## Abstract

**Context:** A significant forest decline has been noticed these last years in Europe. Managers need tools to better anticipate these massive events.

**Objectives:** We evaluated the efficiency of easily available data about environmental conditions and stand characteristics to determine different levels of vulnerability.

**Methods:** We combined remote sensing images, photo-interpretation, and digital models describing environmental conditions within a modelling approach to achieve spatial vulnerability assessment of the stands. We focused on silver fir and Norway spruce stands in the Vosges mountains (8,900 km<sup>2</sup>, northeastern France), where severe symptoms of decline are visible.

**Results:** Silver fir were predicted highly vulnerable on 7% of their area *versus* 33% for Norway spruce. Using an independent dataset, we observed ten-times (silver fir) and two-times (Norway spruce) higher mortality rates in the units with a high level of vulnerability than in the others. About half of the model deviance was directly or indirectly explained by variables related to water stress (soils displaying low water availability, having suffered severe drying events these last years). Furthermore, the stands acclimatised to drought conditions were more resilient. Stand characteristics also influenced dieback spread, suggesting that an evolution of silvicultural practices toward mixed stands with broadleaved species and uneven-aged trees can contribute to better adapt to future climate conditions.

28           **Conclusions:** Vulnerability maps based on easily available geographic information describing climate,  
29           soil, and topography can efficiently discriminate canopy mortality patterns over broad areas, and can be  
30           useful tools for managers to mitigate the effects of climate change on forests.

31

32   **Keywords:** climate change, forest dieback, decline, drought, tree vulnerability, vulnerability map.

33

## 34   **Introduction**

35           With a global mean temperature increase of at least 1.1°C and changes in rainfall patterns, the effects of the  
36           ongoing climate change are more and more visible and consequential on ecosystem functioning (Pörtner et al.  
37           2022). Increased tree mortality and changes in forest structure and composition have been observed in different  
38           biomes (Allen et al. 2015; Michel and Seidling 2018). In the western United States, van Mantgem et al. (2009)  
39           demonstrated a doubling of the rate of background tree mortality every 17 to 29 years, while Peng et al. (2011)  
40           observed a 4.9% increase in tree mortality per year from 1963 to 2008 in Canadian boreal forests. In Europe,  
41           remote sensing data have revealed a 2.4% increase of canopy mortality *per* year between 1984 and 2016 (Senf et  
42           al. 2018), and different hotspots have been identified in the north or the south of the continent (Neumann et al.  
43           2017). These trends were most of the time attributed to the recent changes in climate (Han and Singh 2020; Senf  
44           et al. 2020). An excess of tree mortality has been associated to the current changes in temperature or rainfall for  
45           about half of the most common European tree species (Taccoen et al. 2019). The impact of climate change on  
46           forest decline is expected to persist in the future: climate projections predict that warming will continue, involving  
47           decreased water availability for plants and more extreme weather events (Pörtner et al. 2022).

48

49           Climate-related forest dieback is a major concern for forest ecosystems because it influences species  
50           composition and structure, affects forest carbon sequestration and water cycle regulation, soil protection, refugia  
51           for biodiversity, provision of forest products, recreational uses ... (Brockerhoff et al. 2017). Forest dieback also  
52           has an effect on local or regional climate conditions by modifying the albedo and heat fluxes (Anderson et al.  
53           2011). Despite the major importance of the issue, the way forests will cope with climate change remains highly  
54           uncertain. Vulnerability assessments are done *a posteriori* most of the time, and forest managers cannot anticipate

55 massive mortality events. The choice of the tree species – traditionally based on specific ecological requirements  
56 – can no longer correspond to current climate conditions (Torssonen et al. 2015). In a context of increasing impacts  
57 of recent droughts on ecosystems in a large part of Europe (Buras et al. 2020), evaluating the mortality risk across  
58 broad areas is crucial to adapt management strategies to the new ecological conditions and make the forest more  
59 resistant and resilient to ongoing changes (Bastin et al. 2019; Bonan 2008).

60

61 Species mortality is a natural component of the forest dynamics that can be increased by different stresses.  
62 Tree decline is often described as a gradual process involving a combination of interchangeable predisposing,  
63 inciting, and contributing factors that interact at different time and spatial scales (Sinclair, 1965), sometimes with  
64 delayed effects (Lebourgeois 2007). This conceptual framework was popularised by the decline spiral in the 1980s  
65 (Manion 1981). Predisposing factors reduce tree ability to withstand a stress on the long term. Tree growth leads  
66 to overcrowding and natural mortality through self-thinning, particularly for suppressed trees or in high-density  
67 stands (Charru et al. 2012). Predisposing factors are related to tree or stand characteristics (age, competition for  
68 light, species interactions), but also poor site conditions (high temperature, low water availability, soil properties),  
69 or air pollution (nitrogen, sulphur deposition, ozone) (Brandl et al. 2020; Dietze and Moorcroft 2011; Taccoen et  
70 al. 2019). Inciting factors usually result from extreme events like drought, heat waves, frost, snow, forest fires,  
71 floods, or storms (Maringer et al. 2021). The deleterious effects of droughts and heat waves on tree fitness are  
72 probably the most extensively studied (Choat et al. 2012; Urli et al. 2013; Williams et al. 2013). Allen et al. (2010)  
73 identified more than 150 references on forest mortality driven by extreme events since 1970. The impact of inciting  
74 factors is expected to increase in the current climate change context (Hartmann et al. 2018; Schelhaas et al. 2003).  
75 Contributing factors are often insects or pathogens that cause the final decline of the trees that have already suffered  
76 from predisposing or inciting factors through hydraulic failure or carbon starvation (Maruini et al. 2017; McDowell  
77 et al. 2008). Several recent outbreaks of bark beetles are considered as some of the most severe outbreaks ever  
78 seen (Lundquist 2019). At the end of April 2019, the French National Forest Office (ONF) estimated that 60% of  
79 spruce were affected by bark beetle attacks, *versus* 15% in the usual course of events (Office National des Forêts  
80 2020<sup>1</sup>).

81

<sup>1</sup> <https://www.onf.fr/+4bd::ces-arbres-forestiers-qui-souffrent-de-la-secheresse.html>

82           The decline of silver fir or Norway spruce is not new in Europe (Maringer et al. 2021). Northeastern  
83 France already experienced severe tree decline events during the last century, during the 1916-1925 or 1943-1951  
84 periods for example. During this latter period, an up to 40 % decrease in radial growth of silver fir was attributed  
85 to drought (Becker 1987). The 1973-1981 period was also marked by another important crisis. After Germany and  
86 many countries of central Europe, severe decline was observed on several thousand hectares in the Vosges  
87 mountains (Bouvarel 1984). In 1984, an observatory network recorded that 26% of silver fir, 20 % of Scot pine  
88 and 17% of Norway spruce had lost more 20% of their needles. More mortality was observed on old trees in the  
89 east of the mountain range, and on acidic substratum whatever the altitude (Bonneau 1985; Thomas et al. 2002).  
90 Climatic stress after the 1976 drought and air pollution that increased the nutritional difficulties and led to  
91 magnesium deficiencies were identified as the main drivers of this forest decline (Elling et al. 2009; Landmann et  
92 al. 1987; Vitali et al. 2017). Following the reduction in SO<sub>2</sub> concentrations in the air and a period with more  
93 suitable climatic conditions, strong recovery was observed after 1981 (Lévy 1987). Tree decline was observed  
94 again more recently, mainly on Norway spruce and silver fir, after important drought events followed by an  
95 increase of bark beetle attacks, as in 2003 (Ciais et al. 2005) or 2018 (Buras et al. 2020). Silver fir and Norway  
96 spruce have been gradually declining in Europe since 2016, questioning managers and policy makers about the  
97 future of these species (Obladen et al. 2021). In 2019, Norway spruce represented 32 % of damage at the European  
98 scale, with an estimated wood loss of approximately 36 million m<sup>3</sup>. The countries of central Europe were most  
99 affected. Although forest decline has been extensively studied, the causes of mortality and the ecological limits of  
100 the species that trigger mortality are not well understood, and this restrains our capacity to consider the risk of  
101 dieback in forest management.

102

103           The vulnerability assessment evaluates the ability of a tree or a forest stand to tolerate a stress. The  
104 level of vulnerability varies according to the species sensitivity (its capacity to resist to changing climate), local  
105 exposure (related to the intensity of the effects of climate change), and the adaptive capacity of the species (its  
106 ability to cope with the new climate conditions) (McCarthy et al. 2001). Different approaches have been  
107 implemented for managers to facilitate forest adaptation to the new climatic conditions, e.g., recommendations by  
108 expert knowledge according to site type maps, or more sophisticated vulnerability assessment based on large  
109 databases from forest inventories or remote sensing data, coupled with mechanistic or statistical models. One of  
110 the most popular approaches is based on empirical niche models or process-based models (Coops and Waring

111 2011; Fremout et al. 2020). It simulates the suitable areas of the species according to contemporary or simulated  
112 climate. These models can be used to evaluate if the species can maintain itself under warmer climate conditions,  
113 or to track their current climate niche (Aubin et al. 2018). They have important limitations because the numerous  
114 assumptions often lead to overestimating the risk (Das et al. 2022). Vulnerability can also be estimated by  
115 modelling the level of dieback using the different factors that can alter tree fitness (Archambeau et al. 2019; Lu et  
116 al. 2019). Using this approach for spatial vulnerability assessment over broad areas remains uncertain. Although  
117 many predisposing factors are often easily available, inciting or contributing factors are scarcely available, so that  
118 predictive performances may be poor. Here we evaluated if easily available geographic information describing  
119 climate variability and evolution, and the main soil and topographic characteristics, can be combined with remote  
120 sensing images to efficiently discriminate landscape-level canopy mortality patterns at a regional scale. The  
121 challenge consists in identifying and characterising the different factors correlated with the risk of dieback,  
122 determining which of them can benefit from adaptive management to mitigate the risk, and determining whether  
123 existing maps that describe their geographic distribution can be efficient to calculate a relevant vulnerability map.

124

125

## 126 **Materials and Methods**

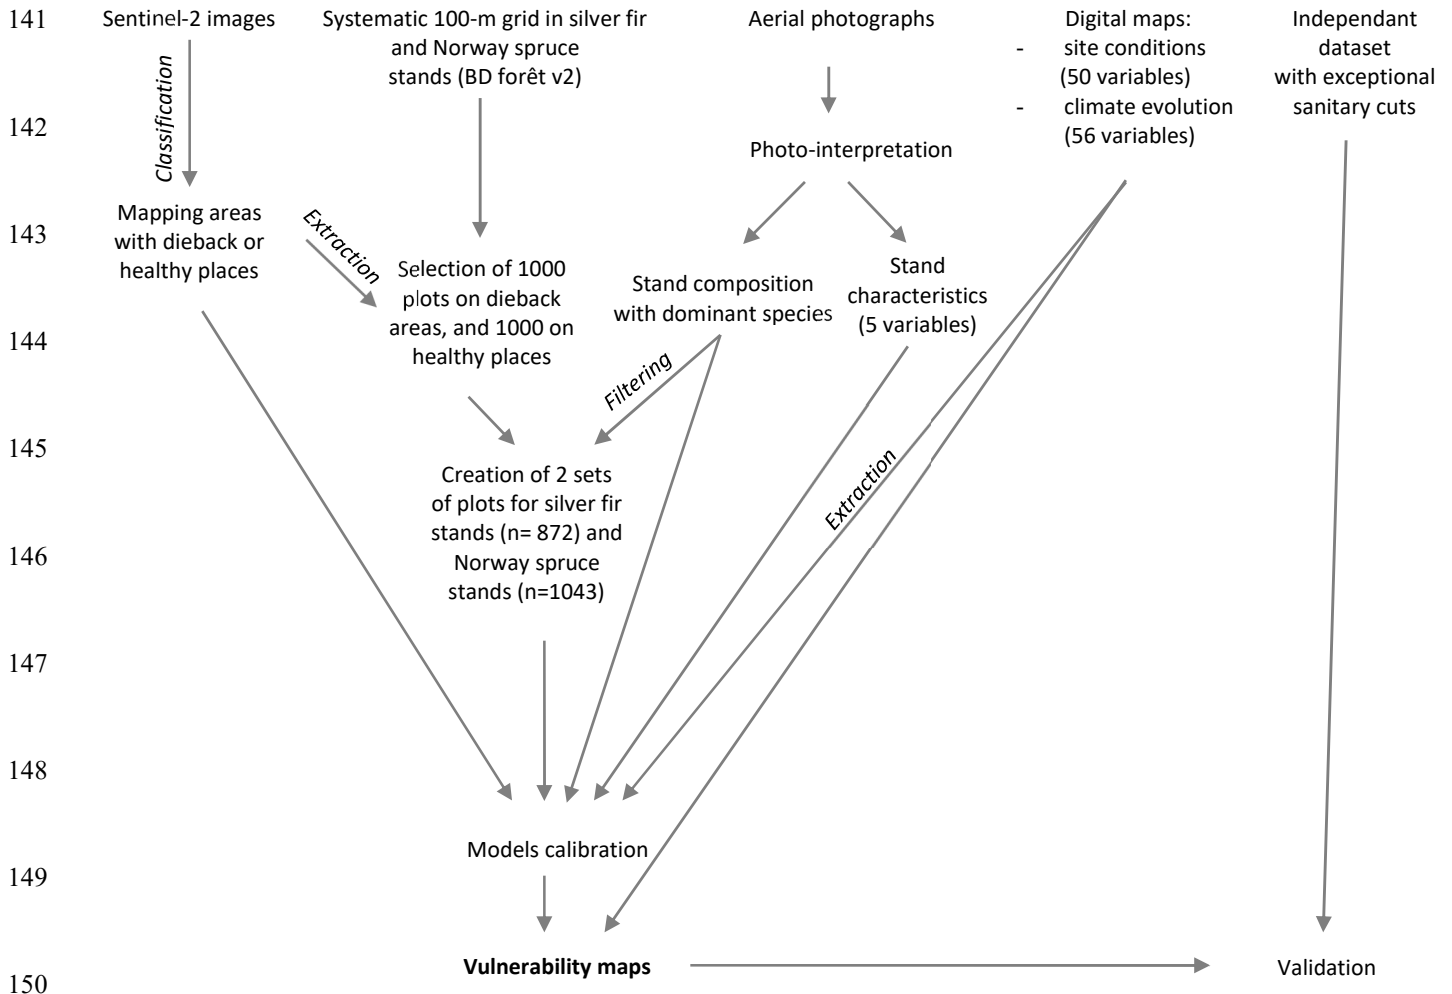

127

128 Focusing on two emblematic stand types of European mountain ranges – silver fir and Norway spruce  
129 – we modelled the tree health status and mapped tree vulnerability across an 8,900 km<sup>2</sup> area located in the Vosges  
130 mountains, in northeastern France. For each species, a dataset was built with randomised plots selected on a  
131 systematic grid, and stratified according the stand status (dieback or healthy) collected from sentinel-2 images in  
132 2019 (Fig.1). To identify the conditions that promoted decline, the plots were characterised with variables  
133 describing the site conditions (climate and soil characteristics, climate evolution) available from Geographic  
134 Information System (GIS) layers, and the stand characteristics interpreted from aerial photographs. Based on these  
135 datasets, models were calibrated and a vulnerability map was calculated at 50 m resolution for each species. The  
136 map performances were evaluated against ground survey data providing the volumes of dead wood harvested from  
137 exceptional sanitary cuts.

138

139

140

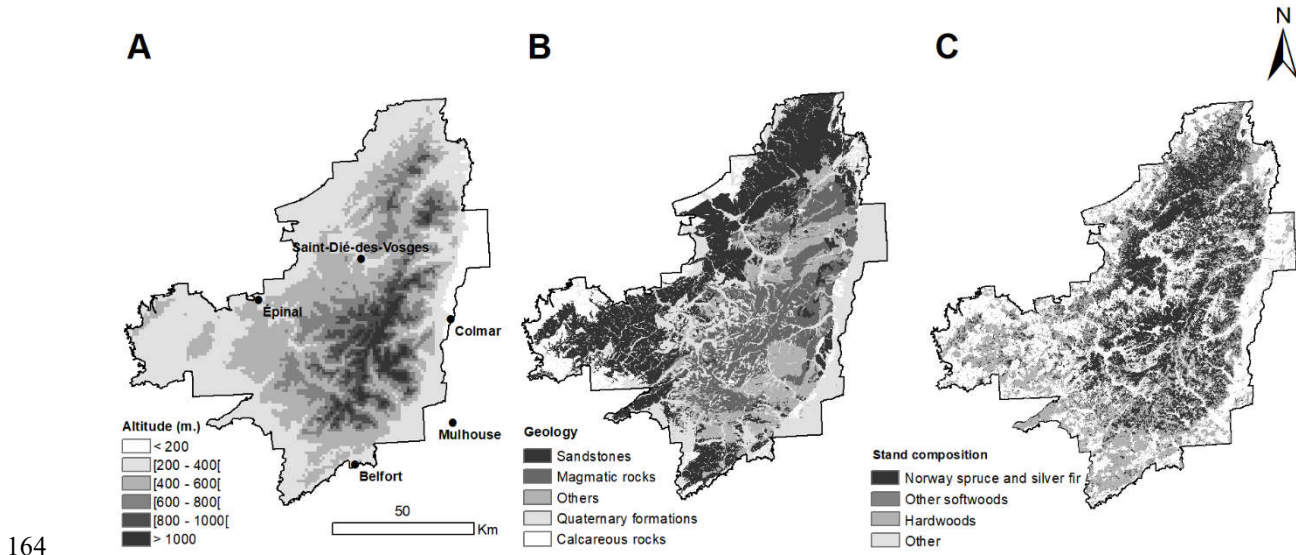

151 **Fig. 1:** Workflow illustrating the different steps leading to the construction of the vulnerability map.

152

### 153 Study area

154 The Vosges mountain range has contrasting soil and climate conditions. Altitude ranges between 200 m  
 155 in the eastern plains of Alsace to 1,424 m at the “Grand Ballon” (Fig. 2A). Rainfall varies between 500 and 2,000  
 156 mm, and mean annual temperatures between 6°C and 11°C for the 1981-2010 period (Aurelhy model, Météo  
 157 France). Geology mainly consists of acidic sandstones in the north and west of the study area, and magmatic rocks  
 158 in the centre of the mountain range (Fig. 2B). Forests cover more than 60% of the territory, and provide important

159 economic and social benefits. In the national forest inventory plots<sup>2</sup>, the most common productive tree species in  
 160 the Vosges mountains are (in order of decreasing frequency): European beech (present in 75% of the plots), silver  
 161 fir (59%), Norway spruce (53%), sessile oak (40%) and Scot pine (25%). Softwoods represent 70% of the stands,  
 162 while silver fir or Norway spruce are the dominant species in 40 % of them (IGN BD forêt v2<sup>3</sup>, Fig 2C). These  
 163 two species represent approximately 50% of the annual timber harvested in the massif (500,000 m<sup>3</sup>).

164

165 **Fig. 2:** Description of the study area: distribution of altitudes (A, IGN BD alti), simplified geology (B, BRGM  
 166 geological map) and simplified stand composition (C, IGN BD forêt v2).

167

## 168 Mapping of dieback using remote sensing data

169 We used three Sentinel-2 images level N2A downloaded from Theia website<sup>4</sup>. We selected images taken  
 170 on July 24, 2019, during a period with little cloudiness and maximum vegetation cover to avoid confusion between  
 171 the soil and dieback, and differentiate dead trees from living trees. These images were corrected for atmospheric,  
 172 topographic and geometric effects. Dieback was identified through a supervised classification by excluding bare  
 173 soil, crops, ground vegetation, urban areas, water, and forested areas. The classification was trained using 288  
 174 units presenting dieback, and validated with 1,814 others units including 285 units presenting dieback, collected

<sup>3</sup> <https://inventaire-forestier.ign.fr/spip.php?article646>

<sup>4</sup> <https://theia.cnes.fr/atdistrib/rocket/#/search?collection=SENTINEL2>

175 by photo-interpretation. The Sentinel-2 images were classified with ArcGIS Pro 2.5.0, using maximum likelihood  
176 classification (MLC, Sun et al. (2013)).

177

## 178 **Sampling strategy**

179 To avoid considering mortality patterns from other species than silver fir and Norway spruce, we used  
180 the IGN BD forêt v2<sup>5</sup> database to select vegetation units recorded on aerial photographs that showed these two  
181 species. A systematic 100-m grid was built, and 1,000 plots were randomly selected in dieback-struck areas and  
182 another 1,000 plots in healthy places.

183

184 We used aerial photos at 20 cm resolution to separate plots according to the dominant species (spruce or  
185 fir) and to identify the stand characteristics on 15-m-radius plots (seven classes, Table S1). We used photos dating  
186 back to 2018, taken prior to the dieback event, to identify the stand characteristics. To avoid the risk of confusion,  
187 only the classes where the studied species was dominant or not in mixture with the other studied species were kept  
188 for each dataset to avoid confusion (classes 1, 2, 3 and 5 in Table S1; 872 plots were selected for silver fir, and  
189 1,043 plots for Norway spruce). For each plot, the stand's status (healthy or dieback) and 112 explanatory variables  
190 were collected in a database: 6 variables described the stand characteristics, 50 described the site conditions, and  
191 56 described climate evolution.

192

## 193 **Variables describing the stand characteristics**

194 We collected six variables to describe the stand characteristics (Table1). We distinguished four levels of  
195 species mixture for stand composition (COMP, modalities 1, 2, 3 and 5, Table S1). For stand density (DENS) we  
196 differentiated dense stands from sparsely forested stands, where the ground was visible on more than 10% of the  
197 plot area. Age and structure effects (STRUCT) were recorded in three classes: old even-aged forest stand, young  
198 even-aged forest stand, and heterogenous structure. We also identified the presence of edges due to interfaces  
199 between different land uses (TYP\_EDGE: absence of an edge, edge between two forest stands of different heights,  
200 and with an open environment), and the presence of edges facing south (variable EDGE\_S). These variables were

---

<sup>5</sup> <https://inventaire-forestier.ign.fr/spip.php?article646>

201 collected using aerial photographs, on 15-m-radius plots (similar to classical forest inventory plots in France), for  
202 COMP, DENS, and STRUCT, and on 50-m-radius plots for TYP\_EDGE and EDGE\_S to consider data around  
203 the plot that could influence the stand health. Finally, we added data about the 1999 windstorm damage that had a  
204 strong impact on the Vosges mountains forests by rejuvenating some forest stands (STORM). These IGN maps  
205 differentiated areas with less than 10% damage from those with 10 to 50% damage or more than 50% damage.

	Category	Variable	Description	Source
STAND DESCRIPTION	STAND	COMP **	Stand composition: 4 levels of mixture	2018 aerial photographs
		DENS **	Stand density	
		STRUCT **	Stand structure	
		TYP_EDGE **	Presence of edges in the plot	
		EDGE_S **	Presence of an edge southward	
		STORM **	Forest damaged by the 1999 storm	IGN
SITE CONDITIONS	GEOLOGY	GEOL**	Simplified geological map	BRGM
	TOPOGRAPHY	ALT *	Altitude (m)	50 m resolution digital elevation model (DEM)
		COS ASP *	Cosine of aspect	
		SIN ASP *	Sine of aspect	
		SLO*	Slope (°)	
		CONT*	Containment in a 1,500-m radius (m.)	
		CURV*	Shape of the topographical surface (1,500-m radius)	
		TOPO*	Relative distance between ridge and talweg (m.)	
		REL_ALT*	Relative altitude between ridge and talweg (m.)

206

207 *Table 1: List of the 113 explanatory variables. All climate data were averaged over the 2009-2019 period,*  
208 *climate anomalies were differences between the 2009-2019 and 1961-1985 periods, and climate trends were the*  
209 *coefficients of regression calculated over the 1986-2019 period. wi = winter, sp = spring, su = summer, au =*  
210 *autumn, an = annual values. \* monotonic and quadratic responses were evaluated, \*\* qualitative variables.*

211

## 212 **Variables describing the site conditions**

213 Fifty variables described the site conditions. They concerned geology (n=1), topography (n=9), soil  
214 nutrition (n=2), waterlogging (n=2), energy for plants (n=12) and water availability (n=24) (Table 1). A simplified  
215 geological map (GEOL) was drawn by merging similar substrates on the local maps at 1:50,000 scale elaborated  
216 by the BRGM. Topographical indices were calculated with the IGN 50-m digital elevation model for altitude  
217 (ALT), aspect – cosine of aspect (COS\_ASP), sine of aspect (SIN\_ASP), and slope (SLO). Topographical position  
218 was represented by four indices: containment (CONT), the difference of altitude between the pixel and the average  
219 altitude within a 1,500-m radius, curvature (CURV) that describes the shape of the topographical surface in the  
220 direction of the maximum slope within a 1,500-m radius (convex, flat or concave), and the relative distance  
221 (TOPO) and altitude (REL\_ALT) of the cell along the toposequence (the ratio of the distance or altitude between  
222 the cell and the nearest ridge to the total length or the difference of altitude found in the toposequence),  
223 respectively. We characterised soil nutrition and waterlogging according to 1-km resolution maps built using  
224 bioindication techniques (Gegout et al. 1998) for soil surface pH, nitrogen nutrition estimated from the C/N ratio  
225 (CN), temporary waterlogging (TW) and permanent waterlogging (PW).

226

227 GIS layers of monthly climate variables were used to estimate energy and water available for plants over  
228 the 2009-2019 period (Table 1). Solar radiation (RAD) was calculated at 50 m resolution using Helios model  
229 (Piedallu and Gegout 2007). Monthly minimum, average and maximum temperatures and rainfall (TMIN,  
230 TMEAN, TMAX, and RAIN, respectively), were modelled and mapped at 1 km resolution (Piedallu et al. 2016).  
231 Climatic water balance (CWB) is the difference between rainfall and potential evapotranspiration according to  
232 Turc's formula (Turc 1961). One-km resolution maps of soil depth (DEPTH) and soil water holding capacity  
233 (SWHC) (Piedallu et al. 2011) were used to evaluate the soil water content (SWC, available water in the soil) and

234 the soil water deficit (SWD, the difference between potential evapotranspiration and actual evapotranspiration)  
235 according to Thornthwaite formula (Thornthwaite and Mather 1955). In addition, three indices characterising  
236 lateral fluxes in the soil were extracted from GIS layers. Kh and Kv represented the horizontal and vertical  
237 hydraulic conductivity at soil saturation, respectively, and FLUX estimated the balance between the input and  
238 output surface and subsurface fluxes (Ondo et al. 2017).

239

240 All the variables including climate were averaged over the ten years before data collection (2009-1019),  
241 *per* season (winter -wi, December to February-; spring -sp, March to May-; summer -su, June to August; and  
242 autumn -au, September to November), and over the whole year (an).

243

#### 244 **Variables describing climate evolution**

245 Two sets of calculations – climate anomalies and climate trends – were used for temperatures (TMIN,  
246 TMEAN, TMAX), and water availability (RAIN, CWB, SWC and SWD, Table 1). Climate anomalies represented  
247 the evolution between a reference period and a contemporary period. A period of ten years before data collection  
248 (2009-2019) was selected to represent the contemporary period because tree death can be triggered by the  
249 cumulative effects of many disturbances (Das et al. 2013). We selected 1961-1985 as the reference period because  
250 significant warming occurred in France after 1986 (Taccoen et al. 2019).

251

252 Climate trends were calculated for the same variables over the 1986-2019 period. For each variable and  
253 each pixel of 1-km resolution, the trends were regressed against time for the 32 studied years, and the linear  
254 regression coefficients were mapped. A positive slope indicated an increase of the climatic constraint for TMIN,  
255 TMEAN, TMAX and SWD, and a decrease for RAIN, CWB and SWC.

256

#### 257 **Modelling approach and vulnerability map calculation**

258 We modelled silver fir and Norway spruce mortality with logistic regression (McCullagh and Nelder  
259 1997). For each species, we evaluated the 113 explanatory variables through a forward stepwise procedure. At

260 each step, the variable explaining the maximum deviance was selected if it was statistically significant ( $P < 0.01$ ),  
261 and little correlated with the previously selected variables (Pearson's  $r < 0.7$ ). Because monotonic responses were  
262 expected, quadratic responses were not considered for the climate variables. However, monotonic and quadratic  
263 response curves were both evaluated for the other variables. The process ended when the selection of a new  
264 variable led to a  $d^2$  increase lower than 0.01 or a p-value  $> 0.01$ .

265

266 The receiver operating characteristic (ROC) curve was calculated to evaluate the performances (Fielding  
267 and Bell 1997), and different metrics were used: the area under the ROC curve (AUC), the kappa index, success  
268 (the rate of good prediction), sensitivity (the rate of good prediction of presence), and specificity (the rate of good  
269 prediction of absence) (Manel et al. 2001). The relative importance was calculated for each variable using the drop  
270 contribution (Lehmann et al. 2002), *i.e.*, the difference in explained deviance between the full model and a partial  
271 model when the variable was dropped. The ratio of the drop contribution of the variable over the sum of the drop  
272 contributions for all the variables gave the relative importance of each predictor.

273

274 The ROC curve also provided the optimal threshold for predicting the presence / absence of dieback. It  
275 was used to calculate the vulnerability map: upper values delineated the "high level of vulnerability" class where  
276 the stands were predicted dead by the model, while lower values were divided in three classes with equal intervals  
277 of increasing vulnerability. The map was calculated using the GIS layers describing the environmental predictors  
278 selected in the model. The best resolution among the selected variables was kept (*i.e.* 50 m). The vector layers  
279 were rasterised, and the 1km resolution maps were resampled using the bilinear interpolation algorithm. The  
280 map included four levels of vulnerability, calculated from a type stand used across the whole area.

281

## 282 **Validation dataset**

283 A map of the volumes of harvested dead wood from exceptional sanitary cuts was provided by the ONF  
284 for public forests, which cover 2/3 of the forested area of the Vosges mountains. We selected areas where one of  
285 the studied species was dominant or not in mixture with the other studied species. For 7,355 management units  
286 identified for silver fir (11,218 for Norway spruce), the average volume of dead wood was compared for the  
287 different vulnerability levels. Our vulnerability maps were drawn using 2019 satellite imagery, but dieback may

288 have occurred before or after this date in the most vulnerable areas. As a consequence, we considered both the  
289 volumes of dead trees recorded in 2019 and the sum of the volumes over the 2018-2020 period.

290

## 291 Results

### 292 Distribution of silver fir and Norway spruce dieback in the Vosges mountains

293 The classification of sentinel-2 data predicted 92% of the stand status of the validation dataset correctly.  
294 It identified 2,072 ha of dieback in the Vosges mountains, representing 1.4% of the studied stands. We observed  
295 dieback on 362 plots out of the 872 plots selected for silver fir, and on 627 plots out of the 1,043 plots selected for  
296 Norway spruce, mainly in the south and the north of the studied area (Fig. 3). Eighty-five plots were deleted due  
297 to the risk of confusion because the two species were in mixture and neither was dominant, or the stands were too  
298 young and the species were impossible to identify. The selected plots were distributed across the whole studied  
299 area: the average distances to the nearest plot were 1,015 and 932 m for silver fir and Norway spruce, respectively.  
300 These distances increased up to 1,105 and 1,356 m in the dieback stands, even though they were oversampled.

302

303 **Fig. 3:** Localisation of the stands with dieback symptoms for silver fir ( $n= 872$ ) and Norway  
304 spruce ( $n= 1,043$ ) in the Vosges mountains.

305

### 306 **Silver fir and Norway spruce dieback modelling**

307 With respective AUCs of 0.80 and 0.78 and nine variables selected, the silver fir and Norway spruce  
308 dieback models showed similar performances and near predictors (Figures 4 and 5). They combined variables  
309 describing stand composition and structure, local conditions and climate evolution to various extents according to  
310 the species (Figure S1). Environmental conditions explained 59% of the deviance for silver fir *versus* 62% for  
311 Norway spruce. Geology and stand composition were among the most important variables correlated with dieback  
312 for both species, in addition to the presence of an edge southward for silver fir and temporary waterlogging for  
313 Norway spruce. The trend in summer soil water deficit was directly linked to climate change (relative importance  
314 ranging between 6 and 7%).

315 Less dieback occurred for both species when they were in mixture in stands dominated by broadleaved  
316 species. Mortality was significantly higher in pure stands for Norway spruce (Fig. 4 and 5). More dieback was also  
317 identified in even-aged stands compared to uneven-aged or young stands when a forest edge was present (with a  
318 clear effect of a south forest edge for silver fir), and in stands that underwent little damage during the 1999 storm.  
319 Silver fir and Norway spruce mortality also responded to five environmental variables (Fig. 4 and 5). Silver fir  
320 showed a higher risk of dieback when it grew on volcanic pyroclastic rocks, neutral to basic rocks, principal  
321 conglomerate or acidic granite. Norway spruce showed lower substratum-dependent differences than silver fir did,  
322 and was more prone to dieback on sedimentary basic rocks, Voltzia or shell sandstone. Both species were also  
323 sensitive to topographical position, with a higher risk of dieback in areas near the ridges, on the south slopes, and  
324 when waterlogging was present. Finally, increased dieback was observed with soil drying. High values  
325 corresponded to a strong increase of the soil water deficit during the 1986-2019 period (Fig. 4 and 5, equations for  
326 the two species can be found in Table S2 and S3).

327 The risk of dieback linked to environmental conditions and stand characteristics varied according to the  
328 location for both species (Fig. 6, 7, B, C). The vulnerability maps<sup>6</sup> calculated at 50 m resolution (Fig. 6-D and 7-

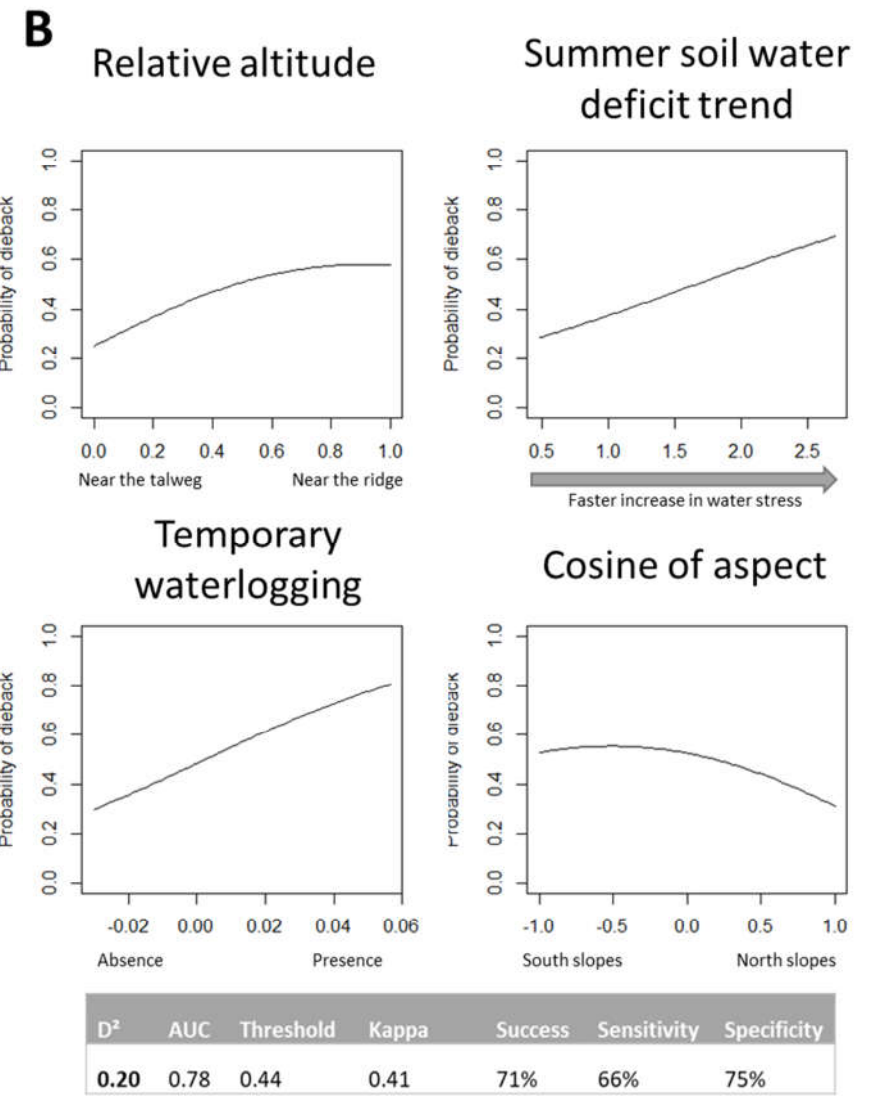

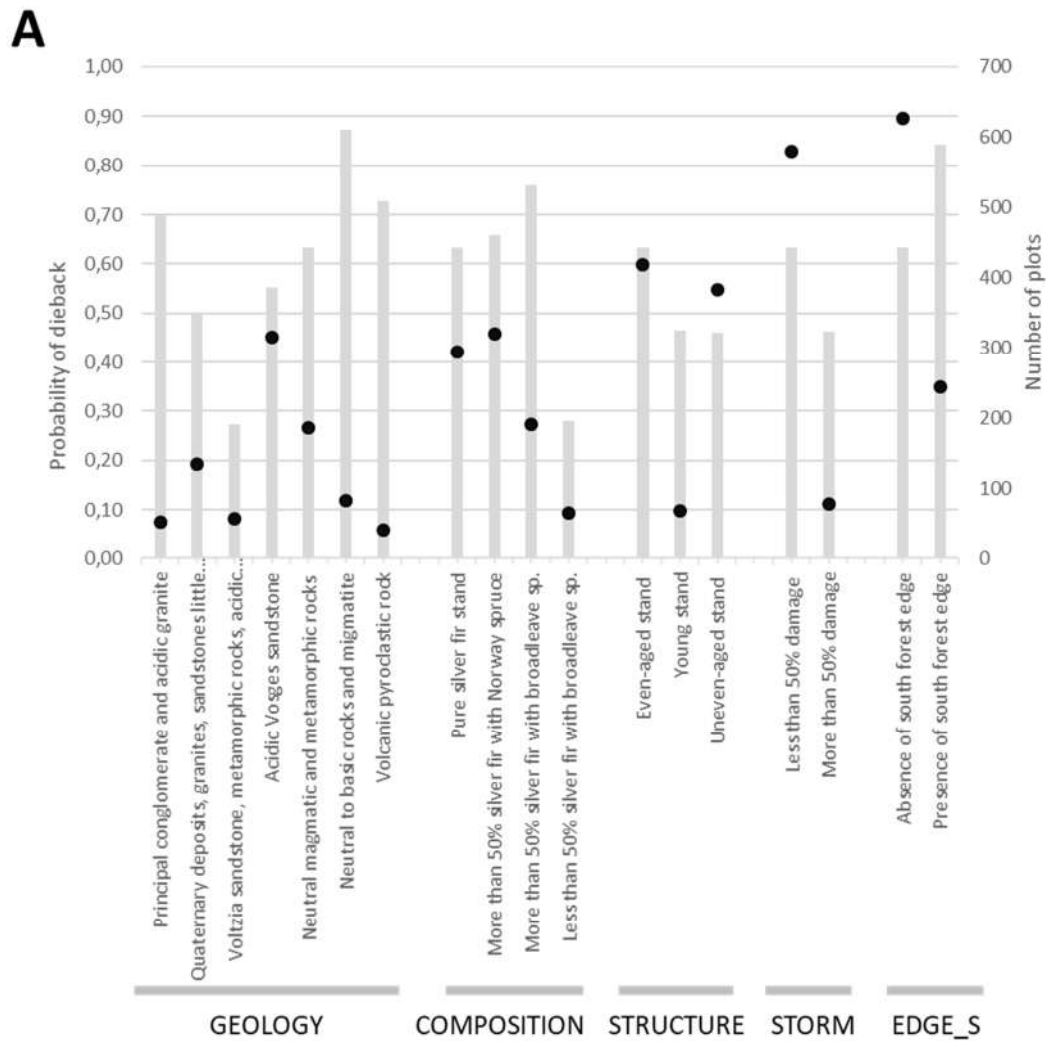

---

<sup>6</sup> The vulnerability maps for silver fir and Norway spruce dieback can be downloaded from the SILVAE website (<https://silvae.agroparistech.fr/home/>)

329 D) identified 7% of the stands with a high level of vulnerability for silver fir *versus* 33 % for Norway spruce, while  
330 83% of the stands were classified as presenting a low or very low level of vulnerability for silver fir *versus* 26 %  
331 for Norway spruce (Fig. 8). In the validation dataset (Fig. 9), we observed a significantly higher volume of dead  
332 trees for the class showing a high level of vulnerability than for the other classes. This difference was higher for  
333 silver fir (about ten-fold) than for Norway spruce (about two-fold).

334

335

336

337 **Fig. 4:** Performances of the silver fir model and differences in the probability of dieback according to the variables (A: qualitative variables, B: quantitative variables). The  
338 response curves were calculated using mean values for the other quantitative variables, and the following modalities for the qualitative variables: GEOLOGY, “Neutral  
339 magmatic and metamorphic rocks”, COMPOSITION: “Pure silver fir stand”, STRUCTURE, “Even-aged stand”, STORM: “Less than 50% damage during the 1999 storm”.  
340 and EDGE\_S (Presence of an edge southward), “Absence of a south forest edge”. Black dots in fig. 4A: numbers of plots for each modality.

343 **Fig. 5:** Performances of the Norway spruce model and differences in the probability of dieback according to the  
 344 variables (A: qualitative variables, B: quantitative variables). The response curves were calculated using mean  
 345 values for the other quantitative variables, and the following modalities for the qualitative variables:  
 346 GEOLOGY, “Vosges or intermediate sandstone, granites, gneiss”, COMPOSITION: “pure Norway spruce  
 347 stand”, STRUCTURE, “even-aged stand”, STORM, “Less than 10% damage during the 1999 storm”, and TYPE  
 348 EDGE “Absence of a forest edge”. Black dots in fig. 5A: numbers of plots for each modality.

349  
 350 **Fig. 6:** Silver fir dieback observed (A) or predicted in the sampled plots (B, C, n = 872), and vulnerability map  
 351 (D). B: Dieback explained by environmental conditions only (variables GEOL, REL\_ALT, regSWD\_su, TW and  
 352 COS\_ASP). C: modulation of vulnerability predicted on map B due to the stand characteristics (variables  
 353 COMP, STRUCT, EDGE\_S and STORM). D: The vulnerability map was calculated with the modalities  
 354 “Absence of a south forest edge”, “Even-aged stand”, “Pure silver fir stand” for the variables EDGE\_S,  
 355 STRUCT and COMP, respectively). The “high level of vulnerability” class corresponds to the values greater

356 than the optimal threshold obtained from the ROC curve; lower values were divided in three classes of equal  
357 interval (the break values are used for the legend on map B).

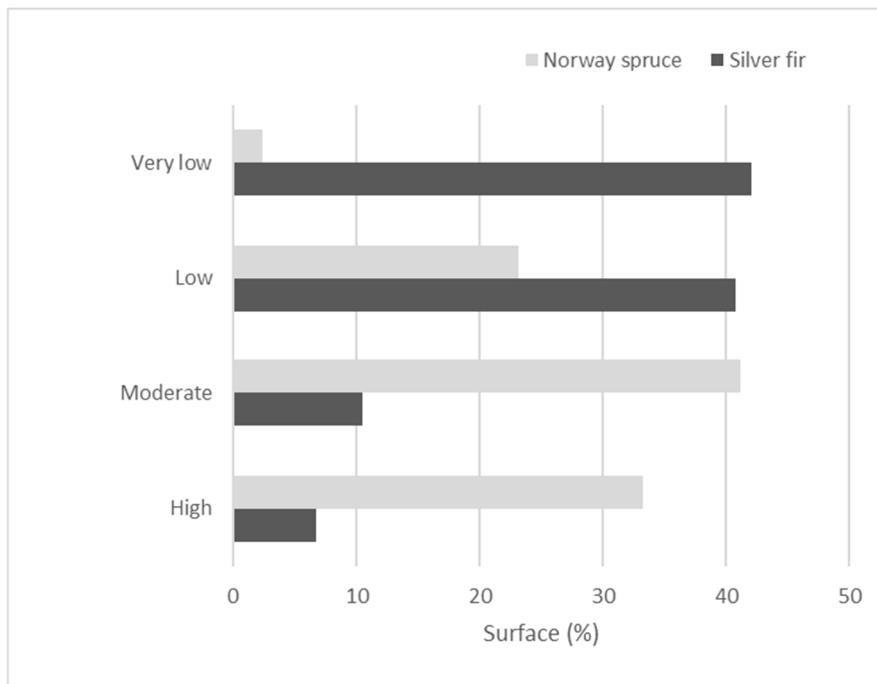

358

359

360

361 **Fig. 7:** Norway spruce dieback observed (A) or predicted in the sampled plots (B, C,  $n = 1,043$ ), and  
362 vulnerability map (D). B: Dieback explained by environmental conditions (variables GEOL, REL\_ALT,  
363 regSWD\_su, TW and COS\_ASP). C: modulation of vulnerability predicted on map B due to the stand  
364 characteristics (variables COMP, STRUCT, STORM and TYP\_EDGE). D: The vulnerability map was calculated  
365 with the modalities "pure Norway spruce stand", "even-aged stand", and "absence of a forest edge"  
366 for the variables COMP, STRUCT and TYP\_EDGE, respectively. The "high level of vulnerability" class corresponds to  
367 the values greater than the optimal threshold from the ROC curve; lower values are divided in three classes of  
368 equal interval (the break values are used for the legend on map B).

377

378

## 379 Discussion

380

### 381 A relevant method for large-scale spatial vulnerability assessment

382

383 Tree species vulnerability is an issue of growing concern round the world, but it is not new in managed  
 384 forests. After the 1911 drought in the centre and west of France, Roulleau already reported, “I see everywhere  
 385 [...], in the cooler parts like the drier ones, a lot of trees are dying [...] I have long recommended caution in the  
 386 use of Norway spruce” (Roulleau 1912). These observations concerned lowland areas, where the species was

387 introduced outside of its natural range. Conditions are different in the Vosges mountains, that benefit from colder  
388 and wetter conditions typical of middle mountains of European climate. In this area, silver fir is a native,  
389 emblematic species, while Norway spruce is considered as natural near the top of the mountain range (Guinier  
390 1959). Yet, we found large surfaces threatened by forest decline (ranging between 7% for silver fir and 33% for  
391 Norway spruce). In agreement with observations in Germany (Maringer et al. 2021), we observed a higher  
392 vulnerability of Norway spruce than of silver fir.

393

394           The levels of vulnerability estimated on the map successfully discriminated the volumes of dead trees  
395 recorded in public forests, highlighting the benefit of using easily available geographic information for the spatial  
396 vulnerability assessment of silver fir and Norway spruce dieback. Despite less precision compared to traditional  
397 ground surveys, the use of satellite imagery, photointerpretation and digital maps of environmental factors allowed  
398 us to sample a large number of plots distributed along large environmental gradients. As far as the mapping results  
399 are concerned, the better performance of silver fir compared to Norway spruce can be explained by the large extent  
400 of Norway spruce dieback across a wide variety of ecological conditions, and its higher susceptibility to bark beetle  
401 attacks (de Groot and Ogris 2019). Existing vulnerability assessment was mostly based on mortality observed the  
402 previous years (Preisler et al. 2017), changes in tree fitness visible by satellite imagery (Verbesselt et al. 2009), or  
403 the identification of weakened trees with declining growth (Suarez et al. 2004). We propose a method based on  
404 easily available geographic information, that can be implemented over broad areas, to monitor dieback of different  
405 species and over different periods of time. When data is available, it can be coupled with forest inventory  
406 information for a better description of the stand characteristics.

407

408           The selected variables were linked to stand characteristics, geology, and water availability, with a clear  
409 effect of climate change. Large differences were highlighted relatively to the latest important tree decline event  
410 experienced in Europe during the 1973-1981 period. At that time, more mortality was observed for old trees located  
411 at low or high altitudes, on acidic substratum, and in the east of the mountain range (Bonneau 1985; Thomas et al.  
412 2002). We are now observing lower mortality at high altitude, no more mortality on acidic substratum compared  
413 to the other areas, and a greater decline in the south and the north of the mountain range. These differences suggest  
414 that dieback is currently triggered by different factors than those identified during the 1980s.

415

## 416 **Importance of water availability in silver fir and Norway spruce dieback**

417 Dieback of both silver fir and Norway spruce responded markedly to water balance variables in our  
418 models. The soil water deficit trends performed better than climate anomalies or variables describing average  
419 climate. This result stresses the importance of the dynamic of soil water availability in dieback evaluation. The  
420 effects of drought on tree decline have been largely studied, but most of the large-scale studies tried to relate forest  
421 dieback to average climate conditions over long periods (Lu et al. 2019). For a given current soil water deficit, we  
422 observed that impacts on trees were greater when the deficit had sharply increased in the last years compared to  
423 areas under recurring deficit (Figure S2). These outcomes suggest that a tree of a given species can be more  
424 resilient to drought when it has grown in drier conditions, as observed by Gazol (2017) both in the north of America  
425 and Europe. They also highlight that the dynamic of water stress over time should be considered rather than average  
426 climate to forecast mortality patterns. Our understanding of the time span that should be investigated to efficiently  
427 evaluate stand vulnerability should also be improved.

428

429 Several other selected variables were related to water availability. The higher risk of dieback observed  
430 near the ridges was related to the lateral redistribution of the soil moisture along a topographical hillslope gradient  
431 (Ondo et al. 2017). Some authors reported 15 to 90% lower soil moisture near the crests compared to the valleys  
432 (Western et al. 2004). The more severe dieback symptoms on south slopes can be attributed to their higher  
433 evaporation and transpiration, and differences in thawing. Rouse et al. (Rouse and Wilson 1969) observed 50%  
434 more water stored in the north slope soils than in the south slope soils in early spring. The increasing mortality  
435 with temporary waterlogging intensity can be interpreted in different manners. Both silver fir and Norway spruce  
436 avoid compact or waterlogged soils. Waterlogging also influences the plant water uptake by affecting the spatial  
437 distribution of fine root growth and limiting their depth (Fujita et al. 2021). Finally, the presence of edges  
438 (particularly south edges for silver fir), stresses the importance of microclimatic conditions. Increased temperature,  
439 light, and wind speed that increased evapotranspiration and decreased the soil water content have been recorded  
440 from 40-50 m from the edge (Chen et al. 1995), leading to higher tree mortality rates (Mesquita et al. 1999). These  
441 predictors related to the water balance represented 51% and 48% of the explained model deviance for silver fir  
442 and Norway spruce, respectively. They all showed an increase of dieback when the water balance components  
443 shifted toward less available water for trees.

444

## 445 **Stand characteristics complement environmental predictors to explain dieback**

446           Although stand data were collected by photo-interpretation – a less accurate method than field inventories  
447 – we demonstrated that stand characteristics could also explain dieback, with similar responses of the two studied  
448 species. We observed less mortality for uneven-aged stands and mixtures. These results are in agreement with  
449 previous studies showing lower resistance to disease and damage in even-aged stands than in uneven-aged stands  
450 (Pukkala et al. 2013). The negative effect of pure stands supports the results of previous studies demonstrating the  
451 benefits of functional diversity on tree resilience (Gazol and Camarero 2016), which can be explained by  
452 facilitation and resource partitioning. Facilitation is an interaction between species that benefits to at least one of  
453 them, while resource partitioning refers to the way different species can share resources over time or across space  
454 (Mc Cook 1994). Lower Norway spruce dieback was shown in stands dominated by beech (Pretzsch et al. 2020),  
455 attributed to complementarity in water uptake. A temporal shift between the two species provided Norway spruce  
456 better resistance to drought events (Rotzer et al. 2017). These effects are greater in low-productivity sites, as  
457 already observed in the Vosges mountains (Lebourgeois et al. 2013).

458

459           We also found less dieback in young stands or stands that had suffered important damage during the 1999  
460 storm. The lower mortality of small trees compared to large ones could be attributed to differences in fine root  
461 distribution, in vulnerability to biotic factors, and to the greater water uptake difficulties of tall, large trees (Pfeifer  
462 et al. 2011). Because silver fir and Norway spruce dieback increase with basal area (Taccoen et al. 2019), this  
463 lower mortality could also be linked to limited competition for light or water in young stands. Lowering the basal  
464 area is often considered as a silvicultural tool to decrease tree vulnerability to drought and improve productivity  
465 (Pretzsch 2005). In agreement with studies demonstrating the strongest negative growth trends in pure and even-  
466 aged productive forests of conifers (Ols and Bontemps 2021), we suggest to promote an evolution of silvicultural  
467 practices toward mixed stands of uneven-aged trees to limit the stand basal area and avoid brutal cuts to limit edge  
468 effects (that can also reduce wind damage). The cumulated effect of these measures would lead to a significant  
469 decrease of the dieback vulnerability for the two studied species.

470

471 **Using the map to mitigate the effects of climate change on silver fir and Norway spruce**  
472 **forests**

473           The map makes it possible to prioritise the level of vulnerability for each studied species in view of  
474 helping forest managers to mitigate the effects of climate change. It can help to adapt the stands by forward  
475 planning, by guiding forest policies and silvicultural practices and helping to select suitable species or  
476 provenances. The map can be used directly because it instantly provides an evaluation of the vulnerability based  
477 on environmental conditions according to the geographic location. When basic information about stand structure  
478 and composition can be surveyed (using ground surveys or aerial photographs), the prediction can be improved:  
479 the effects of the stand characteristics can be evaluated, and the map gives information about the potential  
480 decreasing vulnerability if the stand characteristics allow for better tree resilience.

481

482           The future of Norway spruce and silver fir is probably strongly compromised in the most vulnerable areas  
483 identified by a high level of vulnerability on the map. These two species should be monitored in these areas on a  
484 priority basis, e.g., by raising the rate of transparency of the crown in some representative plots, or by using NDVI  
485 indices based on remote sensing data (Rogers Brendan et al. 2018). They should be preferentially cut when the  
486 first signs of degradation appear, and should not be replanted afterwards. Reforestation should rely on adequate  
487 forest regeneration promoting drought-tolerant species if available. Species more resistant to drought could also  
488 be introduced by selecting species that are visually close to those they replace in areas of high landscape interest.  
489 When the level of vulnerability is low or moderate, the strategy can be to promote a rapid evolution of silvicultural  
490 practices to adapt stand structure and composition in priority. The aim is to mitigate the effects of climate change  
491 in areas that can become highly vulnerable in the next decades. The areas with the lowest level of vulnerability  
492 would not be a priority in the first place but should also be monitored. The vulnerability map should be updated at  
493 regular time intervals to take the evolution of the soil water deficit and observed mortality changes into account,  
494 and adjust recommendations accordingly.

495

## 496 **Limitation and uncertainties**

497

498           The risk of decline was predicted efficiently although inciting and contributing factors were not explicitly  
499 considered. We expected them to be indirectly and partly taken into account by the climate variables selected in  
500 the models. The trend of the soil water deficit variable was probably influenced by the extreme drought events and

501 linked to the distribution of pathogens, which is also influenced by climate – particularly temperature (Baier et al.  
502 2007). This result was probably observed because bark beetle attacks – which are severe in the area – occur  
503 preferentially on weakened trees (Kolb et al. 2019). Data describing the dynamics of pathogen populations could  
504 probably successfully complement the variables selected in the model, but spatial data depicting their spatial  
505 distribution and evolution remains scarce (Jaime et al. 2019). The model performance could also probably be  
506 improved by including variables of extreme events and disturbances when available, e.g., wind conditions and  
507 storm frequency, drought intensity, forest fires (Carnicer et al. 2011), or air pollution (Pedersen 1998). In addition,  
508 different modelling techniques could be compared to evaluate if the map performance could be improved.

509

510           We chose a spatial approach aimed at linking spatial heterogeneity related to the site conditions and stand  
511 characteristics on the one hand with the regional patterns of dieback on the other hand. We probably under-  
512 estimated the surfaces concerned by dieback because isolated dead trees or low symptoms were probably not  
513 identified by remote sensing approaches, and the dead trees in some of the dead stands were probably felled by  
514 forest managers before the satellite images were taken. This probably decreased the model performances, but with  
515 a limited influence on the estimation of vulnerable areas, as cuts probably concern a wide variety of ecological  
516 and stand conditions. This approach should be complemented by a temporal follow-up of the dieback dynamic  
517 using time series images and requiring inventories at different periods, to better identify recent cuts of dead trees,  
518 take the effect of extreme events into account, and simulate probabilities of dieback according to future climate  
519 conditions (Knight et al. 2013; Staupendahl and Zucchini 2011).

520

521           According to the classification of sentinel-2 images, dieback observed at a specific date is a relatively  
522 rare statistical event. To overcome this limitation, the proportion of areas with dieback was oversampled by  
523 selecting 50% of plots in dieback areas to calibrate the models. This method yielded correct regression coefficients,  
524 but it increased the intercept value, so that the probability of dieback in the model outputs was overestimated (King  
525 and Zeng 2001). Therefore, the probability of dieback provided by our model should not be interpreted as real  
526 probabilities, but it makes it possible to compare the effects of the qualitative variables and to interpret the shape  
527 of the response curve for the quantitative ones. This oversampling effect was corrected for the vulnerability map  
528 by using the ROC curve, which determines the classes of increasing levels of vulnerability according to the optimal

529 statistical threshold for each species. Despite a great average distance between each plot and its nearest neighbour,  
530 further analysis could also test for an effect of autocorrelation.

531

532 The resolution of the GIS layers describing the spatial variations of the environmental predictors also  
533 probably influenced the performance of the vulnerability map (Cavazzi et al. 2013). The variables selected in the  
534 models were at different spatial resolution: 50 m for relative altitude and the cosine of aspect, 1:50,000 map scale  
535 for geology, and 1 km resolution for temporary waterlogging and the trend in soil water deficit. We calculated the  
536 map at the finest spatial resolution (i.e., 50 m) to keep the contribution of local information available in the models.  
537 The other raster variables were resampled at 50 m resolution using the bilinear method, and geology was rasterised  
538 at 50 m resolution. It would also have been possible to aggregate the 50m resolution variables at 1km resolution.  
539 These different approaches could be compared to evaluate the effect of spatial resolution on the map performance.  
540 Dieback can vary at a very local scale, so we can reasonably believe that finer resolution predictors could improve  
541 the vulnerability map. Further work could also evaluate if the spatial resolution of the different predictors can be  
542 decreased with efficiency.

543

544 We demonstrated a good correlation between the different vulnerability levels and the ground survey  
545 quantifying the volumes of dead wood. However, the data or methods used in this study have their own limitations.  
546 Validating dieback data is a tricky task because it is difficult to collect independent and relevant datasets about  
547 dead trees, which are usually rapidly harvested and do not appear in forest inventory plots. In the studied area, this  
548 level of information is available about public forests through recordings of volumes of harvested dead wood from  
549 exceptional sanitary cuts. It was first collected for each management unit by different managers, and then  
550 aggregated at the massif scale. As a consequence, uncertainties can exist due to differences or changes in the  
551 methods, or locally lacking data (mainly for private forests which cover 1/3 of the forested area of the Vosges  
552 mountains), leading to uneven data quality according to the location. However, our validation is based on a high  
553 number of observations (7,300-11,200 management units *per* species), hence a high number of replicates for each  
554 of the vulnerability classes, scattered across large ecological gradients. The smallest number of observations was  
555 172 for silver fir for the moderate level of vulnerability, and 286 for Norway spruce for the very low level of  
556 vulnerability. This large dataset limits the effect of local uncertainties on the global estimation of map performance.

557

558

## 559 **Conclusion**

560 Our results demonstrate an important impact of recent climate change that increased forest dieback by  
561 limiting water availability in Norway spruce stands, and also in silver fir stands to a lesser extent. Vulnerability  
562 maps can help to adapt forests to current new climate conditions. Harvesting trees following dieback events causes  
563 a financial loss, is a logistical challenge, contributes to pathogen infestation, and creates an important opening up  
564 of the environment that modifies microclimates and impairs future reforestation. The massive disappearance of  
565 trees could also have significant impacts on biodiversity and human activities by increasing the risk of natural  
566 hazards, preventing the preservation of water resources, and altering landscape quality on the long term. We  
567 calculated a vulnerability map for the current period; its extrapolation to future conditions remains questionable.  
568 The risk of decline will probably be influenced by the evolution of water availability in the next years, and the  
569 maps should be updated at regular intervals. In the short term, a potential succession of wet summers might limit  
570 dieback. In the long term, increasing temperatures and drought leave little hope for the future of Norway spruce in  
571 a large part of the Vosges mountains, where its decline is already widespread. The situation is more contrasted for  
572 silver fir, and the evolution of water availability in the coming years will influence its evolution. We can reasonably  
573 expect stands with a low level of vulnerability to be spared in the next decades.

574

## 575 **Statements & declarations**

576

### 577 **Fundings**

578 The Unité Mixte de Recherche (UMR) SILVA is supported by a grant overseen by the French National Research  
579 Agency (ANR) as part of the ‘Investissements d’Avenir’ program (ANR-11-LABX-0002-01, Lab of Excellence  
580 ARBRE).

581

### 582 **Competing Interests**

583 The authors declare no conflict of interest or competing interests.

584

585 **Author's contribution**

586 D.D. performed the remote sensing analysis, C.B. contributed to the GIS analysis, I.S. and J.C.G. provided  
587 bioindicated indices, R.P. provided data from exceptional sanitary cuts, M.L. and C.P. developed the study  
588 conception and design, C.P. performed the data collection, realized the analysis and wrote the paper. All of the  
589 authors read and corrected the paper, and gave their final approval for publication.

590

591 **Data availability of data**

592 The datasets analysed during the current study are available from the corresponding author on reasonable request.

830

831 **Figure S2:** Comparison of the summer SWD trend (variable regSWD\_su) for three contrasted locations over the  
 832 1986-2019 period: A) map of summer SWD trends and localisation of the three time series, B) summer SWD  
 833 time series for the 1986-2019 period. Vulnerability was most important in site n°1 (regSWDsu > 2), where the  
 834 time series showed a substantial increase of water stress from 2012, with a high probability of dieback (0.70 and  
 835 0.78 for silver fir and Norway spruce respectively, see figures 5 and 6). Site n°3 showed similar water stress  
 836 levels from 2012, but a higher one than site n°1 between 1986 and 2012. The probability of dieback was much  
 837 lower (0.15 and 0.30 for silver fir and Norway spruce, respectively), suggesting that trees were more adapted to  
 838 drought than in site n°1. Site n°2 was at a higher altitude, with little moisture stress and a low level of risk  
 839 despite a slight increase of the water deficit from 2015 (probability of dieback: 0.15 and 0.30 for silver fir and  
 840 Norway spruce, respectively).
