Abstract

Objective: It is unknown whether HCV-cured people with HIV (PWH) without cirrhosis reached the same mortality risk as HCV-uninfected PWH. We aimed to compare mortality in PWH cured of HCV by direct-acting antivirals (DAAs) to mortality in individuals with HIV monoinfection.

Design: Nationwide hospital cohort.

Methods: HIV-controlled participants without cirrhosis and HCV-cured by DAAs started between 09/2013 and 09/2020, were matched on age (± 5 years), sex, HIV transmission group, AIDS status, and BMI (± 1 kg/m²) to up to ten participants with a virally suppressed HIV monoinfection followed at the time of HCV cure ± 6 months. Poisson regression models with robust variance estimates were used to compare mortality in both groups after adjusting for confounders.

Results: The analysis included 3961 HCV-cured PWH (G1) and 33 872 HCV-uninfected PWH (G2). Median follow-up was 3.7 years in G1 (interquartile range (IQR): 2.0–4.6), and 3.3 years

(IQR: 1.7–4.4) in G2. Median age was 52.0 years (IQR: 47.0–56.0), and 29 116 (77.0%) were men. There were 150 deaths in G1 (adjusted incidence rate (aIR): 12.2/1000 person-years) and 509 (aIR: 6.3/1000 person-years) in G2, with an incidence rate ratio (IRR): 1.9 [95%CI, 1.4–2.7]. The risk remained elevated 12 months post HCV cure (IRR: 2.4 [95%CI, 1.6–3.5]). Non-AIDS/non-liver-related malignancy was the most common cause of death in G1 (28 deaths).

Conclusions: Despite HCV cure and HIV viral suppression, after controlling on factors related to mortality, DAA-cured PWH without cirrhosis remain at higher risk of all-cause mortality than people with HIV monoinfection. A better understanding of the determinants of mortality is needed in this population.

Keywords: HIV/Hepatitis C coinfection, Direct-acting antiviral agents, Sustained Virologic Response, Mortality.

Introduction

Over the past 20 years, all-cause mortality in people living with HIV (PWH) has declined thanks to combination antiretroviral therapy (cART) [1,2]. However, mortality remains higher than in the general population [1,3]. Among causes of death, AIDS-defining events were predominant before 2012 and were often associated to late HIV diagnosis [4]. Yet, deaths related to AIDS-defining events tended to be replaced by non-AIDS defining causes : non-AIDS infections, cancers, cardiovascular disease, liver disease, and substance use-related deaths [1,5]. Coinfections with chronic hepatitis viruses, including hepatitis C virus (HCV), were particularly associated with a higher mortality [6–8]. Predictors for death in this population were poor HIV control with lower CD4 cell counts and a higher HIV viral load [9]. The introduction of interferon-free therapies with direct-acting antivirals (DAAs) in 2014 resulted in the cure of more than 90% of persons living with HCV with and without HIV infection [10], and positively impacted overall mortality in the following years [11,12]. Still, despite recovery from HCV, people with HIV coinfection have a higher residual risk of death than people with an HCV monoinfection, and this risk persists long after HCV cure [13]. This is mainly due to the presence of non-hepatic factors often existing in individuals living with HIV/HCV, such as cardiovascular disease, diabetes, alcohol consumption, drug use, and smoking [14]. Few studies have compared the mortality in people with HIV monoinfection to the mortality in PWH cured of HCV by DAAs in the absence of cirrhosis and studied potential predictors of mortality risk in HCV-cured PWH. To better explore mortality in HCV-cured PWH without severe hepatic disease and with HIV control this study estimated the incidence of death and compared all-cause mortality in PWH achieving HIV viral suppression (< 200 copies/mL) and cured of HCV by DAAs without cirrhosis, to all-cause mortality in individuals with a virally suppressed HIV monoinfection.

Methods and participants

ANRS CO4 FHDH cohort

For this analysis, participants were selected from the ANRS CO4 FHDH Cohort Study, a nationwide hospital-based multicenter, open cohort with ongoing inclusions since 1989. By December 2020, 217 257 participants with HIV infection had been included from 186 hospital centers located throughout France. Individuals are included in FHDH if they have documented HIV-1 or HIV-2 infection and have given their written informed consent for their data to be used for research purposes. Participants are followed at each outpatient visit or hospital admission, and standardized variables are collected if a new clinical manifestation, a new treatment, or a change in biological markers is noted in a six-month interval[15].

The cohort was initially approved by the French data protection agency (Commission Nationale de l'Informatique et des Libertés; CNIL) on 27 November 1991 (Journal Officiel, 17 January 1992). The research authorization was updated to comply with the new regulations, including the General Data Protection Regulation. The ANRS CO4 FHDH cohort was approved by the CEREEES (Comité d'Expertise pour les Recherches, les Études et les Évaluations dans le domaine de la Santé) on 20 July 2018 and as a hospital data warehouse by the CNIL on 19 February 2021. The CNIL authorized the cohort to conduct research projects on the data warehouse on 30 March 2021.

Data collection

Demographic characteristics are collected at study inclusion. HIV-related biomarkers, AIDS and non-AIDS clinical events, and antiretroviral treatment are collected prospectively at study entry and at each follow-up visit. Since 2005, information on coinfection with hepatitis B and C has been added to the database. Data on hepatitis C includes HCV-related biomarkers and information on HCV treatments at study entry and each follow-up visit. Deaths are also recorded prospectively with their date and cause, using the Cause of Death (CoDe) in HIV protocol[3], which is specifically designed for classifying causes of death in HIV-infected persons.

Eligibility criteria

Participants with HIV/HCV coinfection and HCV cured with DAAs

For this analysis, participants with HIV/HCV coinfection cured by DAAs (Group 1 [G1]) were eligible if they were over 18 years old, if they had at least one cohort visit after baseline, at least one HIV viral load <200 copies/mL within 6 months before the index date (date of HCV cure), and if they started DAAs between September 2013 and September 2020. The <200 copies/mL threshold was used for HIV suppression to account for changes in lower detection limits of viral load assays. We included participants that were enrolled in clinical trials in 2013-2014 and received DAAs before marketing authorization, as well as non-responders to interferon therapy. Participants treated with boceprevir or telaprevir (first generation DAAs)

and those who did not have at least one cohort visit after baseline were excluded from the analysis, as well as participants with reinfection, defined as the first positive HCV RNA test after the index date. Participants with cirrhosis, as determined by the algorithm provided in Figure S1, <http://links.lww.com/QAD/C862>, were also excluded. This was done to avoid selection bias, as cirrhosis prevalence was higher in G1, probably due to a better screening in this group, and is related to liver mortality. These participants were included in a sensitivity analysis. Follow-up began at the index date, i.e., the date of HCV cure in participants living with HIV/HCV.

HCV cure was determined by the presence of a sustained virological response (SVR12), defined as an undetectable HCV RNA in serum or plasma (≤ 15 IU/mL) 12 weeks after DAA completion, as defined by the European Association for the Study of the Liver (EASL) [16]. Since some participants did not have an SVR strictly evaluated at 12 weeks after the end of treatment, and since median treatment duration was 12 weeks [12;13] for 3898/3961 participants with available DAA treatment dates on medical records, a negative HCV PCR > 24 weeks after treatment initiation or an SVR12 date registered in the database before the end date for this analysis (31/12/2020) were used as a surrogate definition for SVR12.

Participants with HIV monoinfection

Up to ten participants with HIV monoinfection followed at the index date were matched to PWH cured of HCV by DAAs. In participants with HIV monoinfection, the index date corresponded to the HCV cure date of the matched participant living with HIV/HCV ± 6 months. Participants with HIV monoinfection were selected if they were over 18 years old, had at least one follow-up visit after the index date, had at least one HIV plasma viral load <200 copies/mL within 6 months before the index date, did not have cirrhosis, and if they never had a positive HCV-RNA or anti-HCV antibody test. Matching was performed on age (± 5 years), HIV transmission group (men who have sex with men (MSM), injecting drug users (IDUs), or other), AIDS status, and body mass index (BMI) (± 1 kg/m²). Multiple selections of a given participant with HIV-monoinfection, possibly at different index dates, were allowed. When BMI values were missing, participants living with HIV cured of HCV by DAAs were matched only on the other matching factors.

Statistical analysis

Continuous baseline characteristics were described by their median (interquartile range), and categorical baseline characteristics by their absolute and relative frequencies. The Pearson χ^2 test was used to compare categorical variables, and the Wilcoxon test for continuous variables.

The primary outcome was death. Follow-up began at the index date and continued until the date of death, last visit, 31 December 2020, or 60 months, whichever occurred first. Loss to follow-up was defined as not having a visit for 18 months or more. The maximum follow-up (60 months) was selected based on the DAA availability for PWH (2015). Follow-up of participants with HIV-monoinfection was right-censored to the follow-up duration of the

participant with DAA-cured HIV/HCV-coinfection to which they were matched, as the main interest was to measure the effect of past coinfection in participants with HIV/HCV coinfection and HCV cured with DAAs.

Kaplan-Meier 5-year survival rates were estimated in participants with DAA-cured HIV/HCV-coinfection and in those with HIV-monoinfection. All-cause death rates per 1000 person-years (PY) and 95% confidence intervals (CI) were estimated using Poisson regression with robust sandwich variance estimators calculated using a GEE model with an independent correlation structure; to account for clustering and multiple selection of a given participant with HIV-monoinfection [17]. Poisson regression models with robust sandwich variance estimators were used to compare mortality between participants with DAA-cured HIV/HCV-coinfection and those with HIV-monoinfection adjusting for age, sex, HIV transmission group, AIDS status, year of HIV diagnosis, CD4 T-cell nadir, and BMI. Primary analyses were done to evaluate the risk of death from 0 to 60 months, and separate models evaluated the risk between 0–12 and 12–60 months. The 12-month cutoff was selected according to the incidences per 6-month period of follow-up as shown in Table S1, <http://links.lww.com/QAD/C856>. Four sensitivity analyses were performed, adding time with ART exposure in the model, including participants with cirrhosis, restricting analyses to participants with HIV viral load <200 copies, and modelling with Cox Proportional Hazards. Statistical significance was defined as a p-value <0.05. All statistical analyses were completed using SAS software, Version 9.4 (SAS Institute Inc., Cary, NC, USA).

Role of the funding source

The funding sources did not have any role in study design, collection of data, analysis, manuscript writing or the decision to submit for publication.

Results

Population characteristics

G1 participant selection is described in Figure 1. In the ANRS-CO4 FHDH cohort, there were 3970 participants living with HIV cured of HCV by DAAs (G1) who had at least one HIV-1 viral load <200 copies/mL in the 6-month period before HCV cure, and no HCV reinfection nor cirrhosis. Of these, 3961 were matched to 33 872 participants with HIV monoinfection (G2) who had at least one HIV-1 viral load <200 copies/mL in the 6-month period preceding the index date. Matching on the five criteria was possible for 3690 (93%) G1 participants, and there were 30 835 participants in G2 that were matched more than once. Participants in G1 who inject drugs had a smaller number of matched participants with HIV monoinfection than the other HIV transmission groups, resulting in some imbalance of the baseline characteristics of the two groups despite matching.

Participants' characteristics are described in Table 1. Median age was 52.0 years (interquartile range IQR, 47.0–56.0). Male participants were predominant (n=29 116, 77.0%). Median BMI

was 22.9 (IQR 20.8–25.2). The HIV transmission group was IDUs for 12 326 participants (32.6%) and MSM for 12 480 (33.0%). Also, 7892 participants (20.9%) had an AIDS status before the index date.

Compared to those in G2, participants in G1 were diagnosed with HIV infection at an earlier period (median: 1993 vs. 2000) and had a lower median CD4 T-cell nadir before HCV cure (183 [81–304] vs. 214 [88–341] cells/mm³). Median time between first positive anti-HCV antibody test and DAA treatment was 14.0 years (IQR 3.2–22.5) in G1. The proportion of HBV coinfection was low in both groups. The median testing frequency for HCV antibodies during the study period was every 343 days (IQR: 167–552).

Median follow-up time was 3.7 years in G1 (IQR = 2.0–4.6), and 3.3 years (IQR = 1.7–4.4) in G2, corresponding to 12 915 PY and 103 778 PY, respectively. Overall, 307 (7.8%) individuals in G1 and 2368 (7.0%) in G2 were lost to follow-up, respectively.

Incidence of all-cause mortality

During the first 5 years of follow-up, 150 participants died in G1 and 509 in G2, yielding respective 5-year death probability estimates of 6% (95% CI 5–7%) and 2% (95% CI 2–3%) respectively (Figure 2). The adjusted incidence rate (aIR) was 12.2/1000 PY (95% CI 8.7–17.1) in G1 and 6.3/1000 PY (95% CI 4.9–8.0) in G2 (Table 2). The absolute risk of death in G1 was not significantly different in the 0–12 and 12–60 months periods (aIR/1000 PY 9.8 [5.9; 16.4] vs. 12.1 [7.9; 18.7] respectively, $p = 0.06$), while the risk of death in G2 was lower in the 12–60 months period compared to the 0–12-month period (aIR/1000 PY 0–12 months: 8.1 [5.8; 11.3] vs. 12–60 months: 5.1 [3.8; 7.0], $p < 0.0001$) (Table 2).

Causes of death

During the 0–60 month- period of follow-up, cause of death was reported for 118 of the 150 deaths in G1 and 400 of the 509 deaths in G2. The most common causes of death in G1 were non-AIDS/non-liver related malignancies ($n = 28$ [17.3%]), liver-related disease ($n = 26$ [17.3%]), cardiovascular disease ($n = 12$ [8.0%]), and AIDS-defining disease ($n = 11$ [7.3%]). G2 had a higher proportion of non-AIDS/non-liver related malignancies ($n = 134$ [26.3%]) and cardiovascular disease ($n = 59$ [11.6%]) but a lower proportion of AIDS-defining disease ($n = 23$ [4.5%]) and liver-related disease ($n = 20$ [3.9%]). There were 5 deaths (2.5%) attributed to overdose in G1 and 0 in G2. Liver-related deaths were deaths related to HCC: 8 in G1 and 10 in G2; hepatic failure: 1 in G1 and 1 in G2; and progression of viral hepatitis disease: 17 in G1 and 9 in G2 (Table S2, <http://links.lww.com/QAD/C857>).

Risk factors of death after HCV cure

Results from model evaluating the risk of death from 0 to 60 months are presented in Table 3. HCV past coinfection was associated with a higher risk of all-cause death despite cure (Incidence rate ratio IRR = 1.9, 95% CI 1.4–2.7), as first HIV diagnosis before 2000 (IRR = 2.7, 95% CI 1.7–4.3), and BMI <18.5 (IRR = 2.1, 95% CI 1.5–3.1).

In the first 12 months of follow-up, HCV past coinfection was not associated with mortality (IRR = 1.2, 95% CI 0.78–1.9) (Table S3, <http://links.lww.com/QAD/C858>). After 12 months of follow-up, the risk of death was higher in G1 compared to G2 (IRR = 2.4, 95% CI 1.6–3.5). The same factors identified in the model with 0–60 months of follow-up were associated with the risk of death after 12 months of follow-up (Table S4, <http://links.lww.com/QAD/C859>). Sensitivity analyses adding time with ART to the model with 0–60 months of follow-up, resampling the dataset to include 362 (in G1) and 118 (in G2) patients with cirrhosis, and restricting analyses to participants with HIV viral load <200 copies during follow-up retrieved similar results (Table S5, <http://links.lww.com/QAD/C860>). A time-to-event analysis using a Cox proportional hazards model with robust sandwich variance estimators for paired data that excluded participants with HIV VL <200 copies during follow-up and adjusted for matching variables, year of HIV diagnosis, time-varying CD4 T-cell values, and BMI also retrieved similar results (Table S6, <http://links.lww.com/QAD/C861>).

Discussion

In the ANRS-CO4-FHDH cohort [15] the overall mortality in participants with HIV and a DAA-virologically cured HCV infection without cirrhosis was found to be higher compared to participants with HIV mono-infection, all with cART-mediated HIV suppression (12.2/1000 PY vs. 6.3/1000 PY, adjusted IRR = 1.9 95% CI 1.4–2.7). The risk of death was significantly higher after 12 months following HCV cure while there was no difference in the first 12 months of follow-up.

One of our major results is that, despite being HCV cured and after adjusting for potential confounding factors such as CD4 cell counts and group of transmission described in previous studies, participants with HIV/HCV cured with DAAs were more likely to die than participants with HIV mono-infection in the first 5 years following cure [6]. In a study of HIV/HCV coinfecting and HCV-mono-infected participants by Chalouni *et al.*, individuals with HIV/HCV were found to remain at a higher risk of all-cause mortality than participants with an HCV mono-infection, despite HCV cure with DAAs [18]. In conjunction with our results, this suggests that HIV/HCV coinfection leads to worse survival outcomes than either HIV or HCV mono-infection, even after HCV cure, at least in the first 5 years following cure. Chalouni *et al.* also found that the higher risk of all-cause death in participants with HIV/HCV compared to those with HCV mono-infection was related to an elevated risk of non-liver-related death, in a population of tobacco and alcohol users [18]. This concurs with our findings, where non-liver non-AIDS related malignancies account for a high proportion of deaths in participants with a previous coinfection, whatever the period of follow-up considered.

Contrary to Chalouni *et al.* [18], we found that liver-related deaths are still a common cause of death in this population despite HCV cure even in the absence of cirrhosis at time of DAA treatment. We also found that all-cause mortality was associated with male sex, HIV diagnosis before 2000, AIDS status, and low BMI—risk factors that have also been described elsewhere [19,20]. In vitro studies have shown a persistent T-cell exhaustion after HCV-RNA cure in HCV infection that depends on time with the infection. In addition, persistence of low levels

of chronic immune activation as well as an immune suppressive environment may contribute in some cases to an increased risk of cardiovascular diseases and to decreased immune control against cancer and viral reactivation, especially in people with an HIV/HCV coinfection [21,22]. Participants in the HIV/HCV coinfection group in our study had a median time between first positive anti-HCV antibody and DAA treatment of 14.9 years [3.7; 22.8]. This could support the hypothesis of a longstanding HCV infection that could lead to worse outcomes in the group of people with HIV/HCV coinfection compared with people with HIV monoinfection. A longer follow-up may show whether this will disappear overtime.

Another finding in our analysis was that participants with HIV monoinfection had a lower risk of death after the first 12 months from baseline compared to the first 12 months, while the absolute risk of death was consistent at 0-12 months and at 12-60 months in participants living with HIV/HCV cured of HCV with DAAs.

A higher risk of all-cause mortality compared to the general population has been described to persist in HCV monoinfected patients in the years following HCV cure [23,24]. It has been hypothesized that late presentation and frequent lost-to-follow-up periods in people living with HCV, due to the silent progression of the disease and experience with previous ineffective HCV treatments, hinders the care cascade and results in poorer outcomes [25,26]. To our knowledge, the difference in mortality between periods in participants with HIV/HCV cured by DAAs and in those with HIV-monoinfection has not been described elsewhere, due to the relatively recent arrival of DAA treatments and thus short follow-up periods after DAA cure.

Strengths and limitations

A major strength in our study is the large number of participants. As a result, the comparison between the mortality of participants living with HIV/HCV to participants with HIV monoinfection can yield estimates that are more precise. This, combined with a median follow-up of 3.7 and 3.3 years for G1 and G2, respectively, permitted the observation of a sufficient number of events in both groups. Moreover, our population is comparable to other major European and American cohorts and population-based studies: [27,28] The EUROSIDA study reported 74% of males, a median age of 56 years, 27.8% of prior AIDS diagnosis, and 8% of cirrhosis in 1178 participants with HIV/HCV from Western European countries.[27] Similarly, a U.S. based study including 1346 Medicare beneficiaries with HIV/HCV and who were DAA treated had 87.5% men, a median age of 56 years, and 7.3% participants with cirrhosis [28]. These findings give us greater confidence in the generalization of results for the HIV/HCV and DAA-cured population globally.

This study has several limitations. First, behavioral data were often missing (alcohol and tobacco) or not collected (active IDU). These factors have been independently associated with mortality in previous studies [29,30]. Secondly, there may be an underreporting of deaths in the ANRS CO4 FHDH cohort but, if so, the proportion of underreported deaths should be the same in G1 and G2, as illustrated by the similar percentage of lost-to-follow-up participants in the two groups. In addition, not all causes of death were available, but most were well

characterized. Thirdly, as we considered only treatments that are currently the standard of care, PWH cured for HCV with interferon were excluded from our study. This is a potentially different HCV-cured population, which used to be carefully selected for treatment, without decompensated liver disease or other comorbidities. Lastly, we observed an absolute risk of death that remains high in HIV/HCV participants cured of HCV after 12 months while it decreases in HIV monoinfected patients. A longer period of follow-up may change this estimation and be necessary to eventually witness a decrease in mortality.

Conclusions

PWH enrolled in the ANRS-CO4 cohort with HCV infection, without cirrhosis, and cured with oral DAAs have worse survival outcomes than participants with HIV monoinfection, despite HIV viral suppression, after adjusting for confounding factors, with no significant difference in the first 12 months, and a significant difference from 12 to 60 months. Tailoring health services to reach WHO targets for HCV micro-elimination in the HIV population is one component of the strategy to defeat HCV as a public health threat [31]. In addition, it is paramount to address the issue of mortality in PWH with cured HCV, even in those who do not have cirrhosis. A closer and longer follow-up and further research on the determinants, including the social and behavioral ones, of liver and non-liver-related causes of death are needed to elucidate the reasons for the persistence of a higher relative risk of death over the first 5 years in people with HIV who are cured of HCV compared to people with HIV monoinfection.

Figure 1. Participant Selection – Group 1: Participants with DAA-Cured HIV/HCV Coinfection. Abbreviations: HCV: hepatitis C virus; HIV: human immunodeficiency virus; AIDS: acquired immunodeficiency syndrome; DAA: direct-acting antiviral; SVR12: sustained virologic response 12 weeks after the end of treatment

*HCV cure: evidence of negative HCV PCR >24 weeks after treatment initiation or HCV cure date registered before December 2020.

Figure 2. Predicted probability of death over time according to HCV coinfection.

Log-log transformation was used to compute confidence intervals.
