual rainfall. (b) Mean
monthly rainfall. (c) Maximum monthly rainfall. Red letters: Measurement sites (see Table 1);
circles: biocrust sites according to Chen et al., 2020; right cross: Gobabeb site studied by
Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site studied by
Baier (1966).

Fig. 5. Difference between 2020 and 2011 of the annual rainfalls (mm). Red letters:
Measurement sites (see Table 1); circles: biocrust sites from Chen et al., 2020; right cross:
Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross:
Potchefstroom site studied by Baier (1966).

Fig. 6. Daily correlation coefficients $r[h_r(t), h_d(t+\tau)]$ for time $\tau \in [-31 - +31]$ days. For

stations with incomplete cloud cover data, the curves are presented assuming N = 0 (blue), N = 1 (red) and N = 3 (grey).

Fig. 7. Two typical evolutions (Upington and Cape Town sites) of dew and rain summed yields in the studied period (2001 – 2020). The vertical dotted line corresponds to year 2010 where rainfalls begin to significantly decrease. (a) $\operatorname{sum}(h_d)$ and $\operatorname{sum}(h_r)$ with N = 0 missing data scenario (see text and Table 1). (b) Ratio $a(t) = [\operatorname{sum}(h_d)]_t / [\operatorname{sum}(h_r)]_t$. The horizontal straight lines are fits to $a(t) = a_0 = \text{constant}$.

Fig. 8. Map of ratio a_0 corresponding to the average of a = sum(dew)/sum(rain) (Eqs. 8, 9) for the period 2001 – 2020 and three scenarios for missing *N* data (see text and Table 1). Letters: meteo sites; circles: biocrust sites according to Chen et al., 2020; right cross: Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site studied by Baier (1966).

Fig. 9. Variation between 2020 and 2011 of the ratio a = sum(dew)/sum(rain), corresponding to 3 scenarios for missing *N* data (see text and Table 1). Letters: meteo sites; circles: biocrust sites according to Chen et al., 2020; right cross: Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site studied by Baier (1966).

885

Fig. 10. Typical histograms of time period θ (day) beetween (a) rain events, (b) dew events (c) rain and dew events. θ_0 is the mean time and θ_M is the maximum time. Note that dew or rain events have diseppeared in the histogram dew + rain because dew or rain events occur during the dew or rain time periods.

891

Fig. 11. Annual mean in the period 2001 – 2020 of the maximum time θ_M (day) (left column) and mean time θ_0 (day) (right column). (a), (b): Rain; (c), (d): Dew; (e), (f): Rain+dew. Red letters: Measurement sites (see Table 1); circles: biocrust sites according to Chen et al., 2020;

- right cross: Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined
- 899 cross: Potchefstroom site studied by Baier (1966).

900

Fig. 12. Difference between 2020 and 2011 of the maximum time θ_M (left column, day) and mean time θ_0 (right column, day). (a), (b): Rain; (c), (d): Dew; (e), (f): Rain+dew. Red letters: Measurement sites (see Table 1); circles: biocrust sites from Chen et al., 2020; right cross: Gobabeb site studied by Henschel et al., 2007 and Soderberg, 2010; inclined cross: Potchefstroom site studied by Baier (1966).

907

Fig. SM1. Evolution of the summed values $sum(h_d)$ (dew, mm, full blue line) and $sum(h_r)$ (rain, mm, interrupted red line) for the studied sites. The vertical interrupted line corresponds to a significant decrease of rainfall after 2010 with dew yield remaining constant or weakly increasing.

Fig. SM2. Evolution of mean time θ_0 (day) and maximum time θ_M (day) between (a) rain (orange line), dew (blue short interrupted line) and rain plus dew events (green long interrupted line). Some curves are interrupted because data are missing.

Table SM2. Yearly (H_d) and monthly (h_d) mean, minimum and maximum dew yields calculated from meteorological data. The mean evolution data during from 2001 to 2020 are fitted to Eq. 5 with free parameters $\alpha_d = dh_d/dt$ and $h_{d,0}$. Red values correspond to a decrease of dew yield evolution, blue values to an increase. Cloud coverage *N* is assumed to be 0, 1 or 3 oktas when cloud cover data are missing (see text and Table 1).
