#### **Abstract**

PFEA800219DM0940001, 2019].

Port areas are socio-ecosystems impacted by chronic mixture pollution. Some marine species benefit from living there and may be studied to define the ecological state of such environments. In this study, the risks of chronic chemical contamination and its consequences on three marine molluscs were evaluated in North Corsica (France) port areas. Mediterranean mussel Mytilus galloprovincialis, tubular sea cucumber Holothuria tubulosa and Mediterranean limpet Patella sp. were sampled in three port areas and a reference location. A set of biomarkers was analysed to evaluate oxidative stress, detoxification, energetic metabolism, neurotoxicity, immunity and bioaccumulation (metallic trace elements and organic pollutants). The objectives were to assess pollution-induced effects in organisms, to determine the best bioindicator species for the selected locations and to validate a "pool" sampling technique (when the analysis is done on a single pool of samples and not on individual samples). The results validate the sampling techniques as "pool" for management purposes. St-Florent was demonstrated as the most contaminated location. All the other locations present a low contamination, below the recommended threshold values (for metallic trace elements and organic pollutants). Finally, the limpet appears to be the best bioindicator for the selected locations. Mussel and sea cucumber are inappropriate due to their absence in this oligotrophic region and the lack of responses observed, respectively.

Keywords: pollution mixture, bioindicators, multibiomarkers approach, trace element, organic pollutants, IBR.

#### Introduction

Human activities at sea (e.g. fisheries and shipping), on land (e.g. agriculture and industries) or along the coastline (e.g. wastewater treatment plant and massive tourism) cause chronic and diffuse pollution in the marine environment (Islam and Tanaka 2004). Urban ports are thus subjected to a myriad of pollutants coming from terrestrial discharges or anthropogenic contaminations (Andral et al. 2004; Benali et al. 2015; Lafabrie et al. 2008). These pollutants may represent a subsequent risk to human health (Fasulo et al. 2012; Maisano et al. 2017). In these environments, biota is facing diverse stressful conditions and is exposed to a complex mixture of organic and inorganic pollutants. Despite the growing interest in recreational boating and the increasing number of marinas along coastlines all around the world, ecological understanding of these ecosystems is still very scarce (Guerra-García et al. 2021).

In 2008, the Marine Strategy Framework Directive (DCSMM 2008) incited European states to reduce the impact of activity in the marine environment, to achieve or maintain a good environmental status. This status is one of the decisive factors for awarding eco-labels or eco-certifications, such as Blue Flags in marinas (Guerra-García et al. 2021). It is thus crucial to develop a strong method to assess and monitor contamination in the marine environment, and also to understand the direct or combined effects of pollutants on organisms. Determining how pollutants interact with other chemical stressors to cause additive or synergistic effects on organisms remains one of the greatest challenges in ecotoxicology today. Also, direct chemical analyses of water samples only give a snapshot of the presence of pollutants at a specific date and time. Moreover, many environmental parameters (e.g., temperature, salinity, etc.) affect the

bioavailability of pollutants and their toxic effect on organisms could be modified. Bioindicators are used to consider such influence. Bioindicators are sensitive organisms used to observe induced effects of pollutants and therefore provide information on the impacts to the environment. This evaluation can be measured at several levels, from the molecular and cellular individual levels to the populations up to whole biocenosis level (Bondaruk et al., 2015). The use of these bioindicators is particularly relevant from a biological point of view. The measured concentrations reflect the bioavailable fractions in the marine environment (Wang 2016) and confers an integrative measurement of their exposure and effect on ecologically available fractions of environmental pollutants over time (Rainbow 2002). Bivalves and more precisely mussels received the greatest attention (Luna-Acosta et al. 2015; Rainbow and Phillips 1993) thanks to their biological characteristics (filter-feeders, global distribution, large abundance, low mobility, easiness to sample, etc.). Mussels are routinely used in regional environmental biomonitoring plans such as OSPAR's Coordinated Environmental Monitoring Programme (CEMP), PNUMA's Program for the Assessment and Control of Marine Pollution within the Mediterranean Action Plan (MED POL agreement of the Barcelona Convention) or the Mussel Watch Project (USA), which was initiated in 1976 and includes the surveillance of coastal regions for their pollutant contents (Goldberg 1975). However, other species (seagrass, fish, marine sponges, holothurians, limpets, etc.) are sometimes better adapted to the environmental conditions of the studied environment and their potential as bioindicators starts to increase (Beg et al. 2018; Lafabrie et al. 2007; Mohammadizadeh et al. 2016; Orani et al. 2018; Parra-Luna et al. 2020; Pérez et al. 2019; Richir and Gobert 2014). The use of native biota as a monitoring tool for bioavailable pollutants in aquatic ecosystems was demonstrated to constitute a highly valuable approach (Bertrand et al. 2018).

In the present study, a multibiomarkers approach was chosen to assess the impacts of multiple contaminants. The term biomarker refers to "all the biochemical, cellular, physiological or behavioural parameters which can be measured in the tissues or fluids of an organism or on the whole organism, to highlight the exposure to, or the effects, one or more contaminants" (Garric et al., 2010). Biomarkers were classified into two class: biomarkers of exposure indicate the presence of a contaminant inside an organism due to its interaction with biological molecules, and biomarkers of effect reflect the toxic or sublethal effect of the contaminant on the organism (Luna-Acosta et al. 2017a). In this study, the bioaccumulation of multiple metallic trace elements and organic pollutants represent the biomarkers of exposure. The activity of enzymes involved in several metabolic processes were analysed as biomarkers of effect: antioxidant defences (superoxide dismutase SOD - EC 1.15.1.1 and glutathione-S-transferase GST - EC 2.5.1.18), energetic pathways (lactate dehydrogenase LDH – EC 1.1.1.27, pyruvate kinase PK – EC 2.7.1.40 and phosphoenolpyruvate carboxykinase PEPCK – EC 4.1.1.32), neurotoxicity biomarker (acetylcholinesterase AChE - EC 3.1.1.7) and immune defence mechanisms (laccase type phenoloxidase LAC - EC 1.10.3.2). This multibiomarkers approach was shown to be efficient as it brings a better understanding and an integrated view of the biological responses in environmental risk assessment (Cravo et al. 2009; Delahaut et al. 2019). However, this approach needs to be coupled with an integrated tool such as the Integrated Biomarker Response (IBR). The IBR summarizes biomarker responses and simplifies their interpretation in biomonitoring programs (Beliaeff and Burgeot 2002). It was described to be useful for evaluating the impact of environmental conditions on the health and physiological status of organisms (Serafim et al. 2012). Compared to individual biomarkers, the IBR was useful to distinguish locations along a stress gradient (Bertrand et al. 2018). In the present study, different sampling techniques (with organisms collected as individual or collected as a pool of individuals) were tested. The objective was to evaluate if analysing the

data as a pool, a less expensive and less time-consuming method, would give comparable results to individual analyses. We hypothesised that this "pool" method could be proposed as a simple and effective tool to local authorities for future environmental management.

The secondary objective was to select the best bioindicator for port areas, from several native species. Two molluscs (*Mytilus galloprovincialis*, *Patella* sp.), and one echinoderm (*Holothuria tubulosa*) were selected. *Mytilus galloprovincialis* was included to obtain a reference species to compare with other studies while the other two species were available all year long in all the sampling locations, easy to sample, and were identified as potential bioindicator species in previous studies (Campanella et al. 2001; Mohammadizadeh et al. 2016; Parra-Luna et al. 2020; Reguera et al. 2018). These three species allow a global view of the different biological compartments since the mussel is a filter-feeder, the limpet is a grazer, and the sea cucumber is a deposit-feeder. Our hypothesis was that both mussel and limpet would give similar results while sea cucumber would be more contaminated due to its direct presence on the sediment (where contaminants would accumulate).

Finally, the levels of contamination and the subsequent pollutant-induced stress syndrome were compared in several North Corsica port areas, never studied before. We hypothesised that the level of contamination would be quite low due to the restricted size of the considered port areas.

#### Material and methods

St-Florent (N 42° 40' 50.362"; E 9° 17' 54.373"), Île Rousse (N 42° 33' 59.116"; E 8° 56' 7.778") and Calvi (N 42° 33' 59.116"; E 8° 45' 29.094") ports were chosen as exposed locations (Figure 1). These three ports are small marinas with low hydrodynamism. St-Florent, Île-Rousse and Calvi ports can respectively accommodate 950, 250 and 500 boats. All are located close to boat rental agencies and oil stations; St-Florent and Calvi are also subjected to the

impact of their fairing area; and St-Florent is located at the mouth of the Aliso River. The STARESO station in the Revellata bay (N 42° 34' 49.584"; E 8° 43' 31.511") was chosen as the reference location (Figure 1). It is distant from any city and is used for only 2 boats. One water sample was taken from each location to evaluate the environmental trace element contamination.

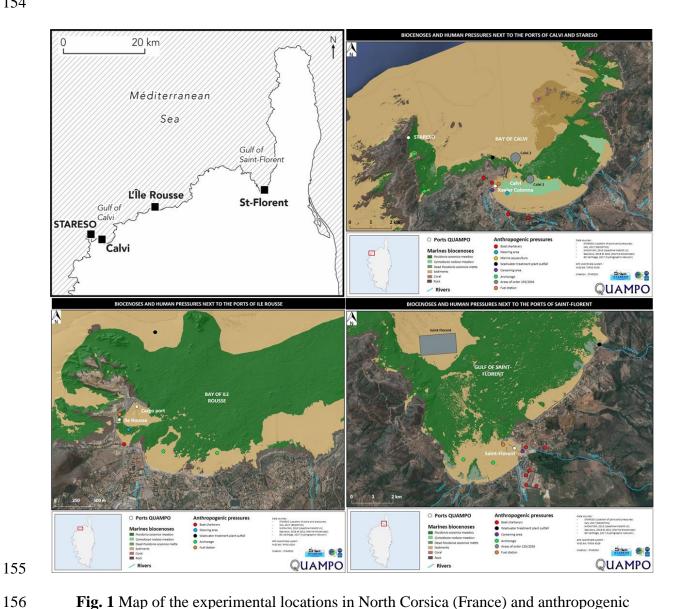

Fig. 1 Map of the experimental locations in North Corsica (France) and anthropogenic pressures observed next to the different ports

Three species (Mytilus galloprovincialis, Patella sp. and Holothuria tubulosa) were sampled in January 2020 in four different locations of North Corsica (France) (Figure 1). The objective was to collect 20 mussel and limpet individuals (10 for bioaccumulation analyses and 10 for other analyses) and 10 sea cucumber individuals (both kind of analyses being possible on one individual thanks to the large size of sea cucumber). The final number of individuals was dependent of the available wild organisms on each site. Mussels (n=17; length =  $76.75 \pm 9.03$ mm) were found only in St-Florent port. Limpets (n = 13-14 per location; length =  $35.24 \pm 5.36$ mm) were found everywhere except in St-Florent port. Sea cucumbers (n = 5-7 per location; length =  $154.1 \pm 43.77$  mm) were collected in the four locations. During the sampling, additional organisms were collected in one location to test the "pool" sampling techniques: 13 mussels (length =  $68.56 \pm 8.84$  mm) and four sea cucumbers (length =  $193.25 \pm 34.67$  mm) were collected in St-Florent and 14 limpets (length =  $32.34 \pm 4.93$  mm) in Île Rousse. Tissues were dissected, pooled and processed following the same method than for the "individual" sampling technique (detailed below for all the analyses). After sampling, individuals were immediately placed in dry ice and shipped to La Rochelle (France) within 48 h in order to be analysed. In the lab, half  $(n = \sim 7)$  of the mussels, limpets and sea cucumbers tissues were kept at -20°C for bioaccumulation analyses. The other half was kept at -80°C for all the other analyses.

- A. Biomarkers of exposure (bioaccumulation)
- a) Trace element assessment

The soft tissues of mussel and limpet were hand grinded with a ceramic mortar and pestle. The body wall of sea cucumber was chopped into small pieces. The samples were freeze dried for 48-72 h. Then, the samples and the two reference materials (DOLT-5, dogfish liver, and TORT-3, lobster hepatopancreas, National Research Council Canada) were weighted around

- 184 0.25 mg and digested by addition of 6:2 (v/v) 67-70% HNO3/34-37% HCl mixture (Fisher, 185 trace metal quality). The digestion process was carried out overnight at room temperature 186 followed by a microwave digestion (30 min with constantly increasing temperature up to 120 187 °C, then 15 min at this temperature). At the end of these steps, the volume of the samples was 188 completed with ultrapure water until 50 mL. Silver (Ag), barium (Ba), cadmium (Cd), cobalt 189 (Co), chromium (Cr), manganese (Mn), molybdenum (Mo), nickel (Ni), lead (Pb), antimony 190 (Sb), selenium (Se), tin (Sn) and vanadium (V) contents were analysed using an Inductively 191 Coupled Plasma Optical Emission Spectrometry (ICP-OES) Vista-Pro (Varian Inc., Palo Alto,
- 192 California, USA). Aluminium (Al), arsenic (As), copper (Cu), iron (Fe) and zinc (Zn) were
- analysed using an Inductively Coupled Plasma Mass Spectrometry (ICP-MS) XSeries 2
- 194 (ThermoFisher Scientific, Waltham, Massachusetts, USA).
- Mean recovery rates were 76% (Al / DOLT-5), 55% (Ag / DOLT-5), 93% (As / DOLT-5) and
- 196 100% (As/TORT-3), 90% (Cd / DOLT-5) and 95% (Cd / TORT-3), 82% (Co / DOLT-5) and
- 98% (Co / TORT-3), 97% (Cr / TORT-3), 97% (Cu / DOLT-5) and 95 (Cu / TORT-3), 105%
- 198 (Fe / DOLT-5) and 98% (Fe / TORT-3), 92% (Mn / TORT-3), 87% (Mo / DOLT5) and 85%
- 199 (Mo / TORT-3), 83% (Ni), 103% (Pb / DOLT-5) and 79% (Pb / TORT-3), 93% (Se / DOLT-
- 200 5) and 91% (Se / TORT-3), 92% (V / TORT-3) and 95% (Zn / DOLT-5) and 101% (Zn / TORT-
- 201 3).
- 202 Limits of quantification were 19.28 (Al), 0.01 (Ag), 0.1 (As), 0.1 (Ba), 0.01 (Cd), 0.01 (Co),
- 203 0.1 (Cr), 0.96 (Cu), 3.86 (Fe), 0.01 (Mn), 0.1 (Mo), 0.04 (Ni), 0.01 (Pb), 0.04 (Sb), 0.39 (Se),
- 204 0.02 (Sn), 0.96 (V) and 3.86 (Zn) μg.g<sup>-1</sup> of dry weight.
- The trace element contamination of the water samples was also analysed using ICP-OES
- 206 (dilution to 1/5 for water samples and seawater standards, in 2 % nitric acid) and ICP-MS
- 207 (dilution to 1/20 for water samples and seawater standards, in 2 % nitric acid).

#### b) Organic pollutants assessment

209

210 Tissues of organisms (soft tissues of mussel and limpet and body wall of sea cucumber, 211 measured as a pool of seven individuals) were analysed for organic pollutants contents. 22 212 polycyclic aromatic hydrocarbons (PAHs), including the 16 Environmental Protection Agency 213 (EPA) PAHs, 14 polychlorinated biphenyls (PCBs) and seven pesticides were 214 analysed in tissues by stir bar sorptive extraction-thermal desorption-gas chromatography-215 tandem mass spectrometry (SBSEGC-MS/MS) following Lacroix et al. (2014) method. Tissues 216 were briefly digested by saponification and analytes were extracted for 16 h at 700 rpm using 217 polydimethylsiloxane stir-bars (Twister 20 mm × 0.5 mm, Gerstel). Bars were subsequently 218 analysed using a gas chromatography system Agilent 7890A coupled to an Agilent 7000 triple 219 quadripole mass spectrometer (Agilent Technologies) and equipped with a Thermal Desorption 220 Unit combined with a Cooled Injection System (Gerstel). The GC column was a Restek Rxi-5 221 ms (30 m, 0.25 mm, 0.25 µm). Analytes were quantified relatively to deuterated compounds 222 using a calibration curve ranging from 0.01 ng to 30 ng per bar. Results are expressed as ng.g<sup>-1</sup> 223 dry weight. Limits of quantification (LOQ) were calculated by the calibration curve method 224 (Shrivastava and Gupta 2011) and were 25 (naphthalene, phenanthrene and PCB 138), five 225 (dibenzothiophene, fluoranthene, 2-methylfluoranthene, chrysene, benzo(b)fluoranthene, 226 benzo(k)fluoranthene, benzo(e)pyrene, benzo(a)pyrene, perylene, indeno(1,2,3-cd)pyrene, 227 dibenzo(a,h)anthracene, benzo(g,h,i)perylene, PCB 153 and 4-4-DDE), 2.5 (benzothiophene, 228 biphenyl, acenaphthylene, acenaphthene, fluorene, anthracene, pyrene, benzo(a)anthracene, 229 PCB 7, PCB 28, PCB 52, PCB 35, PCB 101, PCB 77, PCB 135, PCB 118, PCB 156, PCB 180, 230 PCB 169, aldrine, isodrine, dieldrine and endrine) and 0.5 (PCB 105, hexachlorobenzene and 231 2-4-DDE) ng.g<sup>-1</sup> dry weight. Analytical quality control was done using the Standard Reference Materials 1974c "Organics in Mussel Tissue (Mytilus edulis)" provided by the National Institute 232 233 of Standards (SRM) and Technology (NIST, Gaithersburg, USA).

## B. Biomarkers of effect analyses

#### a) Enzymatic biomarkers

Individuals were dissected to keep the digestive gland for mussel, the whole soft tissues for limpets and the body wall for sea cucumber. The tissues were weighted and grounded in liquid nitrogen using a MM400 Retsch<sup>©</sup> (GmbH, Éragny, Luxemburg) mixer mill. Then they were hand homogenized on ice in one volume of phosphate buffered saline (PBS) solution (100 mM, pH 7.5) containing 0.1 % Triton X-100 and one mM ethylenediaminetetraacetic acid (EDTA) to avoid protein degradation. The samples were centrifuged 15 min at 12500 g at 4°C (Sorvall Legeng Micro 17R, ThermoFisher Scientific, Waltham, Massachusetts, USA). The supernatant was collected, divided into aliquots and used for the subsequent biomarkers of effect and protein analyses. The capacity to respond to oxidative stress was evaluated using SOD. SOD activity protocol is based on the inhibition of a superoxide-driven NADH oxidation and was measured following the rate of NADH oxidation at 340 nm (Paoletti et al. 1986). The GST is an enzyme involved in detoxification process. It was determined by measuring the production of GS-DNB at 340 nm (Habig et al. 1974). The activities of the indices of glycolysis and gluconeogenesis pathways (PK, PEPCK, and LDH) were determined by measuring the NADH consumption at 340 nm. The method used for PK and LDH followed the Childress and Somero (1979) protocol modified by Bailey et al. (2005). For PEPCK, the Petrescu et al. (1979) method, adapted by Jamieson et al. (1999) was used. However, LDH and PEPCK activities were below the detection levels in mussel and sea cucumber respectively. AChE is widely used to estimate neurotoxic impacts of pollutants, especially organophosphates, carbamates, several heavy metals and surfactants. Its activity was assayed by recording the production of 5-thio-2-nitrobenzoate at 405 nm (Ellman et al. 1961).

259 Finally, the LAC enzyme is involved in immune, antioxidant and detoxification processes 260 (Luna-Acosta et al. 2017a). Its activity was measured according to Luna-Acosta et al. (2010). 261 following the oxidation of p-phenylenediamine at 420 nm. 262 The total protein content was measured with the bicinchoninic acid protein assay kit (Sigma-263 Aldrich®) that is similar to the Lowry et al. (1951) procedure. 264 All activities measurements were done on a SpectroStar Nano spectrophotometer (BMG 265 labtech, Champigny-sur-Marne, France). 266 All chemicals were obtained from Sigma-Aldrich®. All analyses were performed in technical 267 duplicates for each sample, using standard methods adapted for a microplate reader. For all 268 enzymatic analysis, homogenates were diluted to obtain linear reaction slopes for a minimum 269 of five minutes at 25 °C. Total and specific enzymatic activities were measured and expressed as U (µmol.min<sup>-1</sup>).g<sup>-1</sup> of wet tissue and U.mg<sup>-1</sup> of protein, respectively. 270 271 272 b) Glycogen and total lipids Tissues were grounded in liquid nitrogen using a MM400 Retsch<sup>©</sup> (GmbH, Éragny, 273 274 Luxemburg) mixer mill and then hand homogenized on ice in one mL of citrate buffer (0.1 M, 275 pH 5). Half of the sample was placed immediately at -80 °C until the total lipid analyses. The other half was incubated for four min in boiling water and then placed at -80 °C. 276 277 The determination of the total lipid concentration is based on the improved sulfo-phospho-

vanillin reaction from Frings et al. (1972). For the glycogen, the sample was incubated with

amyloglucosidase resulting in the complete hydrolysis of glycogen to glucose as described in

278

279

280

281

Carr and Neff (1984).

### 282 C. Statistics analyses

a) Test on the "pool" technique

To test the "pool" technique, the mean of the "individual" samples was compared to with the one of the "pooled" samples. The percentage of difference between these two values was compared for biomarkers of effect and exposure.

## b) Biomarkers

Normality and homogeneity of variances were verified by Shapiro and Levene tests. Data were log10 transformed to avoid heteroscedasticity when possible.

Pearson's and Spearman's (in case of heteroscedasticity) correlations between total and specific enzymatic activity responses were verified for all enzymes.

In limpet and sea cucumber, one-way ANOVAs (or non-parametric Kruskal-Wallis tests in case of heteroscedasticity) were used to test the effects of location on the biomarkers of effect and trace element bioaccumulation, followed by respectively Tukey or Mann-Whitney Wilcoxon post-hoc test when a significant effect was found (P < 0.05). Due to many values below the limit of quantification (<LOQ), testing the difference between location was not possible for the organic pollutants' bioaccumulation data. To determine the most important parameters in our multi-parameter analysis, principal component analysis (PCA) was performed on trace element and organic contaminants concentration in tissue of limpet and sea cucumber grouped per location.

Finally, for limpet and sea cucumber, the "Integrated Biomarker Response" (IBR, (Devin et al. 2014)) was calculated using the response of biomarkers of effect (results from the "individual" sampling technique). On R software, the functions from the package IBRtools were used (Devin et al. (2014) based on Beliaeff and Burgeot (2002)).

#### Results

## A. Test on the "pool" technique

For all the biomarkers, the difference between the value obtained for "pooled" samples and the average of the values obtained for each "individual" samples were classified into three categories: < 10% of difference, 10-30% of difference and > 30% of difference (Figure 2).

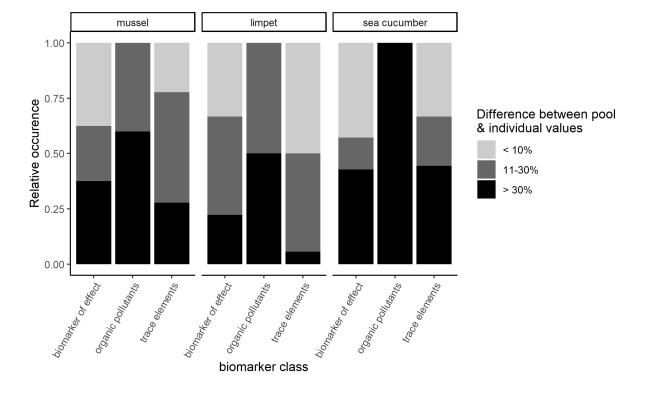

Fig. 2 Occurrence of the different class of difference (in %) between « pool » and « individual » techniques, for biomarker of effect and exposure (trace element and organic pollutant bioaccumulation) in the three marine molluscs

The difference between the "pool" and the "individual" samples varied according to the species and class of biomarkers. In mussels, the difference between "pool" and "individual" techniques was less than 30% in 6.25, 7.22 and four times out of 10 for the biomarkers of effect, the metallic trace elements and the organic pollutants bioaccumulation respectively. For limpet, the same

was observed 7.8, 9.4 and five times out of 10 and for sea cucumber, it was 5.7, 5.5 and 0 times out of ten. On the contrary to the other biomarker classes, the difference was superior or equal to 30% in all species for the organic pollutants.

#### B. Trace element contamination of water

Among the 18 metallic trace elements measured in water samples (Table 1), only five (Co, Cu, Mn, Mo and Pb) were above the limit of quantification. The highest values for Cu and Mn were observed in St-Florent and the one of Mo was detected in Calvi. The higher number of metallic trace elements was detected in Île Rousse. No trace element contamination was observed at STARESO.

**Table 1**: Trace element concentration ( $\mu$ g/L) in water sample collected in the different locations in January. Grey cells indicate values higher than the limit of detection.

	STARESO	Calvi	Île Rousse	St-Florent
Ag	< 10	< 10	< 10	< 10
Al	< 200	< 200	< 200	< 200
As	< 10	< 10	< 10	< 10
Ва	< 10	< 10	< 10	< 10
Cd	< 2	< 2	< 2	< 2
Со	< 1	1,0	< 1	< 1
Cr	< 10	< 10	< 10	< 10

## C. Biomarkers of exposure

For the trace element contamination (Table 2), differences between location were statistically tested only for limpet and sea cucumber as wild mussel was found only in St-Florent. While the difference between location were found only for Mn (P < 0.001) regarding sea cucumber, differences were observed for Al, As, Ba, Co, Cr, Cu, Fe, Mn, Ni, Pb, Se, V and Zn in limpet. The contamination trend in limpet differed according to the trace element: for Al, Cu, Fe, Mn, Se (P < 0.001) and Co (P < 0.01), higher levels were found in Calvi and Île Rousse compared to STARESO; for Ba (P < 0.05) and Pb (P < 0.001), the contamination level is lower in STARESO compared to those in Île Rousse; for Zn and V (P < 0.001), Calvi was the most contaminated location; for Cr and Ni (P < 0.001), STARESO and Calvi contamination was higher than Île Rousse; for As (P < 0.001), Calvi presented a lower contamination than Île Rousse, and STARESO presented intermediate levels. For all the other metallic trace elements (Ag, As, Cd, Mo, Sb, Sn), the contamination registered in organisms was similar among locations.

Table 2: Trace element concentration ( $\mu$ g/g of wet tissue) in soft tissue of mussel and limpet and body wall of sea cucumber collected in North Corsica in January 2020 (mean  $\pm$  standard deviation, N=7). Letters indicate significant difference between the locations (P < 0.05) within the same species.

Organic pollutants bioaccumulation (Table 3) was only detected in St-Florent for mussel and sea cucumber and in Île Rousse for limpet. Mussels accumulated more organic pollutants (14 HAPs, eight PCBs and one pesticide) than limpets (8 HAPs) or sea cucumbers (5 HAPs). Concerning the bioaccumulation of the different organic pollutant categories, mussel was the only organism to accumulate PCBs and pesticides.

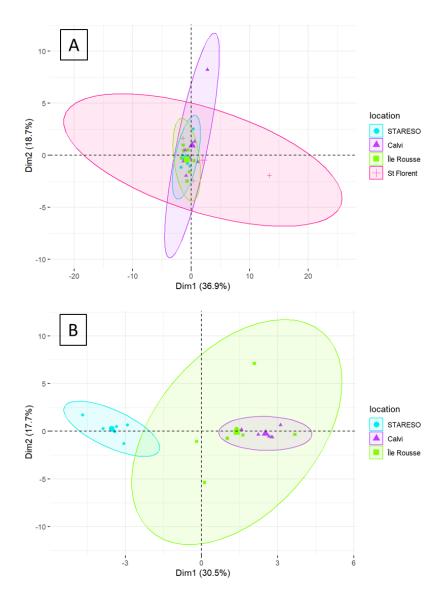

**Table 3**: Organic pollutant concentration ( $\mu$ g/g of wet tissue) in soft tissue of mussel and limpet and body wall of sea cucumber collected in North Corsica in January (mean  $\pm$  standard deviation, N=1-7). <LD = below the detection limit.

No organic pollutants were detected in limpet collected in STARESO and Calvi or in sea cucumber collected in STARESO, Calvi and Île Rousse. However, organic pollutants concentrations in tissues of organisms were below the Environmental Quality Standards (EQS) defined by the 2013/39/EU directive for biota.

When analysing the results of all contaminants (trace element and organic contaminants) in sea cucumber tissues, the PCA principal component (Dim1) explained 36.9% while the second principal component (Dim2) explained 18.7 % of the total variation. It was difficult to determine the most important factors for the model because of the high number of parameters (Figure 3A). Contaminant concentrations in tissue from St-Florent seemed to be more explained by Dim1. Dim1 was related to concentrations of Cd, Co and Mn. In the other locations, contaminant concentrations in tissues seemed to be better explained by Dim2. Dim2 is mainly related to Mo, Sb, Ag, Ba and Ni (Figure 3A, supplementary material 1). In limpet, the PCA principal component (Dim1) explained 30.7% while the second principal component (Dim2) explained 17.7 % of the total variation. While contaminants concentration in tissue from Île Rousse seemed to be explained by both the Dim1 and Dim2, contaminants concentration in tissue from STARESO and Calvi seemed to be more explained by Dim1.

**Fig.3** PCA results for trace element and organic contaminants in (A) sea cucumber and (B) limpet tissues per location

## D. Biomarkers of effect

Specific and total activities measured in mussel, limpet and sea cucumber were significantly correlated (R between 0.89 and one depending of the enzyme, P < 0.001). Total activities and specific activities can be found in Supplementary Tables 1.

The response of the antioxidant system varied according to the species (Figure 4). In limpet the SOD and GST activities were much higher than those detected in mussel (and in sea cucumber for GST). The effect of location was significant for sea cucumber SOD activity. Its SOD activity was 1.2 times higher (P < 0.01) in individuals collected in STARESO and Île Rousse than in those from St-Florent.

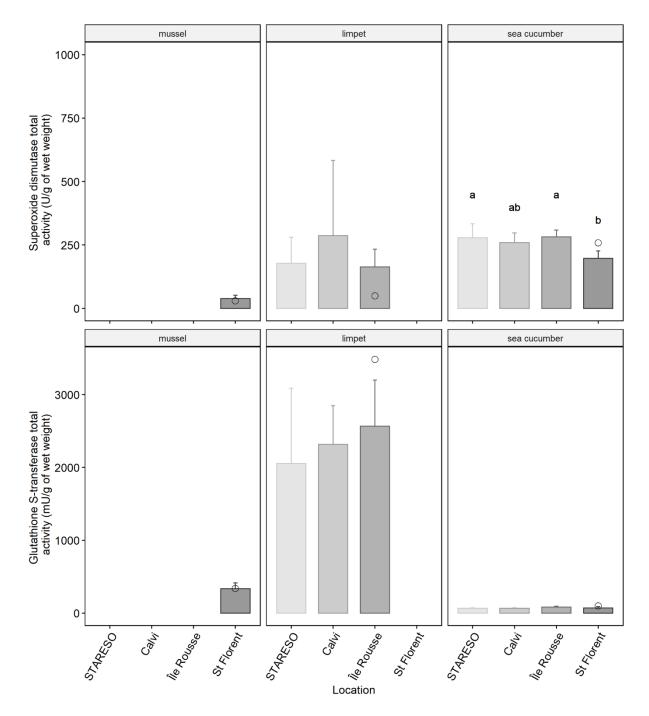

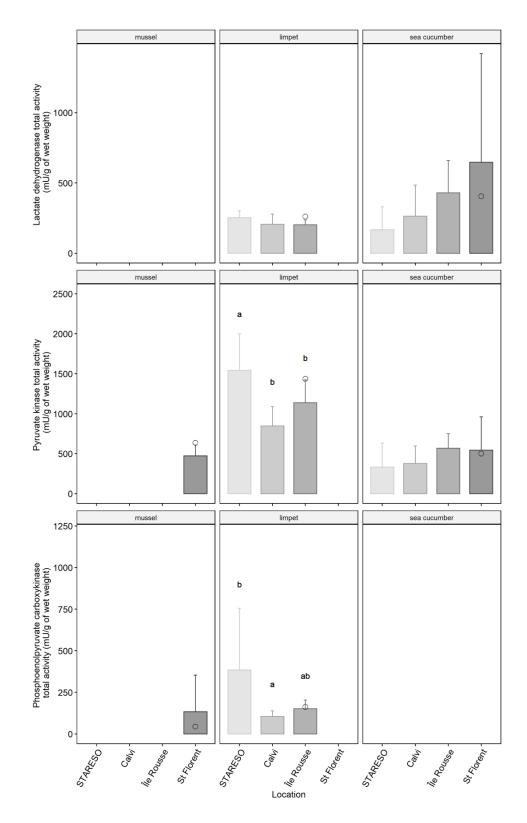

Fig. 4 Total enzymatic activity of superoxide dismutase (U/g of wet tissue) and glutathione S-transferase (mU/g of wet tissue) in digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean ± standard deviation).

Different letters indicate significant difference between the location, within the same species (P < 0.05). Circles indicate the value for the pooled data collected in the same location.

LDH, PK and PEPCK (Figure 5) are respectively involved in fermentation, glycolysis and neoglycolysis. Significant variations of their activities were only observed for limpets. In mussel and sea cucumber, the activity of these three enzymes was similar. In limpet collected in STARESO, the PK activity was significantly higher than in Calvi and Île Rousse, and the PEPCK activity was significantly higher than in Calvi.

**Fig. 5** Total enzymatic activity of lactate dehydrogenase, pyruvate kinase and phosphoenolpyruvate carboxykinase (mU/g of wet tissue) in digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean  $\pm$  standard deviation). Different letters indicate significant difference between the location,

within the same species (P < 0.05). Circles indicate the value for the pooled data collected in the same location

The activity of AChE (Figure 6), used as an indicator of neurotoxicity, was similar according to the location for all three organisms. The same was noted for the activity of LAC, enzyme involved in immunity processes.

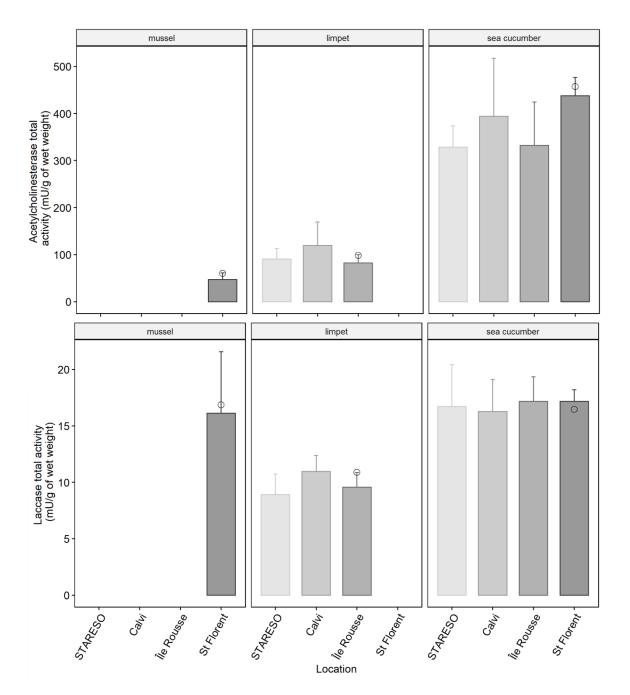

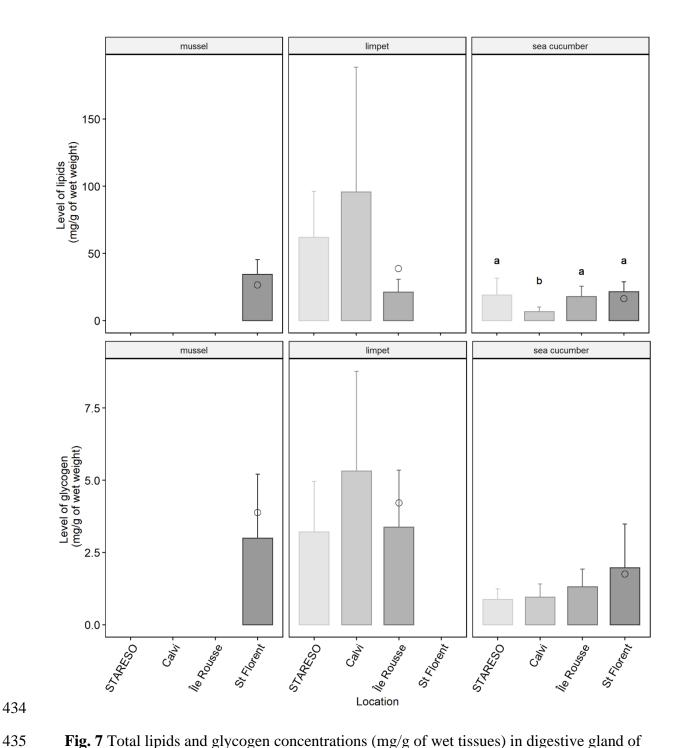

Fig. 6 Total enzymatic activity of acetylcholinesterase and laccase (mU/g of wet tissue) in digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean ± standard deviation). Different letters indicate significant difference between the location, within the same species (P < 0.05). Circles indicate the value for the pooled data collected in the same location

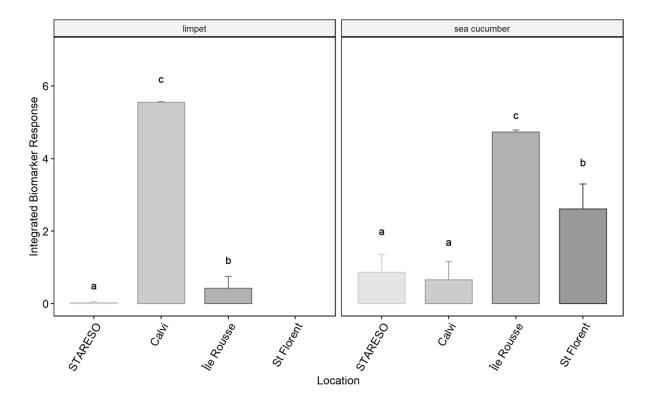

The lipid and glycogen levels (Figure 7) presented approximately the same levels in mussel and in limpet. For limpet, no differences between locations were noted either for the lipids or glycogen contents. In sea cucumber, the glycogen content was similar among location while the lipids content was significantly lower in Calvi compared to the other locations.

**Fig. 7** Total lipids and glycogen concentrations (mg/g of wet tissues) in digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean  $\pm$  standard deviation). Different letters indicate significant difference between the location, within the same species (P < 0.05). Circles indicate the value for the pooled data collected in the same location

## E. Integrated biomarker response (IBR)

The IBR calculated using the biomarkers of effect response gave variable results according to the organism (Figure 8). In limpet, the IBR value was the highest in Calvi, the lowest in STARESO and intermediate in Île Rousse. In sea cucumber, the lowest IBR values were found in STARESO and Calvi, the greatest values were found in Île Rousse.

**Fig. 8** Integrated Biomarker Responses (IBR, mean) calculated for limpet and sea cucumber using the biomarker of effects. Different letters indicate significant difference between the location, within the same species (P < 0.05)

## Discussion

Our study provides the first ecological data based on passive biomonitoring from three port areas in North Corsica. The organisms were collected during the three years of the QUAMPO (QUAlity of the marine environment in the Mediterranean POrt areas) project (2019-2022).

They were analysed considering a multibiomarkers approach (indicators of stress, energetic metabolism, neurotoxicity, immunity, metallic trace elements/organic pollutants bioaccumulation).

In accordance with our first hypothesis, the results of this study validate the use of the "pool" sampling technique. This work therefore confirms the conclusion of several other studies focusing on the analyses of organic pollutant in herring gulls (Larus arentatus) (Turle and Collins 1992) or on the analyses of metallic trace elements and biomarker of effect on black scallop (Mimachlamys varia) collected in port areas (Breitwieser et al. 2018). Both authors showed the reliability of the "pool" sampling technique, as the means of individual analyses and those of pooled samples was lower than the normal analytical variation. A validation was however necessary in the present study because the results might differ according to the studied organisms and the considered biomarkers. Here, the "pool" technique was especially reliable for Al, Cd, Co, Cu, Mo, Ni, Pb, Se and Zn accumulations in limpet; for LAC activities, Cd, Co, Cr and Se accumulations in mussel; and for AChE and LAC activities, Ag, Cr, Mo, Ni, Se and Zn accumulations in sea cucumber. The reliability of the "pool" technique for metallic trace element accumulation was especially observed in limpet. However, the "pool" sampling techniques is not adapted to the organic pollutant bioaccumulation analyses in our study. This is mainly because most of the analysed organic pollutants are close to or below the detection limit. Considering this, the "pool" technique allows researchers to obtain reliable results at lower costs (Breitwieser et al. 2018). This can be advantageous when the analyses are quite expensive (trace element or organic pollutants analyses for example), when the population is composed of a limited number of individuals, to gain time in laboratory analyses or to reduce the number of organisms (3 R's: Reduce, Reuse, Recycle). This technique has however some disadvantages as it does not allow to precisely assess the impact of a mix of contaminants nor to detect extreme or abnormal values as with inter-subject studies. Also, it may have negative consequences when the biological variation is important or not known (Bignert et al. 1993; Bignert et al. 1994).

Our second hypothesis supposed that both mussel and limpet would give similar results while sea cucumber would be more contaminated. This was shown to be wrong by our results. In fact, biomarkers gave more responses in limpet than in sea cucumber. They allowed statistical discrimination of the studied locations. Mussel had a similar response as limpet, however, mussel are only found in St-Florent, where the primary production is enhanced by freshwater inputs coming from the Aliso River. In the other locations, the oligotrophic conditions are not suitable for the installation of mussel. In mussel, it is then difficult to affirm that the biomarker response reflects the pollution on the locations rather than the starvation effect. Considering this and despite the bioindicative capacity of mussel shown in many studies (Caricato et al. 2010; Lehtonen et al. 2019; Uluturhan et al. 2019), mussel is not adapted to the environmental conditions of North Corsica port areas. Mussel should only be used in complementarity with other organisms. In sea cucumber, the only effect of location observed on the biomarkers of effect was for the lipids content and SOD activity. Compared to the other locations, lipid contents were lower in Calvi. This might reflect a lower food supply at this location. The SOD activity was higher in STARESO and Île Rousse compared to the one in St-Florent. SOD is involved in antioxidative defences, and this response could reflect more stress in STARESO and Île Rousse. However, the significant difference in SOD activity was only detected in total activity and not in specific activity, meaning there is no significant difference at a protein level. The variation in SOD total activity is not confirmed by the trace element bioaccumulation in sea cucumber: most metallic trace elements (except Mn) have similar levels among location. Mn bioaccumulation varied across sites and St-Florent seems to be the most polluted one. The

higher metallic contamination in St-Florent compared to the other locations is also confirmed by the multivariate analysis that includes all contaminants. The biomarkers of exposure and biomarkers of effect gave contradictory responses in St-Florent. This could be explained by the presence of some HAPs detected or even of other pollutants not analysed in the present study (e.g., emerging contaminants). Considering these results, the sea cucumber might not be an efficient bioindicator species in North Corsica. However, previous studies demonstrated the reliability of sea cucumber as bioindicator (Aydin et al. 2017; Parra-Luna et al. 2020; Turk Culha et al. 2016), especially for bioaccumulation analyses. For example, Turk Culha et al. (2016) detected average levels of metallic trace elements equal to 0.18 µg/g for Cd, 2.43 µg/g for Cu, 2.09  $\mu$ g/g for Pb, 14.58  $\mu$ g/g for Ni, 16.86  $\mu$ g/g for Zn, and 73.46  $\mu$ g/g for Fe in sea cucumber (H. tubulosa) sampled in the Dardanelles Strait (Turkey). In our study, for the similar metallic trace elements, the levels were lower for Cd, Pb and Ni (respectively 0.05; 1.55 and  $2.52 \mu g/g$ ) and higher for Cu, Zn and Fe (respectively, 4.8; 41.67 and  $126.45 \mu g/g$ ) in the same species. Our results confirm the bioaccumulative capacities of sea cucumber, but the lack of correlation with the biomarker of effects should be considered when using this species as bioindicator. The tissue analysed in the present study (body wall of sea cucumber), could also impacted our results. The sensibility of body wall might be lower compared to the one of other tissues such as respiratory tree or intestine (Aydin et al. 2017). The limpet seems to be the most promising organism to monitor the effects of pollutants in North Corsica port areas. In our study, it bioaccumulates more metallic trace elements in Calvi and Île Rousse (significant difference between location for Al, As, Ba, Co, Cu, Cr, Fe, Mn, Pb, Se, V and Zn) and some HAPs (benzothiophene, biphenyl, fluorene, anthracene, 2methylfluoranthene, chrysene, benzo(e)pyrene and benzo(g,h,i)perylene) in Île Rousse. Limpets also seem more impacted in Calvi and Île Rousse than in STARESO. For example, PK activity is lower in Calvi and Île Rousse, and PEPCK activity is lower in Calvi, compared to

those in STARESO. The biomarkers of exposure response are correlated with the biomarkers of effect response (for both total and specific activities). Our results confirm the reliability of limpets as a bioindicator, their sensibility to detect contamination difference among locations and the possibility to use them as a good substitute or complement to mussels for biomonitoring marine pollution. Our results verified the bioaccumulative capacities of limpets for various contaminants (but especially for Cd, Pb, Cu & Zn) demonstrated by several authors (Conti et al. 2017; Mbandzi et al. 2022; Pérez et al. 2019). From an ecological point of view, limpet is as interesting as a bioindicator species as mussel: its biomarkers of effects responses are linked to those of the biomarker of exposure (Gharred et al. 2019; Gouveia et al. 2019; Pérez et al. 2019; Silva et al. 2018).

Considering the complexity of biochemical responses to chronic pollution, the use of a multibiomarkers approach is strongly recommended (Caricato et al. 2010). The IBR is a method combining several biomarker responses of effect into a general "stress index". In the present study, it was calculated for limpets and sea cucumbers from the different locations. It allowed for the identification of the most impacted location. Firstly, for both species, the IBR was the lowest in STARESO. This underscores the absence of trace element or organic pollutants contamination and confirms the use of STARESO as a reference location. The highest IBR values were not located in the same port for limpet and sea cucumber. The IBR calculated with the limpet responses shows that Calvi seems the most impacted location while the one calculated with the sea cucumber responses shows higher values for Île Rousse and St-Florent. Previous studies used the IBR to provide indication of the environmental stress caused by environmental (Serafim et al. 2012) or anthropogenic (Cao et al. 2019; Ji et al. 2019; Luna-Acosta et al. 2017b; Silva et al. 2018) factors. However, the biological responses must be interpreted cautiously and in combination with chemical data to avoid misinterpretation (Cravo

et al. 2012). The calculation of the IBR is highly dependent on a number of a priori choices (Beliaeff and Burgeot 2002). It will not explain the biological meaning, but will rather provide the mathematical relations between the biological data (Ji et al. 2019). In our study, the IBR gives us a first integrated view of the situation in the North Corsica port. As already shown in previous studies, the IBR is a promising tool for scientists and managers to classify the toxic potential of coastal areas (Beliaeff and Burgeot 2002; Benali et al. 2015).

Finally, in accordance with our last hypothesis, the pollution on the considered areas is still low compared to other bigger port areas in the Mediterranean Sea (Galgani et al. 2006). This is mainly due to the small size of the ports (between 250 and 900 boats) considered in the present study. Despite some anthropic pressures registered close to the ports (such as boats rental agencies), the chemical contamination was still below the reglementary threshold values. For future research, it will be necessary to obtain more data on environmental parameters and on the port contamination. This could be done by measuring environmental conditions (temperature, salinity, oxygen or chlorophyll-a), by collecting more water samples and by adding sediments analyses. Furthermore, it will be necessary to integrate more biomarker data (for example other contaminants such as tributyltin) or condition index to consider the intraspecific variability of wild organisms and how their feeding mode influence their response to chemical exposure. Longer biomonitoring is also needed to improve the evaluation of the contaminated locations. Finally, to more precisely test the bioindicative capacities of species, some experimental studies with controlled conditions would be essential.

This study is the first to give information on the ecological quality of the port areas in North Corsica. The biomonitoring carried out using three bioindicator species (M. galloprovincialis, Patella sp. and H. tubulosa) demonstrated that the choice of a species adapted to the local environment is of primary importance for efficient biomonitoring. In North Corsica, the limpet is present in most locations in comparison to the mussel, and it responds better than the sea cucumber. For future biomonitoring, it would be very interesting to use the limpet in combination with the mussel to have a global view of the ecological quality of the water in the area. The combination between limpet and mussel will also allow the comparison with worldwide biomonitoring surveys that mainly use *Mytilus* sp. The results of the present study show that the water contamination in North Corsica port areas is relatively low compared to other ports areas in the Mediterranean Sea. For future research, it is necessary to continue this monitoring over time and at different seasons to obtain more reliable data. Finally, the validation of the sampling techniques as "pool" is important for management purpose. Even if the "pooled" data limits the analyses for fundamental research, this method gives reliable results to help the local managers and authorities for planning integrated environmental management of the port area.

802	Michèle Leduc: methodology, data collection.
803	Quentin Fontaine: formal analyses.
804	Stéphane Le Floch: methodology, formal analyses.
805	Valérie Huet: formal analyses.
806	Carine Churlaud: formal analyses.
807	Pierre Lejeune: conceptualization, funding acquisition.
808	Hélène Thomas: supervision, project administration, funding acquisition.

**Ethical Approval** This study does not involve human participants or vertebrate animals. **Consent to Participate** Yes **Consent to Publish** Yes Availability of data and materials The datasets generated during and/or analysed during the current study are available from the corresponding author on reasonable request. 

- 823 List of captions:
- 824 Fig. 3 Map of the experimental locations in North Corsica (France) and anthropic pressures
- observed next to the different ports
- Fig. 4 Occurrence of the different class of difference (in %) between « pool » and « individual »
- 827 techniques, for biomarker of effect and exposure (trace element and organic pollutant
- bioaccumulation) in the three marine molluscs
- Fig. 3 PCA results for trace element and organic contaminants in (A) sea cucumber and (B)
- 830 limpet tissues per location
- Fig. 4 Total enzymatic activity of superoxide dismutase (U/g of wet tissue) and glutathione S-
- transferase (mU/g of wet tissue) in digestive gland of mussel, soft tissue of limpet and body
- wall of sea cucumber collected in North Corsica in January (mean ± standard deviation).
- Different letters indicate significant difference between the location, within the same specie (P
- < 0.05). Circles indicate the value for the pooled data collected in the same location
- 836 Fig. 5 Total enzymatic activity of lactate dehydrogenase, pyruvate kinase and
- phosphoenolpyruvate carboxykinase (mU/g of wet tissue) in digestive gland of mussel, soft
- tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean  $\pm$
- standard deviation). Different letters indicate significant difference between the location, within
- the same specie (P < 0.05). Circles indicate the value for the pooled data collected in the same
- 841 location
- 842 Fig. 6 Total enzymatic activity of acetylcholinesterase and laccase (mU/g of wet tissue) in
- 843 digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in
- North Corsica in January (mean ± standard deviation). Different letters indicate significant
- difference between the location, within the same specie (P < 0.05). Circles indicate the value
- for the pooled data collected in the same location

**Fig. 7** Total lipids and glycogen concentrations (mg/g of wet tissues) in digestive gland of mussel, soft tissue of limpet and body wall of sea cucumber collected in North Corsica in January (mean  $\pm$  standard deviation). Different letters indicate significant difference between the location, within the same specie (P < 0.05). Circles indicate the value for the pooled data collected in the same location **Fig. 8** Integrated Biomarker Responses (IBR, mean) calculated for limpet and sea cucumber using the biomarker of effects. Different letters indicate significant difference between the location, within the same specie (P < 0.05)
