ABSTRACT: R	esearch on metal halide t	perovskites as absorbers f	or X-ray V V	V = 0

7 detection is an attractive subject due to the optimal optoelectronic properties of 8 these materials for high-sensitivity applications. However, the contact degradation 9 and the long-term instability of the current limit the performance of the devices, in 10 close causality with the dual electronic-ionic conductivity of these perovskites. 11 Herein, millimeter-thick methylammonium-lead bromide (MAPbBr₃) single and 12 polycrystalline samples are approached by characterizing their long-term dark 13 current and photocurrent under X-ray incidence. It is shown how both the dark 14 current and the sensitivity of the detectors follow similar trends at short-circuit (V15 = 0 V) after biasing. By performing drift-diffusion numerical simulations, it is

16 revealed how large ionic-related built-in fields not only produce relaxations to equilibrium lasting up to tens of hours but also 17 continue to affect the charge kinetics under homogeneous low photogeneration rates. Furthermore, a method is suggested for 18 estimating the ionic mobility and concentration by analyzing the initial current at short-circuit and the characteristic diffusion times.

19 KEYWORDS: ion migration, X-ray detectors, metal halide perovskites, sensitivity, ion diffusion

1. INTRODUCTION

20 The use of methylammonium-lead bromide (MAPbBr₃) as an 21 absorber for X-ray detection has been established since $22\ 2016^{1-3}$ thanks to the high mobility-lifetime product and 23 small surface charge recombination velocity, which allow 24 relatively high sensitivity (see Table S1 in the Supporting 25 Information, SI). Yet, even though the high quality of the 26 single crystals and the thickness of polycrystals are 27 challenging,⁴ the instability of the contacts⁵ and the long- 28 term current response⁶⁻¹⁰ remain arguably the key issues for 29 the development of perovskite X-ray detectors (PXDs) in 30 general¹¹ and MAPbBr₃-based devices in particular. Monitor-31 ing the photocurrent at a given reverse bias voltage with 32 respect to the reference and stable dark saturation current is a 33 primary requirement for typical applications in ionizing 34 radiation imaging. Directly related to both contact degradation 35 and long-term current evolution,¹² the dual ionic-electronic 36 conductivity of these materials continues to be a puzzling 37 subject of intensive research.¹³

The ionic properties of millimeter-thick perovskite samples with symmetric or rectifying contacts have been theorized in previous works.^{6,8–10,13–15} Notably, a method for estimating in ionic mobility from the short-circuit (SC) diffusion regime after bias polarization has been proposed following the ionic adynamic doping (IDD) model.⁶ Similarly, exotic behaviors upon poling suggesting bias dependency of mobility have also been approached in the ballistic-like voltage-dependent mobility (BVM) model. Furthermore, numerical drift-diffusion 46 simulations of the dark saturation current of PXD have pointed 47 out the major influence of the ionic charge field screening in 48 biasing conditions (voltage $V \neq 0$ V).¹³ Yet, a description of 49 the charge density profile and the field distributions as these 50 samples relax toward equilibrium at SC (V = 0 V) after external 51 pre-biasing is still missing. 52

An interesting behavior has been revealed while character- $_{53}$ izing MAPbBr₃ single and polycrystalline samples, as shown in $_{54}$ Figure 1a. A detailed description of the fabrication method and $_{55}$ fi material characterization of similar samples can be found in $_{56}$ previous works^{9,16} and further specifics on our studied samples $_{57}$ are in the experimental section S2 in the Supporting $_{58}$ Information. The general energy diagrams, with processes of $_{59}$ charge carrier generation, recombination, and injection, are $_{60}$ schemed and commented on in Figure S1 for typical photon $_{61}$ detectors based on intrinsic semiconductor absorbers. Figure $_{62}$ lb shows the dark current density (J_{dark}) and the X-ray- $_{63}$ absorbing photocurrent (J_{ph}) during polarization (V = 10 V) 64

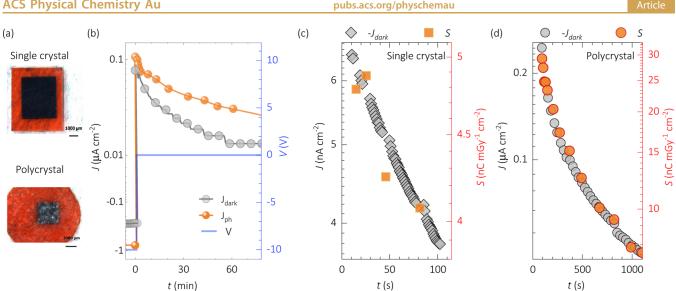

Figure 1. Time evolution of dark current (b-d), photocurrent (b), and sensitivity (c,d) of millimeter-thick MAPbBr₃ single (c) and polycrystal (b,d) samples such as those pictured in (a). The transition from biasing to the SC condition is shown in (b), while the corresponding sensitivities are in (c,d).

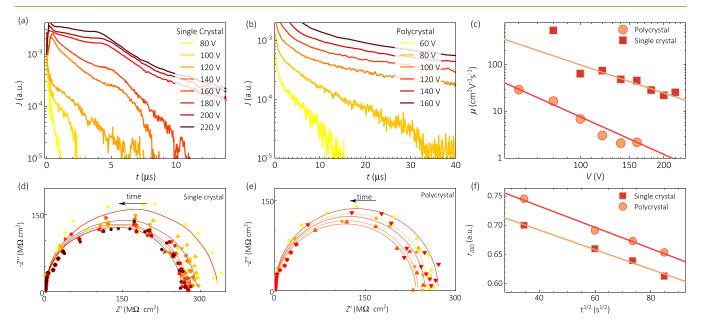

Figure 2. Experimental characterization of charge carrier mobility: electronic (a-c) and ionic (d-f). The time-of-flight measurements versus voltage are shown for single (a) and polycrystalline (b) samples with the corresponding maximum hole mobilities (c). The impedance spectroscopy spectra in Nyquist representation are presented for single (d) and polycrystalline (e) samples with the corresponding IDD model ratio as a function of the square root of time (f) for estimation of the ionic diffusivity. The solid lines in (c-f) indicate fittings: (c) $\mu \propto V^{-n}$, $n \sim 2$ (d,e). The full data for (a,b) is shown in Figure S4 in the SI.

 $_{65}$ and the subsequent SC (V = 0 V) regimes for the studied $_{66}$ samples. During the polarization time, $J_{\rm ph}$ reaches values nearly $_{67}$ three times higher than those of \hat{J}_{dark} . Furthermore, no ₆₈ reproducible similarities in the current-time curves $J_{\rm ph}-t$ 69 and $J_{\text{dark}}-t$ during biasing were observed in our samples (neglected range in Figure 1). This could be explained due to 70 71 the combination of electron injection and generation, which 72 changes the charge mobilities and ionic-electronic concen-73 tration ratios, producing different kinetic mechanisms with 74 respect to the dark condition. However, in the absence of ₇₅ injection due to external biasing (i.e., at V = 0 V after biasing), 76 the current sign is inverted, and not only is the absolute value 77 of $J_{\rm ph}$ just slightly higher than that of $J_{\rm dark}$, but also the

corresponding $J_{ph}-t$ and $J_{dark}-t$ curves seem to mirror each 78 other while transiting from a current maximum toward 79 equilibrium. Notably, the reproducibility of the $J_{\rm ph} \sim J_{\rm dark \ 80}$ trend at SC was found regardless of the fabrication method, 81 crystallinity, and contact materials (e.g., Cr/MAPbBr₃/Cr and 82 $ITO/MAPbBr_3/Cr$) of the samples. This behavior is magnified $_{83}$ in terms of the X-ray detection sensitivity (S) for different 84 samples of single and polycrystalline natures in Figure 1c,d, 85 respectively. Apparently, similar sections of the dark current 86 decay at SC produce different values of S, i.e., a higher 87 sensitivity is reported for the polycrystalline samples over the 88 single crystal ones. Yet, the similarity of the time evolution $S-t_{89}$ with respect to $J_{\text{dark}}-t$ is remarkable. This suggests that the 90

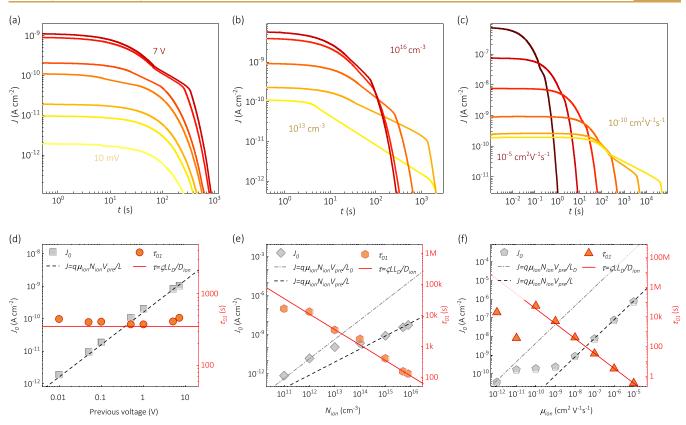

Figure 3. Numerical simulation of current versus time at SC (V = 0 V) after biasing. The effect of different polarization biases prior to the SC regime is shown in (a), whereas the change in ion concentration and ion mobilities are shown in (b) and (c), respectively. In (d–f) are the corresponding initial currents J_0 and time τ_{01} to achieve 1% of that J_0 for (a–c), respectively. Herein, $L = 100 \ \mu\text{m}$, $\mu_e = 1 \ \text{cm}^2 \ \text{V}^{-1} \ \text{s}^{-1}$, and $\mu_p = 10 \ \text{cm}^2 \ \text{V}^{-1} \ \text{s}^{-1}$ for (a–f); $\mu_{\text{ion}} = 10^{-8} \ \text{cm}^2 \ \text{V}^{-1} \ \text{s}^{-1}$ for (a,b,d,e); $N_{\text{ion}} = 10^{15} \ \text{cm}^{-3}$ for (a,c,d,f); previous $V_{\text{pre}} = 5 \ \text{V}$ for (b,c,e,f), $\varsigma = 0.5 \ \text{in (d-f)}$.

91 inner field distribution caused by the mobile ion rearrangement 92 after polarization in the early moments of the SC regime is not 93 significantly changed with respect to the dark situation for 94 small generation rates in the order of those reported in the 95 studied samples.

In this work, the electrical response of millimeter-thick 96 97 MAPbBr₃-based PXD at SC after polarization is characterized and modeled. The similar time evolution of dark current and 98 sensitivity is highlighted, and several time-dependent current-99 100 voltage experiments are conducted for attesting reproducibility. 101 The behavior and orders of magnitudes of the electronic and 102 ionic mobilities are explored in a set of simulations and 103 analyzed. The simulated devices follow the Schottky-diode-like 104 configuration from previous works, 13,14,17 where up-to-105 millimeter-thick perovskite pellets are sandwiched between 106 metals of different work functions (WFs). For the numerical 107 simulations, the open-source MATLAB code Driftfusion¹⁸ was 108 employed. Our results indicate the importance of interface 109 phenomena and field screening behind the slow kinetics of 110 thick PXDs during the diffusion regime of relaxation toward 111 equilibrium at SC after biasing.

2. RESULTS AND DISCUSSION

¹¹² Our first approach is to evaluate the charge carrier mobility of ¹¹³ the samples, which will allow us to use the proper parameter ¹¹⁴ ranges in the numerical simulations. Regarding the electronic ¹¹⁵ (hole) mobility, the time-of-flight (ToF) current decay as a ¹¹⁶ function of pulse bias is shown for single and polycrystalline ¹¹⁷ samples in Figure 2a,b, respectively. As is typical in metal ¹¹⁸ halide perovskite (MHP) samples,^{15,19} there is more than one decay regime where exponential and/or power law behaviors ¹¹⁹ can be argued. Nevertheless, assuming the smallest (sharpest-¹²⁰ exponential-like region) transit time (τ_{ToF}), a maximum ¹²¹ mobility can be estimated from the Mott–Gurney relation²⁰ ¹²² $\mu \cong L^2/(\tau_{\text{ToF}}\cdot V)$, where *L* is the thickness of the sample. ¹²³ Apparently, the τ_{ToF} between electrodes is smaller for the ¹²⁴ single crystal (1–20 μ s) than for the polycrystalline sample ¹²⁵ (10–40 μ s), which results in maximum mobility values ranging ¹²⁶ from 20–300 and 2–30 cm² V⁻¹ s⁻¹, respectively (see Figure ¹²⁷ 2c). The negative slope of the mobility versus voltage curve has ¹²⁸ also been previously reported in the literature for other ¹²⁹ MHPs.^{15,21}

The impedance spectroscopy over time at SC (after pre- 131 biasing) was measured within the framework of the IDD 132 model⁶ and shown for the single and the polycrystal samples in 133 Figure 2d,e, respectively. The high resistivity of the samples 134 (slightly higher for the single crystal sample) results in noisy 135 spectra, yet a decreasing trend can be extracted where the 136 resistance transits from an initial value R_{t0} toward a saturation 137 value $R_{t\infty}$, which is typically^{8–10,14} around 10% from the initial 138 value, i.e., $R_{t\infty}/R_{t0} = \alpha \sim 0.1$. Even though the stability of the 139 contacts prevented us from measuring $R_{t\infty}$, the IDD model 140 ratio (see derivation in Section S3.1) can be rewritten as

$$r_{\rm IDD} = \frac{R - R_{\rm t0}}{R_{\rm t0}(1 - \alpha)} = -\frac{3\sqrt{2D_{\rm ion}t}}{L}$$
(1) 142

where the ion diffusivity D_{ion} can be used to estimate the ion 143 mobility by means of the Einstein equation as $\mu_{ion} = qD_{ion}/k_BT$, 144 where *q* is the elementary charge and k_BT the thermal energy 145

146 (see detailed derivation is Section S3.1 of the Supporting 147 Information). Figure 2 shows the linear behavior between the 148 $r_{\rm IDD}$ and $t^{1/2}$, where a ratio-time slope *RTS* can be used to 149 obtain $D_{\rm ion} = (RTS \cdot L/3)^2/2$ following the approximation of eq 150 1. The values resulted in $D_{\rm ion} \sim 2 \times 10^{-9}$ cm² s⁻¹ and $\mu_{\rm ion} \sim 9$ 151 $\times 10^{-8}$ cm² V⁻¹ s⁻¹, which agree with previous estimations in 152 the literature.^{6,8-10,14}

The drift-diffusion numerical simulation is a common 153 154 approach among perovskite photovoltaic cells^{18,22-24} and 155 similar formalisms have been explored for X-ray detectors.^{13,25} 156 In our case, the simulation of current versus time follows the 157 same assumptions as our previous work¹³ at SC, as illustrated 158 in Figure 3a-c for different previous applied voltages, mobile 159 ion concentrations, and ion mobility, respectively. Figure 3d-f 160 shows the corresponding initial current density J_0 in each case, 161 as well as the time τ_{01} for which the current is 1% of the initial 162 one, i.e., $J(\tau_{01})/J_0 = 0.01$. The effect of previous bias is shown 163 in Figure 3a,d to have no significant impact on the relaxation 164 time, whereas the initial J_0 increases linearly with the previous 165 voltage. This suggests a typical capacitive discharge behavior, 166 where the response time $\tau = RC$ is affected by both the 167 capacitance (C) and the resistance of the sample and is 168 independent of the charging voltage. Similarly, the higher the 169 voltage, the higher the discharge current, in order to converge to equilibrium within the same timescale. 170

The effect of mobile ions in the simulated current relaxation 171 The effect of mobile ions in the simulated current relaxation 172 is shown to have a major impact in Figure 3b,c,e,f. The ion 173 concentration $N_{\rm ion}$ not only significantly increases the initial J_0 174 at the same previous voltage but also decreases the relaxation 175 time. The higher the value of $N_{\rm ion}$ the higher that of J_0 and the 176 lower that of τ_{01} . Interestingly, a clear trend $\tau_{01} \propto N_{\rm ion}^{-1/2}$ can 177 be identified, whereas $J_0 \propto N_{\rm ion}^{1/2}$ is suggested only for specific 178 ranges. Regarding the dependency on ion mobility $\mu_{\rm ion}$ (Figure 179 3c,f), the trends are similar but intensified in terms of the 180 power law: $\tau_{01} \propto \mu_{\rm ion}^{-1}$ and $J_0 \propto \mu_{\rm ion}$ are apparent in the 181 simulated range. From here, one can propose an approach 182 similar to the ToF experiment,¹³ but based on the effective 183 ionic field screening $\xi_{\rm ion}$ created by the ions confined within 184 the Debye length

$$L_{\rm D} = \sqrt{\frac{\varepsilon_0 \varepsilon_{\rm r} k_{\rm B} T}{q^2 N_{\rm ion}}}$$
(2)

186 where ε_0 is the vacuum permittivity, and ε_r is the dielectric 187 constant. Subsequently, the relaxation time can be approached 188 by the diffusion time, $\tau = LL_D/D_{ion}$, ^{6,26,27} and through 189 Einstein's relation, ²⁸ one can define

$$\tau_{01} = \frac{\zeta L}{\mu_{\rm ion}} \sqrt{\frac{\varepsilon_0 \varepsilon_{\rm r}}{N_{\rm ion} k_{\rm B} T}}$$
(3)

191 where ζ is a parameterization dimensionless coefficient 192 introduced with the definition of τ_{01} . Similarly, the parameter-193 ization of the initial current depends on the ionic mobility and 194 concentration. For instance, for high values of $\mu_{\rm ion}$ and $N_{\rm ion}$, an 195 ohmic-like behavior is obtained as a function of the previous 196 voltage $V_{\rm pre}$ and

$$J_0 = \frac{q\mu_{\rm ion}N_{\rm ion}V_{\rm pre}}{L} \tag{4}$$

This trend is represented with dashed lines in Figure 3d–f. 199 However, the smaller the values of μ_{ion} and N_{ion} , the stronger the influence of the Debye length, and thus a better description 200 would be obtained by $J_0 = q \cdot \mu_{\text{ion}} \cdot N_{\text{ion}} \cdot V_{\text{pre}} / L_D$, which results as 201

$$J_0 = q^2 \mu_{\rm ion} V_{\rm pre} \sqrt{\frac{N_{\rm ion}^3}{\varepsilon_0 \varepsilon_r k_{\rm B} T}}$$
(5) 202

This is represented with dot-dashed lines in Figures 3e,f and 203 S5. Notably, the transition between the transport regimes 204 (TTR) expressed by eqs 4 and 5 is found for ionic properties 205 with values smaller than $\mu_{\rm ion} = 10^{-9} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and $N_{\rm ion} = 206$ 10¹⁴ cm⁻³. Accordingly, only samples with high or low enough 207 concentrations would be out of the TTR range and display a 208 linear dependence with $V_{\rm pre}$ whose slope would correspond- 209 ingly match those of eqs 4 and 5. Experimentally, the 210 application of these formalisms for J_0 not only depends on 211 the values of $\mu_{\rm ion}$ and $N_{\rm ion}$ and the TTR. The temperature and 212 the stability of the contacts can also affect the current 213 relaxation. For instance, Figure S6 in the Supporting 214 Information shows several experimental current-time curves 215 at SC after different $V_{\rm pre}$ values, where the linear behavior is 216 similarly found only for $V_{\rm pre}$ larger than a threshold value that 217 depends on the geometric and crystalline properties of each 218 sample. 219

A method for estimating the mobility and concentration of 220 mobile ions for perovskite samples, where further evidence 221 suggests that $\mu_{ion} > 10^{-9}$ cm² V⁻¹ s⁻¹ and $N_{ion} > 10^{14}$ cm⁻³, was 222 already suggested in our previous work (focused on the pre- 223 biasing period).¹³ There, μ_{ion} and N_{ion} were attainable by 224 processing the slopes of the linear trends of the ionic time-of- 225 flight τ_{iToF} versus $LT^{1/2}/V$ and the biased dark saturation 226 current J_B versus qV/L. Complementarily, here, we suggest that 227 eqs 3 and 4 can be used to analyze τ_{01} versus $LT^{-1/2}$ and J_0 228 versus qV_{pre}/L from which the slopes of the linear trends would 229 deduce μ_{ion} and N_{ion} . This diffusion-focused approach to the 230 dark current at SC after biasing should deliver similar values to 231 those of the biasing-focused method suggested in our previous 232 work.¹³

The illustrative time evolution of the simulated electrostatic 234 potential (φ), field (ξ), charge density profiles (electrons, n; 235 holes, p; anions, a; and cations, c), and the corresponding 236 current density components (electron current density, J_n ; hole 237 current density, J_p ; anionic current density, J_a ; and cationic 238 current density, J_c) are presented in Figure 4 as a function of 239 f4 the position x inside the perovskite. After 1 ms without 240 external bias, the electrostatic potential distributes in a way that 241 resembles the one-side abrupt p-n junction, with φ behaving 242 almost linearly in two main regions: the depletion region 243 toward one electrode (at x = 0) and the remaining bulk of the 244 perovskite layer in Figure 4a. Accordingly, the initial electric 245 field due to the ionic reordering is outlined in Figure 4b 246 showing a nearly flat profile in the bulk, increasing by two 247 orders of magnitude in the depletion region. The charge 248 density distribution is presented in Figure 4c, where the initial 249 depletion region occurs with the nearly sole distribution of 250 fixed anions toward the left electrode while electrons, holes, 251 and mobile cations reorder toward the bulk. The situation 252 produces an ohmic-like main contribution of the cationic 253 current in the early moments of the relaxation toward 254 equilibrium at SC after biasing, as can be seen in Figure 4d. 255 At this stage, it is clear that, even though no external bias is 256 applied, the drift effect related to the internal ionic-related 257 remnant field is a major contribution to the current in addition 258 to the expected diffusion process. 259

1

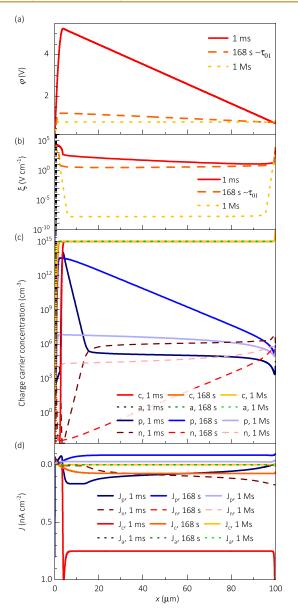

Figure 4. Numerical simulation of (a) electrostatic potential, (b) electric field, (c) charge density profile, and (d) current density components as a function of the position inside the perovskite at SC (V = 0 V) after 5 V of previous biasing for $\mu_{ion} = 10^{-8}$ cm² V⁻¹ s⁻¹ and $N_{ion} = 10^{15}$ cm⁻³.

At the characteristic diffusion time (168 s for Figure 4), 261 most of the electrostatic potential and electric field profiles 262 have flattened in Figure 4a,b. The consequent shrinking of the 263 depletion layer produces an exponential gradient of electronic 264 charge carriers in the perovskite bulk (see Figure 4c). 265 Accordingly, not only is the diffusion electronic current in 266 the order of magnitude of the cationic current, but it has an 267 opposite sign that can cancel the total current or invert its sign 268 (see Figure 4d).

In the long-term (e.g., 1 Ms \approx 278 h), the electrical response approaches equilibrium at SC after biasing. Therefore, not only is the electrostatic potential practically flat, but also the electric field decreases by up to 10 orders of magnitude, as displayed in Figure 4a,b, respectively. Accordingly, the charge carrier concentration reaches a more even distribution, where no significant concentration gradients appear in the bulk, resulting in negligible current contributions from neither the electronic 276 nor the ionic charge carriers, as can be seen in Figure 4c,d, 277 respectively. The longer the time at SC, after the pre-biasing, 278 the lower the field, and thus the diffusion component becomes 279 a principal current mechanism in the electrical response of the 280 samples.

The previously discussed simulations for dark conditions $_{282}$ illustrate the nature and effects of the ionic migration in the L_D $_{283}$ region toward the interface. Subsequently, we present in Figure $_{284}$ fs 5 the simulated behavior of current over time at SC after $_{285}$ fs

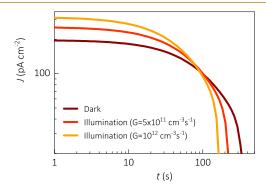

Figure 5. Numerical simulation of the current relaxation in the dark and under low illumination intensities with homogeneous charge carrier generation as indicated at SC (V = 0 V) after 5 V of previous biasing for $\mu_{\rm ion} = 10^{-8}$ cm² V⁻¹ s⁻¹ and $N_{\rm ion} = 10^{15}$ cm⁻³.

previous polarization for dark and homogeneous low 286 generation rates of illuminations. Notably, this may be a 287 rough approximation since the charge carrier generation and 288 consequent recombination mechanisms under X-ray photon 289 flux do not fully agree with the typical visible-to-near infrared 290 radiation considered in the simulation code Driftfusion.¹⁸ 291 Nevertheless, our calculations suggest that, for sufficiently low 292 generation rates, the charge density profiles and electric field 293 distributions are not drastically changed in such a way that the 294 photocurrent follows a general behavior very similar to that of 295 dark conditions. 296

3. CONCLUSIONS

In summary, a set of experiments and simulations have been ²⁹⁷ presented, attesting to the evidence of ionic charge-related field ²⁹⁸ screening in millimeter-thick MAPbBr₃ single and polycrystal- ²⁹⁹ line samples for application in X-ray detectors. By analyzing the ³⁰⁰ dark current and photocurrent under ionizing energy radiation ³⁰¹ at SC after biasing, a similar long-term relaxation trend is ³⁰² reported, which mirrors the sensitivity of the samples as X-ray ³⁰³ detectors. Subsequently, the ToF and impedance spectroscopy ³⁰⁴ measurements allowed us to estimate the electronic and ionic ³⁰⁵ mobility in the ranges of 2–300 and 9 × 10⁻⁸ cm²V⁻¹ s⁻¹, ³⁰⁶ respectively.

A series of simulations have been presented illustrating the 308 effects of ionic concentration and mobility on current 309 relaxation. It is revealed how a high internal electric field can 310 be built upon the migration of the mobile ions when the 311 depleting zone near an electrode during the polarization 312 regime, prior to the relaxation to equilibrium. The tradeoff 313 between the internal built-in and the diffusion of charge 314 carriers is able to enhance the relaxation time by up to tens of 315 hours, depending on the concentration and mobility of the 316 migration ions. Purposely, for perovskite samples with $\mu_{ion} > 317$

³¹⁸ 10⁻⁹ cm² V⁻¹ s⁻¹ and $N_{\rm ion} > 10^{14}$ cm⁻³, a method has been ³¹⁹ proposed for estimation of the mobility and ionic concen-³²⁰ tration based on analyzing J_0 and τ_{01} as a function of the ³²¹ previous voltage, distance between electrodes, and temper-³²² ature.

Last but not least, we approximate the experimental to comparison between dark current and X-ray photocurrent in sour numerical simulations with homogeneous generation rates. It is shown how, in the proper range, the excess photogenerated electronic charge carrier densities do not produce that drastic modifications to the charge balance in such a way that produce the currents follow similar long-term relaxation trends over time.

4. EXPERIMENTAL SECTION

4.1. Sample Fabrication

331 In total, 6 samples were made for this study: 2 single crystals and 4 332 polycrystalline films. The fabrication procedure followed the steps 333 described in our previous work,^{9,16} and a summary is in Section S2 of 334 the Supporting Information. All the samples were polished prior to 335 chromium electrode evaporation to make devices. In the symmetri-336 cally contacted samples, the top electrode (the one which receives the 337 X-ray flux) was thinner (30 nm) than the bottom one (100 nm) in 338 order to perform laser ToF.

4.2. Characterizations

339 The measurement of current–voltage–time characteristics was made 340 with a Keithley 2636 B SourceMeter and a PGSTAT-30 AUTOLAB 341 potentiostat, also used for the impedance spectroscopy measurements. 342 The J_{dark} –t, J_{ph} –t, and S–t measurements were carried out with a 343 Keithley 428 current amplifier and a Keithley 487 power supply. The 344 samples were irradiated using a pulsed X-ray tube with an RQAS 345 spectrum (W anode, 70 kVp, filtration: 23.5 mm Al, and 0.8 mm Be) 346 operated at 4 Hz and 100 ms pulse duration. The incident X-ray dose 347 was calibrated with a PTW Unidos dosimeter. J_{ph} is defined as the 348 maximum photocurrent output for 24 μ Gy_{air} X-ray pulses. The 349 sensitivity is calculated as the integration of J_{ph} over the pulse duration 350 and was averaged for 10 consecutive pulses to reduce experimental 351 error.

The measurement of laser hole ToF was made with a pulsed N_2 laser with a 337 nm wavelength and an 800 ps pulse duration. The laser beam was attenuated with a neutral density filter before irradiating the samples through the top semi-transparent Cr electrode with a 30 nm thickness. A negative voltage was applied to the back Cr lectrode. The ToF current waveforms were acquired with a steatronix TDS 744A oscilloscope and a Stanford Research Systems S9 PS310 high voltage supply.

4.3. Numerical Simulations

360 The simulations were made within the framework of Driftfusio 361 a direct continuation of our previous work on the long 362 polarization regimes of thick PXDs,¹³ including both radiati 363 non-radiative recombination and taking four main assumptions 364 (I) the bulk of the perovskite is initially taken as intrinsic, m 365 that the total equilibrium concentrations of fixed and mobil 366 should be balanced, i.e., the same total number of cations and (our simulation case) or effectively in the order of the intrinsic 367 368 concentration (possible experimental situation). Second, (II) the 369 interface regions between the perovskite and the contacts are 370 unintendedly doped, forming depletion layers with thicknesses in 371 the order of tens of nanometers. Third, (III) only one type of mobile 372 ions is considered to effectively contribute to the current and the 373 reordering of the charge density profile. Lastly, (IV) the built-in field 374 forming the Schottky-diode-like detector is only defined by the 375 difference in WF between the two metals. An illustrative set of 376 simulation parameters is presented in Table S2, and a comprehensive 377 explanation of the use and setting up of the Driftfusion code can be 378 found in the original publication.
