14 Abstract

In order to explore the role of bacteria in the alteration of stained glass windows, and especially 15 on the browning phenomenon, it is necessary to have an overview of the microbial inhabitants 16 likely to be found on this kind of material. In this study, biological samples were collected on 17 stained glass of different colors, both on site and stored in a conservation workshop. Cultivable 18 19 bacterial communities were identified by 16S rDNA sequencing. Similarity values ranged from 99 to 100% to known bacteria. Sequence analysis showed different bacterial communities 20 depending on the sampling site. The more represented genera were Arthrobacter, Micrococcus, 21 22 Paenibacillus and Bacillus. Some of the identified bacteria are known for their weathering

23 potential.

24 Keywords

25 Stained glass, bacteria, 16S rDNA, alteration, manganese, browning, weathering

26 **1. INTRODUCTION**

The conservation of stained glass windows exposed over centuries to episodes of rain and high 27 humidity implies the understanding of the weathering phenomena that undermine their stability 28 over time. The main mechanisms underlying glass alteration involve i) the interdiffusion, or ion 29 exchange, between modifier ions (mainly alkalis) and hydrogenated species (H⁺, H₃O⁺, H₂O) 30 from the environment and ii) hydrolysis of the silicate network iono-covalent bonds (Si-O-Si 31 or Si–O–Al). These mechanisms lead to the formation, at the surface, of an altered layer of glass 32 that is hydrated, porous, and alkali-depleted (Sterpenich and Libourel, 2001; Verney-Carron et 33 al., 2015, 2017; Sessegolo et al., 2017, 2018). The alkali leached from the glass further react 34 with atmospheric gasses and might form salts at the surface of the glass, such as carbonates 35 (calcite) and sulphates (gypsum, syngenite) (Lombardo et al., 2010; Gentaz et al., 2016). The 36 37 alteration kinetics depend on the environmental conditions such as hygroscopic conditions, pH, temperature, rainfall intensity and composition, as well as on the glass surface original state 38 (Wolff-Boenisch et al., 2004; Alloteau et al., 2017, 2019; Sessegolo et al., 2019, 2020; Majérus 39 et al., 2020). The composition of glass is also a key-feature (Wolff-Boenisch et al., 2004; 40 41 Cailleteau et al., 2008; Alloteau et al., 2020).

This article has been accepted for publication and undergone full peer review but has not been through the copyediting, typesetting, pagination and proofreading process, which may lead to differences between this version and the Version of Record. Another factor that should be taken into account is the effect of microorganisms. They can 42 indeed cause physico-chemical damages to the surfaces of the materials they use as a support 43 44 for living (Perez y Jorba et al., 1980; Krumbein et al., 1991; Drewello and Weissmann, 1997; Gorbushina and Palinska, 1999; Carmona et al., 2006; Rodrigues et al., 2014; Weaver et al., 45 2021). Microorganisms are also suspected to play a significant role in the widespread pathology 46 47 called "browning phenomenon". This latter appears as brown spots at the surface of the glass (Schalm et al., 2011; Ferrand et al., 2015), is caused by the oxidation of manganese (originally 48 introduced in the composition in order to obtain colorless or murrey glass (Gliozzo, 2016; 49 Bidegaray et al., 2019; Rossano et al., 2022)) and might be linked to microbiological activity 50 (Perez y Jorba et al., 1980; Orial et al., 2007). 51

52 In order to further explore the role of microorganisms in glass weathering and in the browning phenomenon, a first step is to get an overview of the inhabiting microbial populations on stained 53 glass surfaces. A few studies previously identified several species of fungi and bacteria on 54 55 stained glass windows in Germany (Rölleke et al., 1999; Schabereiter-Gurtner et al., 2001), Spain (Carmona et al., 2006; Piñar et al., 2013) and Italy (Marvasi et al., 2009). Piñar et al., 56 2013 showed that the bacterial communities on stained glass were far more diverse than the 57 fungal communities, and these communities included bacteria known to possess metabolic 58 activities able to cause biodeterioration phenomena. Thus, they concluded that the role of 59 bacteria has probably long been underestimated in the alteration of glass, compared to the easier 60 to identify mechanical effect of fungi with their hyphae leaving marks on the glass surface. 61 62 Although of importance for the study of the effect of microorganisms, these previous works often employed sampling techniques destructive for the glass substrate that discourage the 63 development of more extensive experimental sampling campaigns. Thus, no study of this kind 64 has been realized in France to date, despite the considerable stained glass heritage. Moreover, 65 in order to have a more realistic representation of the microorganisms living on stained glass, 66 the samples should be collected on site, still in their original places in historical buildings, which 67 is rarely possible due to the unreachable positions of the bays. 68

In the present work, sampling campaigns were realized mainly on colourless or murrey stained glass, both deposited and *in situ*, affected by the browning phenomenon or not, in order to identify the bacteria present and especially those likely to participate in the alteration of glass. The aim of the present study is to i) analyze the bacterial communities present on historical glass coming from four different French sites without recurring to destructive sampling, ii) identify possible bacteria involved in glass weathering and iii) collect bacteria possibly suitable for further laboratory-based studies on bioalteration of glass.

76 2. MATERIALS AND METHODS

77 2.1 Sampling sites

Samples were collected *in situ* from the Royal Chapel of Versailles Castle (Île-de-France region) and from the church of Saint-Etienne in Bar-sur-Seine (Grand-Est region) during their restoration campaigns giving an access to the windows with scaffoldings. A few panels of stained glass coming from Lachalade Abbey church (Grand-Est region) and Wissembourg Abbey church of Saint-Pierre-et-Saint-Paul (Grand-Est region) were also sampled in a conservation workshop (Atelier Parot, Bourgogne Franche-Comté region) shortly after their removal from the buildings and before proceeding to their conservation treatments (Figure 1).

Concerning the *in situ* samplings, both Versailles and Bar-sur-Seine have a warm temperate climate, with an annual medium temperature around 12 °C, with respectively 682 and 661 mm of rainfall and 1902 and 1894 hours of sunlight (data MétéoFrance). Different locations were 88 sampled in order to eventually observe differences in the microbial population by changing the 89 exposure conditions. The factors taken into account were the color of the glass pieces 90 (colourless and murrey glasses were preferentially sampled), the internal or external 91 localization of the sampled windows and the geographical exposure. Special attention was 92 given to realize the sampling on original not restored glass pieces when the information was 93 available. These strategies were obviously subjected to the limitations given by the access to 94 the stained glass and were variable depending on the sampling site.

95 The Royal Chapel in Versailles Castle was constructed between 1700 and 1710 at the end of 96 the reign of Louis XIV. Five samples were collected on the external face of the site coming 97 from different expositions: three samples at North-East (B11-2p.68, B11-2 p.11, B11-1 p.15) 98 and two samples at South (B4-2 p.68, B4-1 p.15). Three additional samples were collected on 99 the internal face: two from the north (B91-2 p.17, B91-2p.17 blue) and one from the south (B4-97 2 p.17). The sampling was carried out on wide unpainted colorless sheet of glass except for one 99 blue stained glass panel located in the borders of the bays (Figure 2 A), B), C)).

The Church of Saint-Etienne of Bar-sur-Seine and its stained-glass windows were realized 102 during the 16th century. An equal number of samples were collected both on external and 103 internal faces (seven samples each) with different expositions : nine samples from the north 104 (B101_LD_P7_FI, B101_LC_P7_FI, B101_LD_P7_FE, B101_LC_P7_FE, B103_R16_FE, 105 B103 LC R9 FI, B103 LD P4 FE, B103 R16 FI, B103 LD P3 FI), two samples from the 106 east (B100_LD_P7_FI and B100_LD_P7_FE) and three from the south(B104_R17-FI, 107 B104_R17_FE, B104_LB_P4_FE). The glass pieces in this site are mainly painted and 108 109 samplings were realized on unpainted surface whenever it was possible (Figure 2 D), E), F)).

110 Concerning the stained glass panels in the conservation workshop, one panel was from 111 Wissembourg and three others from Lachalade. Storage conditions in the workshop were 112 around 18-20 °C and 50 % relative humidity (RH), in a dark sheltered space with occasional 113 artificial and natural lightening. The stained glasses from these two sites both suffer from the 114 browning phenomenon, thus the samples were collected on the brown spots.

The Abbey church of Wissembourg is a gothic church and its stained glass windows date from the 13th century. Four samples were collected, two on the internal face and two on the external face of the glass (tracery BOR3, originally with East exposition).

The construction of the Cistercian Abbey of Lachalade lasted from the 12th to the 14th century and its stained glass date from the 14th century. Two samples, both on the internal face, for each of the three panels chosen for this study (B5P4, B0R4, B6P3, all of them originally with East exposition) were collected (Figure 2 I), J), K)).

122 The complete list of the collected samples is available in Table 1.

123 **2.2** Sampling methodology, cultivation and isolation of bacteria

124 Each sample was taken with a sterile cotton swab (sampled surface approximatively 1 cm^2),

then inoculated in Petri dishes (diameter 8 cm) containing Lisogen Broth supplemented with

agar (5 g/l NaCl, 5 g/l yeast extract, 10 g/l peptone). The samples were kept at environmental

temperature following sampling, and only a few hours elapsed from swabbing to cultivation.

128 The inoculated Petri dishes were incubated at 30 °C for 3 days. Then, bacterial strains that

developed on Petri dishes were separated through sub-cultures (Leplat et al., 2017, 2020). The
 isolated bacterial strains were identified to the species level through molecular identification.

131 **2.3 DNA extraction, PCR amplification and sequencing**

DNA (deoxyribonucleic acid) was extracted as described by (Edel et al., 2001). fD1 and rP2 132 primers were used to amplify the 16S ribosomal DNA (16S rDNA) region (Weisburg et al., 133 1991). PCR was performed in 25 µl reactions, with 1.5 µl of each 10 mM primer (Eurogentec, 134 Seraing, Belgium), 1 µl of template DNA, 0.2 µl of Taq DNA polymerase 5 U/µl (Invitrogen, 135 Carlsbad, USA), 2.5 µl of 10X Taq DNA polymerase buffer, 0.75 µl of MgCl₂ 50 mM, 2.5 µl 136 137 of 2 mM dNTPs (Thermo scientific, Waltham, USA) and 15.05 µl of distilled sterile water. Amplifications were performed on a 5 PrimeG thermocycler (Antylia Scientific, Vernon Hills, 138 USA) with the following parameters: a 5 min step at 94 °C, followed by 35 cycles at 94 °C for 139 30 s, at 56 °C for 45 s, and at 72 °C for 90 s, and a final 10 min extension at 72 °C. PCR 140 products were sequenced by Genoscreen (Lille, France) using the same primer set. Isolates were 141 identified by BLASTn comparison to the NCBI GenBank database (Altschul et al., 1990; Clark 142 et al., 2016). The generated sequences were deposited in the Genbank database under the 143 numbers OP574250 to OP574343 (Tables S1 to S6 in Supplementary Materials). 144

145 2.4 Data treatment

2.4.1 Sequence alignment and phylogenetic analysis 146

A phylogenetic tree was built to compare the isolated strains to reference strains known to 147 perform manganese oxidation. The sequences of a too poor quality were not included in the 148 tree. The sequences related to reference strains (Yang et al., 2013) were downloaded from the 149 NCBI GenBank database. Multiple sequence alignment was performed using the FFT-NS-2 150 alignment strategy from the MAFFT v. 7 web server (Katoh et al., 2019). The uninformative 151 gaps and ambiguous regions were removed using the Gblocks program v. 0.91.1 implemented 152 in the NGPhylogeny.fr service(Talavera and Castresana, 2007; Lemoine et al., 2019; Leplat et 153 al., 2021). The maximum likelihood (ML) analysis was performed using the PhyML software 154 with a GTR model of nucleotides substitution, with 100 bootstraps to verify the branches 155 156 robustness (Guindon et al., 2010).

2.4.1 Beta diversity of bacterial communities 157

The β -diversity, i.e. the diversity of the bacterial communities between samples, was assessed 158 through Principal Coordinate Analysis (PCoA, package ape; function pcoa; (Legendre and 159 Gallagher, 2001)) based on the determination of the Bray-Curtis distance (package vegan: 160 function vegdist; method bray; (Legendre and Legendre, 2012)) using R 4.0.1 (R core team, 161 2014),. The significance of differences obtained between sampling groups was assessed with 162 PERMANOVA (999 permutations; package vegan; function adonis; (Anderson, 2001)). The 163 proximity between both sampling sites and between identified species was assessed through 164 hierarchical clustering based on the Bray-Curtis distance (package stats; function hclust, 165 method complete; (Legendre and Legendre, 2012)) and the results were presented through an 166 heatmap representation. 167

3. RESULTS 168

- 102 bacterial strains were isolated and identified by sequencing: 23 strains were isolated from 169
- Versailles samples, 47 from Bar-sur-Seine samples, 17 from Wissembourg samples and 15 170
- 171 from Lachalade samples (Tables S1 to S6 in Supplementary Materials).
- The *in situ* sampling sites were characterized by different comparative abundances of recovered 172
- bacteria depending on internal face (IF) and external face (EF). For the site of Bar-sur-Seine, 173
- seven samples were made on the internal face (IF) and seven samples on the external face (EF). 174
- The majority of bacteria that developed on culture media came from the external face of the 175 stained glass (31 from EF and 16 from IF). For the site of Versailles only 3 samples out of 8
- 176

were collected in IF and 5 bacterial strains developed from them, while 18 bacterial strainsdeveloped from the 5 samples collected on EF.

Most of the sequences showed at least 99 % of similarity with the sequences given in GenBank, 179 and were clearly identified at the species level. Other sequences also showed a high similarity, 180 but were only identified at the genus level because of the phylogenetic proximity between 181 several species regarding the 16S rDNA. Thus, these bacteria were grouped in "clusters" for 182 the statistical data treatment. For example, the Paenibacillus amyloliticus cluster grouped 183 bacteria for which the species was impossible to differentiate among 6 phylogenetic close 184 species. Finally, some sequences presented lower similarity percentages because of a poor 185 quality of these sequences, but they allow to identify the kind of bacteria without a certain 186 identification (<97 % of similarity). 187

The bacterial communities detected on the sites of Bar-sur-Seine and Lachalade were similar 188 based on bacterial Phyla, with a majority of Actinobacteria and lower percentages of 189 Proteobacteria and Firmicutes, but with inversed proportions (Fig. S1 in Supplementary 190 Materials). In Bar-sur-Seine, 66 % of the bacteria were Actinobacteria, 19 % were Firmicutes 191 and 15 % were Proteobacteria. In Lachalade, 67 % of the bacteria were Actinobacteria, 20 % 192 were Proteobacteria and 13 % were Firmicutes. The abundance of recovered bacteria was 193 completely different in Versailles and Wissembourg sampling sites. In Versailles, 87 % of the 194 bacteria belonged to the phylum of Firmicutes, 9 % to Actinobacteria and 4 % to Proteobacteria. 195 Concerning the site of Wissembourg, 100 % of the identified bacteria were Actinobacteria. 196

The most frequently isolated bacterial species belonging to Actinobacteria encountered in this 197 198 study were Arthrobacter spp. and Micrococcus spp., while Paenibacillus spp. and Bacillus spp. were the most frequently isolated species belonging to Firmicutes. Isolated α -Proteobacteria 199 were Sphingomonas spp. and Agrobacterium spp. for example, while γ -Proteobacteria were 200 Pantoea spp., and Psychrobacter spp. (Tables S1-S6 in Supplementary Materials). The 201 202 phylogenetic tree displaying the identified bacteria together with some Mn-oxidizing bacteria from the literature showed that Arthrobacter crystallopoietes, which was only isolated from the 203 204 stained glass of Wissembourg and represented all the strains isolated from this site, was the only recovered species related to known Mn-oxidizing bacteria (Fig. S2 in Supplementary 205 Materials). In particular, Bacillus spp. isolated on stained glass in this study seemed 206 phylogenetically different from the reference Bacillus spp. known to be Mn-oxidizing. 207

The Principal Coordinates Analysis (PCoA) showed that the samples were generally grouped depending on the origin of the stained glass (Fig. 3). The PERMANOVA test associated to this PCoA confirmed that the sampling site had a significant effect on bacterial community composition. Conversely, the PCoA expressed no difference between sampling areas in external or internal face.

- Bar-sur-Seine and Lachalade represent two distinct groups in the PCoA analysis (Fig. 3).
- However, their proximity highlights similarities that can be explained in terms of Phyla distribution.
- 216 The samples from the Versailles site and the samples from Wissembourg formed two different

and distant groups isolated from the other two sites. However, one sample from Versailles was

218 positioned next to the group of Lachalade and Bar-sur-Seine and two external samples from

219 Versailles (13 and 14) were also distant from the other Versailles samples.

The hierarchical clustering study also underlined the importance of the original buildinglocation factor in the composition of bacterial communities (Fig. 4). The communities from

Versailles and Wissembourg being clearly separated from the ones coming from Lachalade and 222 Bar-sur-Seine and from each other. Bacterial communities in Versailles samples were strongly 223 affected by the predominance of the *Paenibacillus amyloliticus cluster*, while samples from 224 Wissembourg site were strongly affected by the presence of Arthrobacter crystallopoietes, this 225 species being the only one identified from this site, and the heatmap showed a low bacterial 226 227 diversity for these two sites (Fig. 4). On the contrary, the sites of Bar-sur-Seine and Lachalade had more diversified bacterial communities. The dendrogram on the columns gives the 228 proximity among the different bacterial clusters. Some clusters were specific to certain sites 229 like A. crystallopoietes for Wissembourg and P. amyloliticus for Versailles. Other clusters, like 230 the Micrococcus luteus cluster, were more transversally distributed and were recovered in 231 samples from Versailles, Lachalade and Bar-sur-Seine. This result explained why one sample 232 from Versailles superimposed with the group of samples from Lachalade and Bar-sur-Seine in 233 234 the PCoA study (Fig. 3).

235 **4. DISCUSSION**

4.1 Bacterial diversity on the sampled stained glass

The results showed that the bacterial communities on stained glass were different depending on the geographical localization of the monuments. The differences between the sites of Bar-sur-Seine and Versailles can mainly be explained by different surrounding environments, as the two sites have almost identical weather conditions through the year, with an annual average temperature of 12° C, \approx 700 mm of rainfall, and \approx 1900 hours of sunlight.

The site of Versailles showed a predominance of *Paenibacillus* species, with a few *Micrococcus, Pantoea*, and *Bacillus. Paenibacillus* species are often associated to soil and plant roots (Grady et al., 2016; Cho et al., 2017; Jeong et al., 2019) and their presence might be explained by the proximity to the Versailles gardens surrounding the Chapel.

The site of Bar-sur-Seine shows more variability among the identified species. This site was 246 particularly chosen to investigate the difference between bacterial communities depending on 247 the internal or external exposure of the sampled surface. Thus, the same number of samples 248 were collected in internal and external exposition. The results showed that more 249 microorganisms developed on the Petri dishes when sampled on external faces (31 isolates out 250 of 7 samplings in external face versus 16 isolates out of 7 samplings in internal face). This result 251 is however to be taken cautiously because a bias can be introduced by the cultivation step: more 252 non-cultivable bacteria could be present in internal face and would therefore not have been 253 detected in this study. Even though this observation is not statistically supported, this finding 254 could suggest that the external face of in situ stained-glass windows is more prone to 255 microbiological contamination caused by the transport and deposition of microorganisms 256 through the atmospheric agents. This could be supported by the presence on the external face 257 of bacteria associated to soil and plants, like for example the genera Paenibacillus, 258 Agrobacterium, Agreia, Plantibacter and Kocuria (Leyval and Berthelin, 1989; Takarada et al., 259 2008; Tuo et al., 2019), probably coming from the surrounding vegetation, the St. Etienne 260 church being located in a rural area. On the contrary, species on the internal face, bacteria 261 mainly belonged to the Sphingomonas, Micrococcus, Staphylococcus and Arthrobacter. The 262 263 only work to our knowledge that attempted to differentiate the bacterial communities from internal and external faces of stained glass was performed by Marvasi et al., 2009. They also 264 isolated cultivable bacteria and they only identified bacteria belonging to Firmicutes phylum 265 (Bacillus, Paenibacillus) from the external faces of the windows, while no Firmicutes were 266 found on the internal face of the windows, suggesting a different microbial presence in the 267 confined environment of the Church. Our study did not display such contrasted results. 268

Firmicutes were identified on both external and internal faces. However, in Bar-sur-Seine, no 269 Paenibacillus nor Bacillus were found in the internal face, although they were detected on the 270 external face. The only Firmicutes recovered from internal face were Staphylococcus spp. 271 which are generally linked to the presence of humans in the Church (Gorbushina et al., 2004; 272 Otto, 2009; Rakotonirainy et al., 2016). Moreover, in Versailles, Paenibacillus spp. were found 273 274 both in external and in internal face, but this might be explained, as stated before, by the close proximity to the gardens and the frequent air exchange with the exterior related to the masses 275 tourism that make Versailles's site a special one, allowing the penetration of plant-associated 276 bacteria also in the interior of the building. 277

The bacteria from the genus Frigobacterium, Psychrobacter glacincola and Brachybacterium 278 arcticum isolated from the site of Bar-sur-Seine both in internal and external face (preferentially 279 in the northern exposition) are associated to tempered and cold environments such as marine 280 environments and hypogeum (Bowman et al., 1997; Agogué et al., 2005; Sprocati et al., 2008; 281 Ettoumi et al., 2016), which suggests that they can resist to ample temperature variations. This 282 characteristic is compatible with microorganisms living on stained-glass windows, exposed for 283 example to low temperature and atmospheric agents during winter. Some of the identified 284 bacteria are halotolerant (i.e. resistant to the presence of salts) and they were previously found 285 on archaeological walls and hypogeum (Saiz-Jimenez and Laiz, 2000; Carrillo-González et al., 286 2016; Grottoli et al., 2020). These characteristics are also compatible with the "system stained-287 glass window" where salts (secondary phases) can be formed during the glass alteration process 288 by reaction of leached glass elements with atmospheric components (Lombardo et al., 2010; 289 Gentaz et al., 2016; Majérus et al., 2020). 290

The panels coming from the site of Lachalade were only sampled on the internal face. The 291 species identified for this site correspond mainly to the genera Micrococcus, Agrobacterium, 292 Bacillus (the three of them are considered plant-related species) and Arthrobacter. The genus 293 Arthrobacter is composed of heterotrophic species ecologically diverse and with metabolic 294 versatility and adaptability (Cacciari and Lippi, 1987; van Waasbergen et al., 2000). At a first 295 observation, the sites of Lachalade and Bar-sur-Seine share some similarities concerning the 296 identified Phyla, but the PCoA that takes into account the information of the species, allowed 297 discriminating at a finer level the communities from Lachalade and Bar-sur-Seine. The 298 similarity between these two sites was given by the presence of bacteria from the genus 299 Arthrobacter and Micrococcus present in both sites and representing the majority of the 300 identified genera on Lachalade panels. 301

Wissembourg panel was sampled on the two faces (internal/external). The only bacterial species identified on this panel was *Arthrobacter crystallopoietes*, belonging to the Actinobacteria Phylum. Numerous isolates of this species were recovered from both faces of the panel. *Arthrobacter crystallopoietes* is known for its ability to survive to extreme desiccation and long starvation (Ensign, 1970; Boylen, 1973), which are conditions compatible to an "extreme environment" such as stained-glass windows.

Independently from the site, and as already noticed in the case of Bar-sur-Seine, some bacteria found on stained glass are typically associated to the natural flora of human skin such as *Staphylococcus hominis, Staphylococcus epidermidis, Acinetobacter lwoffi* (Gorbushina et al., 2004; Regalado et al., 2009; Rakotonirainy et al., 2016). Their presence was probably caused by the manipulation of the stained glass (for example during the transportation of the object for the ones in the workshop), or simply by the presence of the public in their direct environment

as they were mainly found on internal face samplings.

Several species identified in this study were previously identified on other cultural heritage 315 sites. Bacillus muralis was first described on mural paintings (Heyrman and Swings, 2001) and 316 it has since been found on other mural paintings but also on organic materials (Pepe et al., 2010; 317 Pangallo et al., 2013). In the same way, Arthrobacter parietis, Arthrobacter tumbae, 318 Arthrobacter crystallopoietes, Bacillus simplex, Micrococcus luteus, Arthrobacter agilis and 319 320 different species of Paenibacillus were previously found on mural paintings, stones and stained glass (Heyrman et al., 1999, 2000, 2005; Rölleke et al., 1999; Heyrman and Swings, 2001; 321 Gorbushina et al., 2004; Marvasi et al., 2009; Pangallo et al., 2009; Urzì et al., 2010; Piñar et 322 al., 2013; Mihajlovski et al., 2017; Tescari et al., 2018). Concerning stained-glass windows, 323 Rölleke et al., 1999 identified bacteria on German sites belonging to the Flexibacter, 324 Nitrosospira, Arthrobacter, Micrococcus, Streptomyces, Frankia and Geodermatophilus. The 325 bacteria identified by Marvasi et al. 2009 belong to Bacillus, Paenibacillus, Arthrobacter and 326 Leucobacter genera. Pinar et al. 2013 identified complex bacterial communities belonging to 327 Methylobacterium, Ralstonia, Acinetobacter, Micrococcus, Prevotella, Kocuria, Delftia and 328 Arthrobacter. 329

The comparison of the results from these previous works and the present work allow to identify a subgroup of bacterial genera recurrently found on stained-glass windows, such as the *Arthrobacter, Micrococcus, Bacillus* and *Paenibacillus*.

It is important to remind that glass composition changes through the ages due to the raw 333 materials used for glass production (Tite et al., 2002; Shortland et al., 2006; Verità, 2006; 334 Adlington et al., 2019). In this study, it was not possible to associate the microbiological 335 336 sampling with a systematic study of the composition of the glass because sampling of the glass 337 material was not allowed. This factor then could not be fully considered but it definitely deserves to be investigated because i) the substrate composition can cause a selection of the 338 bacterial communities' development (Uroz et al., 2015; Kelly et al., 2016; Colin et al., 2017; 339 Plvmale et al., 2021), and ii) reciprocally, different glass compositions are affected diversely 340 by the presence of microorganisms and their exudates (Koestler et al., 1987; Drewello and 341 Weissmann, 1997; Rodrigues et al., 2014; Valbi et al., 2022). However, some considerations 342 can be done on the basis of what is known about the evolution in the use of glass composition 343 in France through the ages, and on the basis of the color of the sampled glass pieces. In Medieval 344 times, stained glass windows in northern France/central Europe are mostly made with potash-345 lime glass because of the use of plant ashes as a flux, even if some regional differences can be 346 observed (Douglas and Frank, 1972; Dungworth, 2012; Adlington et al., 2019). In the 12th-13th 347 centuries, stained-glass windows like the ones from Wissembourg were made with glass with 348 low silica (around 50 wt% SiO₂) and high amounts of calcium and potassium (around 15 wt%) 349 of K₂O and CaO each) (Sterpenich and Libourel, 2001). In the 14th century, stained-glass 350 windows like the ones from Lachalade and Bar-sur-Seine generally have a similar composition 351 to the previous centuries, but with silica content slightly increasing, and with higher amounts 352 of calcium and lower amounts of potassium (Adlington et al., 2019). In the late medieval time, 353 beginning from the 15th century, the silica rate increases, as well as lime content, while 354 potassium and sodium concentrations decrease to obtain High Lime Low Alkali glass (HLLA) 355 (Schalm et al., 2007; Dungworth, 2012; Trichereau et al., 2022). In the 18th century, glass 356 production is completely changing with the introduction of glass casting. In stained-glass 357 windows like the ones from Versailles, glass sheets may have been produced by blowing or by 358 359 casting as both techniques coexisted (Hamon, 2005). In their composition, the amounts of silica rise up to 65-70 wt%, with varying amounts of CaO, and K₂O (Schalm et al., 2007; Dungworth, 360 361 2012).

The similar bacterial communities between Lachalade and Bar-sur-Seine might then be explained by a similar substrate, since both these sites have stained glass dating from the 14th century. Nevertheless, this kind of comparison should be supported with more data in future works.

If the composition of the studied stained glass is not known, the different colours of the glass 366 on which bacteria were preferentially sampled are also reflecting chemical variations in the 367 composition of the glass substrates. Colourless and murrey glasses were preferentially targeted 368 in this study, in order to improve the understanding of the browning phenomenon occurring on 369 colourless and murrey glass pieces, wich are likely to contain Mn. Nevertheless, two samples 370 were collected for comparison on a blue glass at Bar-sur-Seine, while one sample was collected 371 on a painted glass at Versailles (see Table 1). It is worth noticing that the only sample collected 372 on a painted glass (blue paint, in internal face of the Versailles windows) did not induce the 373 development of cultivable bacteria. This could be attributed to the already discussed factor of 374 375 "internal face", but another possible explanation could be the presence of the paint and its richlead-chemical composition (Schalm et al., 2009) that could have an inhibiting effect on 376 microbial colonization. Similarly, no cultivable bacteria were detected in the sample collected 377 on blue glass (unpainted, but colored in the mass) in internal face in Bar-sur-Seine, while the 378 sample collected on external face on the same blue glass only showed the presence of 379 Arthrobacter parietis, a strain that was previously identified on comparable environments like 380 mural paintings. 381

By contrast, the identification of only one species, *Arthrobacter crystallopoietes*, a bacterial strain known for its Mn-oxidizing ability (Tebo et al., 2005; Yang et al., 2013) on the murrey glass from the Wissembourg panel (Douglas and Frank, 1972; Trichereau et al., 2022) could be explained by the presence of Mn in the glass, introduced as a chromophore in the glass composition (Gliozzo, 2016; Bidegaray et al., 2019; Rossano et al., 2022).

The composition of bacterial communities could also change with time (the bacterial communities living on the stained-glass windows a hundred or two hundred years ago may differ from the ones living on stained glass today) and with environmental conditions. This could especially be a concern for the sampling realized on the stained glass removed and stored in the conservation workshop, which represents a change of environmental conditions as compared with stained glass *in situ*.

4.2 On the sampling and identification methodology

Only a few studies in the past were able to collect microbiological samples on stained-glass 394 windows, using different methodologies. Rölleke et al., 1999 identified bacteria on German 395 stained glass by sequencing excised bands of 16S rDNA fragments after Denaturing Gradient 396 Gel Electrophoresis (DGGE). For that study, 5-10 mg of glass were dissolved in water and 397 subjected to freeze-thawing cycles in order to lyse the bacterial cells for DNA extraction. Piñar 398 et al., 2013 grinded 0.2-0.25 g of glass from Spanish stained glass to obtain a powder that was 399 added to the lyse matrix for DNA extraction, the 16S rRNA fragments were then identified by 400 DGGE. Marvasi et al., 2009 used a non-destructive sampling method with contact plates filled 401 with Nutrient Agar with 1 % glucose for the sampling of microorganisms on an Italian stained 402 403 glass, then they obtained isolated strains by subculture and identified the bacteria through DGGE of 16S rRNA fragments and sequencing. In the present work, a non-destructive 404 sampling method was chosen as well, allowing to collect a limited amount of biological sample, 405 but compatible with the difficulties of accessibility to the bays. The protocol applied here is 406 simple and is standardly used on other kinds of monuments (Leplat et al., 2019) and can be 407 easily used in the future in a wider project in order to extend the knowledge of microorganisms 408

living on French stained-glass windows. However, the culture of the microorganisms results in
a loss of information since only 1% of microorganisms are cultivable (Laiz et al., 2003). This
limit has to be considered and the protocol could be completed by direct DNA extraction from
the cotton-swab followed by metagenomic analyses. However, the results obtained in this study
were in agreement with the existing literature, and the most frequently genera found on stainedglass windows on this basis could be identified as *Bacillus, Paenibacillus, Arthrobacter* and *Micrococcus*.

416 **4.3 Bacteria and weathering potential**

The microorganisms identified on stained glass windows may not all be involved in alteration 417 phenomena. In the environment, bacteria, fungi, lichen and plants all produce organic acids and 418 chelating molecules, such as siderophores, which can strongly affect minerals and glass 419 weathering by increasing the solubility and mobility of elements (Staudigel et al., 1995; Ahmed 420 and Holmström, 2014; Perez et al., 2015, 2016, 2019; Valbi et al., 2022). Most microorganisms 421 are able to release organic acids such as oxalic, citric, acetic, fumaric and malic acid that can 422 cause bioalteration by changing the pH of the environment or by chelating ions from the 423 environment (Gadd, 1999; Neaman et al., 2005; Hausrath et al., 2009; Calvaruso et al., 2013; 424 Salek et al., 2013). Several kinds of bacteria are reported in literature to be able to produce 425 siderophores, such as the genus Pseudomonas, Streptomyces, Nocardia, Arthrobacter, Erwinia, 426 Vibrio, Altermona, Micrococcus, Paenibacillus and Bacillus, especially the siderophores 427 belonging to the families of hydroxamates and catecholates (Liermann et al., 2000; Peña et al., 428 2007; Challaraj-Emmanuel et al., 2012; Perez et al., 2015; Saha et al., 2015; Grady et al., 2016). 429 Some of these genera were identified on stained glass (Arthrobacter, Bacillus, Micrococcus, 430 *Paenibacillus*) and could then have a weathering potential linked to the production of these 431 chelating molecules. Moreover, the weathering ability of some of the identified species was 432 already documented on mineral substrates. Arthrobacter spp. were able to promote the 433 434 dissolution of minerals such as hornblende, feldspar, quartz, and Fe-bearing glass through the production of organic acids and siderophores (Ullman et al., 1996; Barker et al., 1998; Liermann 435 et al., 2000; Kalinowski et al., 2000; Frey et al., 2010). Other studies tested the weathering 436 potential of Bacillus spp. on granite and serpentine (Song et al., 2007; Yao et al., 2013) and of 437 Paenibacillus spp. on biotite, bauxite, and other rocks (Modak et al., 1999; Vasan et al., 2001; 438 Zhou et al., 2010; Liu et al., 2012). Bacillus spp. and other bacterial species like Agobacterium 439 spp. and Shpingomonas spp., were studied for their ability to promote the dissolution of 440 phosphates, phlogopite and biotite in the soil to improve the bioavailability of mineral nutrients 441 for plant roots (Leyval and Berthelin, 1989; Vassilev et al., 2006; Uroz et al., 2007). 442

A complete review of the glass-colonizing organisms is lacking in the literature, as stated in the 443 recent review on microbial interactions with silicate glass by (Weaver et al., 2021). Crossing 444 the results obtained in the present work and the literature previously cited, Arthrobacter, 445 Bacillus and Paenibacillus could be considered as the bacterial genera most likely to be able to 446 contribute to the alteration of stained glass windows as for today's state of knowledge. Notably, 447 the finding of the Mn-oxidizing species Arthrobacter crystallopoietes, which was isolated from 448 449 the murrey glass of Wissembourg suffering from the browning phenomenon could be crucial for the understanding of this pathology, especially since this species has already been identified 450 on stained glass once before (Marvasi et al., 2009). The microbiological samples on the 451 452 Wissembourg panel were specifically sampled on the dark spots caused by the browning phenomenon. Thus, the selection of A. crystallopoietes is an encouraging lead for the 453 investigation of the occurence of this pathology, that has to be further investigated. In the frame 454 455 of a more targeted study of the browning phenomenon, future work should involve a larger in situ sampling of medieval stained glass windows affected by this pathology. The study of the 456

457 effect of *A. crystallopoieties* on glass alteration also deserves further investigation; this 458 cultivable strain could thus be suitable for future laboratory-based glass bioalteration 459 experiments.

460 **5. CONCLUSIONS**

This work focused on the identification of bacteria at the surface of French stained-glass 461 windows and aimed to be a first non-exhaustive screening of the microorganisms likely to be 462 present on stained glass. The bacterial diversity was investigated by DNA extraction from 463 cultivated bacteria, and by amplification and sequencing targeting the 16S rDNA region. The 464 differences observed among the sampling sites showed that the sampling method used allowed 465 studying the microbial diversity without invasive sampling of the glass. Several genera known 466 for their weathering potential on mineral substrates were identified: Agrobacterium, 467 Sphingomonas, Acinetobacter, Arthrobacter, Bacillus and Paenibacillus. In particular, the Mn-468 oxidizing species Arthrobacter crystallopoietes and its interaction with a glass substrate or its 469 involvement in the browning phenomenon need further investigations. 470

471 Acknowledgements

This work was supported by the Paris Ile-de-France Region - DIM "Matériaux anciens et 472 patrimoniaux » and by the Doctoral school "Science Ingénierie et Environnement" of 473 Université Paris-Est. The authors are grateful to the curators from the "Directions régionales 474 475 des affaires culturelles, CRMH" of both the region Île-de-France and Grand-Est for their collaboration. Frédéric Didier and Pierre Bortolussi, chief architects of respectively the Royal 476 477 Chapel of Versailles and St. Etienne church in Bar-sur-Seine are acknowledged for the access to the monuments during their restorations. Pierre-Alain Parot is also acknowledged for the 478 access to the panels from Lachalade and Wissembourg in his workshop. The authors wish to 479 thank Céline Rommevaux for the advice and kind recommendations for the improvement of the 480 481 work.

workshop. All the samplings were effectuated at least 3 cm away from any metal casings/bindings and on unpainted surfaces, except when indicated.

Figure 1 Map of France with the position of the four sites sampled *in situ* (red) or after deposition (green), and the restoration workshop (blue) included in this study.

867

Figure 2 A) Plan of the Versailles Chapel (Didier, 2017) with location of the sampling points 868 and pictures of two sampled glass pieces on B) internal face of panel B91-2 p.17 in transmitted 869 light, and C) external face of panel B4-2 p.68 in reflected light. D) Plan of the church of Bar-870 871 sur-Seine (Prache et al., 1992) with location of the sampling points, and pictures of E) panel B101_LD_P7 on internal face, transmitted light and F) panel B101_LC_P7 on external face, 872 reflected light. G) Plan of Wissembourg Abbey (Hérold and Gatouillat, 1994) with original 873 location of the sampled glass, and picture taken at the restauration workshop (credits Atelier 874 Parot) of the tracery B0R3 on H) internal face and I) external face. J) Plan of Lachalade Abbey 875 (Vincent-Petit, 2016) with original location of the sampled glass, and pictures taken at the 876 restauration workshop of K) tracery B0R4 and L) panel B5P4 both in transmitted light. The 877 sample names include information about the sampling site (VER-BAR-WIS-LAC), the type of 878 879 structure (B=bay, P = panel, R = tracery).

880

881 Figure 3 Principal Coordinates Analysis (PCoA) results showing the groups of samples formed

by bacterial communities similarities. The factors taken into account are the "site" provenance

and the "external/internal" exposure of the sampled panel.

884

Figure 4 Heatmap of bacterial communities according to each sample at the genus level. The most abundant genera are labelled in pale blue, while the less abundant genera are labelled in dark blue. The dendrograms show the proximity between the different samples and the proximity between identified bacterial genera.
